The Late Abbe Moigno.—The late Abbé Moigno, whose death we announced in last week's issue, was buried at Saint Denis, Paris, in the presence of a large number of theologians and scientists, on the 17th inst. The journal, *Les Mondes*, with which he was so long and intimately connected, publishes a portrait of him in its issue of the 19th inst., together with a long biographical notice, from which we make the following extracts. The abbé, whose full name was Francois Napoleon Marie Moigno, was born at Guéméné-sur-Scorf (Morbihan), on the 15th April, 1804, and died 13th July, 1884. His family was noble; but his father, who was called Moigno de Villebeau, abandoned his title after the first revolution. M. Moigno began his education at the College de Pontivy, and terminated it with the Jesuits of Sainte-Anne-d'Auray. He wrote his first article in 1829; and about this time we find him making friends with the men of science of the day, amongst whom were Ampère, Arago, Biot, Becquerel, Dumas, and Chevreul. In 1845, the *Epoque*, a journal then just started by Emile de Girardin, sent the Abbé Moigno on a scientific mission through Europe. In his travels he visited Italy, Austria, Germany, and England, and made lasting friendships with such men as Secchi, Rossi, Clausius, Helmholtz, Humboldt, Maxwell, Thomson, Siemens, Tyndall, and others. After several years of travel he returned to Paris, only to find that petty jealousies had risen up between him and his jesuitical brethren, and that he was regarded with disfavour by them. In 1849 he published his "Traité de Télégraphie Electrique," the first work of its kind which appeared in France. In 1850 the kind of ban under which he had been placed was somewhat relaxed, and he was appointed second almoner at the Louis-le-Grand Lycée. Here he remained three years, during which he contributed many scientific articles to the press of the day. In February, 1851, M. de Montfort started a paper called *La Lumière*, which was the organ of the Société Héliographique of Paris, and to this paper the Abbé was a frequent contributor. It lived but a short time, however, being given up in the following October. In May, 1852, M. de Montfort founded the *Cosmos*, and made the Abbé Moigno editor. The *Cosmos* was soon afterwards carried on under the new name of *Les Mondes*, by which it is still known. For more than thirty years the Abbé gave all his hardest and best work to this paper. Although his troubles with his ecclesiastical superiors were the source of continual worry to him for several years, and although his income was scanty, he never abandoned his *Cosmos*. Among the benefits which the Abbé conferred on his brother scientists was to translate into French the works of Tyndall on heat, light, and sound. In 1870 M. Moigno was residing at Saint Germain des Près, when the Prussians were besieging Paris. One evening, as he entered his library with a candle in his hand, a shell struck the house, fell in the library, and burst into a hundred pieces. The Abbé did not flinch, but quickly relighting his candle, which had been extinguished, calmly surveyed the damage that had been done. The writer of the obituary notice we are abstracting states that he has a fragment of this shell in his possession. Later on, under the Government of M'Mahon, Abbé Moigno was nominated Canon of Saint Denis, and in this retreat he continued to write and to work up to the very last.

Atmospheric Electricity.—Prof. Edlund, of the Royal Academy of Sciences of Sweden, some time ago (1878) published a memoir in which he endeavoured to prove that the unipolar induction produced by the rotation of the earth upon its axis is the principal cause of the electricity of the air. He has recently returned to this subject, *Phil. Mag. Supplement* for June, and we make the following extract from his paper: "If the air were an absolute non-conductor, the production of a difference is electric tenison between the air at the surface of the earth and the air of the upper regions would be totally impossible. But this is only the case when the air is perfectly dry. If, on the contrary, it is saturated with moisture, it forms a comparatively good conductor of electricity, as is proved, amongst other things, by the impossibility of maintaining an electric charge, however feeble, on a body surrounded by air, of which the relative humidity is considerable. Thus, when the air is moist, the difference of tenison may soon attain the limits mentioned; but when the electricity has reached a certain distance from the equatorial plane, it is conveyed by the horizontal force of unipolar induction towards more elevated latitudes—towards the north in the northern hemisphere, and towards the south in the southern hemisphere. The force of unipolar induction is always the same, where not subject to small variations produced by those of the terrestrial magnetism; but the conductibility of the air depends upon the changes which take place in its humidity. The result is a perpetual variation in the electric condition of the air. If the electric tension, at any point under a high latitude, becomes greater than that which corresponds to the vertical component of unipolar induction at the same point (which is possible, since electricity is brought there from points situated in lower latitudes), part of the electricity will flow from the air to the earth. As is shown in the preceding memoir, this takes place especially in the zone surrounding the magnetic poles where we meet with the aurora borealis. If the air is highly saturated with moisture, and if this saturation extends through some considerable space, the air will become more highly electric than when the air is relatively dry; consequently the air will generally be greater in winter than in summer, after cooling at night. The air usually attains its maximum relative humidity in the early hours of the day, diminishing in the morning as the air becomes heated, attaining its minimum soon after noon, and then increasing in intensity towards the evening. All this is in complete agreement with well-known observations. On the other hand it appears more difficult to explain the minimum of aërial electricity, which, according to certain observations, is produced in the course of the night, at least if we do not admit that in those regions where this minimum has been observed, local causes have produced a disturbing effect. It is much to be regretted that observations upon the electricity of the air are too few and imperfect to permit of a more detailed comparison between theory and

Digitized by Google

experiment. The quantity of electricity which, in accordance with the preceding, should exist in the earth's atmosphere in consequence of the unipolar induction of the earth is sufficient, in my opinion, to account for the indications of the electric condition of the air, given under normal conditions by the instruments employed for this purpose."

THE TELEPHONE IN EDINBURGH.—A capital article describing the growth of the telephone in Edinburgh appeared in the *Courant* for the 17th inst. The number of subscribers to the Central Exchange now reaches 290, many of whom reside in Leith, Newhaven, Trinity, and Granton, which lie just outside Edinburgh. The writer of the article has compiled the following statistics as to calls, &c.:—"These 290 subscribers," he says, "make amongst themselves, on an average, 1,480 communications per day. Every subscriber therefore employs his telephone say five times a day, or 1,825 times during the year. As each communication consists of at least one question and answer, this represents 3,650 messages or telelogues—as telephonic despatches have come to be called—per subscriber per year. The rate of subscription being £15 per annum, the cost of each message is rather more than nine-tenths of a penny. Looked at from another point of view, the telephone costs each subscriber rather more than 9¾d. per day, or 5s. 9d. per week. The wages of this novel servant are therefore not in excess of that of an ordinary message boy. The company, moreover, supplies a second line to any subscriber at a cost of £10 per annum, thus materially reducing the expense of telephonic communications where, for instance, a place of business and a residence are both put in connection with the exchange. The utility of the telephone in Edinburgh has lately been greatly increased by the opening of a trunk line to Glasgow, by means of which any subscriber to the Edinburgh Exchange may be connected with any of the subscribers—and they number about 700—to the Glasgow Exchange. The additional charge for this service varies from £50 to £25 per annum, according to the facilities required. The whole of this rental, owing to the conditions imposed by the Post Office, is paid over to the Government, the telephone company working the service free of charge for the benefit of its subscribers. As trunk wires also exist from Glasgow to Paisley and Greenock, Edinburgh subscribers may likewise communicate with the subscribers to the Paisley and Greenock Exchanges upon paying the Government charge. It is an interesting fact that the trunk wire between Edinburgh and Glasgow is the longest telephonic line in the United Kingdom. The communications passing over it sometimes number 50 in one day. The number of wires owned by the Telephone Company in Edinburgh is necessarily very large, the total length exceeding 236 miles. A great improvement has lately taken place in the character of the wire used for overhead purposes. Originally the wires were of iron, weighing 211lb. to the mile; now they are of phosphor-bronze, and weigh only 37lb. to the mile. As a span of wire—*i. e.*, the distance between two supports rarely exceeds 150 yards, and is generally much less, the greatest weight which can fall into the street at once is only about 3lb. This weight of 3lb. again cannot all fall at the same spot, but must be distributed over say 150 yards of ground. Overhouse wires, however, have now become so numerous that great difficulty is experienced in finding room for the new ones which are constantly being required. To meet this difficulty, and to avoid impairing the amenity of the town, the Telephone Company have now an application before the Town Council for permission to lay the wires on one of their most crowded routes underground. Should this application be granted, as it doubtless will be, advantage will be taken of the opportunity to re-arrange the wires, so as to obtain from them better results than is possible at present."

OVERHEAD WIRES.—In the House of Commons, on Tuesday, Sir H. Tyler gave notice that on Thursday he would ask the Home Secretary whether, having regard to the number of overhead wires in the City, and the danger arising therefrom during thunderstorms and high winds, he would take some means to deal with the question.—Sir A. Gordon asked whether Her Majesty's Government would next year introduce a Bill to give to the local authorities of the metropolis and other towns such a power of inspection and control over the construction and maintenance of overhead telegraphic wires as would tend to protect the public using the streets from the dangers incident to such aërial fabrics.—Mr. G. Russell said it was impossible for the Government to undertake to make a statement with regard to the Bills to be brought in next session, but there would probably be some advantage in the appointment of a Select Committee, and the matter would be considered.—According to the *Daily Telegraph*, unless the Government take the initiative in the matter, some private members intend next session to bring in a Bill giving the local authorities of the metropolis and other towns power of inspection and control over the construction and maintenance of overhead wires.—Mr. J. Russell Endean writes to *The Times* of Thursday as follows: "After the judgments recently pronounced in the Wandsworth and in the Bristol cases on the power of local authorities to control the wires of telegraph and telephone companies, the St. Marylebone vestry withdrew the action it had commenced against the Globe Telephone Company for an injunction, on the ground that, for all purposes desired by the Government, the vestry considers the local authorities have now ascertained in the law courts, after 'a well-considered and unanimous judgment,' that there are no existing legal powers by which they can exercise such control. The united vestries of St. Marylebone and St. James, Westminster, have therefore resolved to memorialise the Government to introduce at the earliest possible moment a Bill by which all control over the wires of telegraph and telephone companies through the streets of the capital shall be placed in the hands of the local authorities; and, further, these vestries have invited the other vestries and district boards of London to adopt the same course. When the deputation on this subject recently waited on the President of the Local Government Board he hinted that if legislation were proved to be necessary the Government would not hesitate to legislate, but the power of control would most probably be placed in the hands of some central authority, such as the Metropolitan Board of Works, and would not be intrusted to the local authorities. Sir, I venture to think such a deprivation of control as this implies will not be to deal justly with these authorities. At present all matters connected with the streets and thoroughfares are administered by vestries and district boards, and why these wires should be made an exception I am at a loss to conceive. I would therefore suggest that all wires in London in the public thoroughfares should be controlled by the local authorities of the parishes through which they are conveyed; that, on any question or dispute arising between the parish authority and a company, either party should have power to appeal to the Metropolitan Board of Works for settlement of the matter in dispute, and that the decision of the said Board shall be final and shall not admit of any further appeal. This would prevent useless expenditure in law courts, would meet every requirement that could possibly arise, and would thus confer upon the local authorities the power with which they have just given such conclusive evidence they are fully competent to deal."

INCANDESCENT LIGHTING.

BY T. H. SEYMOUR HAWKER.

(CONTINUED FROM PAGE 208.)

The resistance of a copper conductor increases about ·38 per cent. per degree Centigrade increase of temperature. Therefore, in cases of great current density—that is to say, when the ratio of current to sectional area is considerable—the calculation of the resistance of the conductor, *while carrying a current C*, has to be made from the formula

$$R_2 = \phi \cdot \frac{l}{s} \cdot (1 + a\,T \pm b\,T^2).$$

Here ϕ is the specific resistance of the material, l length (a convenient submultiple of the whole), s sectional area, and T the ultimate temperature in accordance with the formula given in the last article (on p. 208). The constants a and b depend on the material, and for pure copper and most other metals are equal to ·00383 and ·00000126 respectively. The purity of the metal has a deal to do with the value of these constants, however, and Matthieson states that the percentage of decrement in the conducting power of an impure metal between 0° C. and 100° C. is to that of a pure metal, between the same limits, as the ratio of their conducting powers at 100° C.

The "percentage conductivity" here referred to is very essential in all calculations involving resistance. It is the ratio of the reciprocal of the measured resistance of a sample to the reciprocal of the calculated resistance of a conductor of pure copper of similar dimensions. The highness of this percentage determines the value of the copper for conducting purposes, and it is apparent, therefore, that a deal depends on the quality of the metal used. A standard should indeed be fixed upon, and samples of each portion tendered for the contract subjected to a verificatory test.

The next important ruling factor in determining size of cables is that of cost of possession as compared with the value of energy wasted.

It has been frequently pointed out that the greatest economy is attained when the cost of possessing a conductor —that is to say, interest on first cost, depreciation, and redemption—is equal to the money value of the energy wasted in uselessly heating its resistance.

This can be very conveniently formulated and used to determine the weight of copper per unit length which it is advisable to employ. Let k be the prime cost of the conductor of resistance, R, which is to carry an average current, C, and γ the fraction representing the percentage of this value allowable for annual cost. Then with λ as the cost of a year horse-power, and θ the fraction of a year that the conductor is in use

$$k\gamma = \lambda\theta \cdot \frac{C^2 R}{7{\cdot}459 + 10^9}$$

From this we can get the necessary resistance R of the conductor to fulfil these conditions as being

$$R = 7{\cdot}459 + 10^9 k\gamma / C^2 \lambda\theta.$$

By taking the resistance in terms of weight and length, and restricting the previous equation to a small length of l centimetres of the conductor, we can obtain a more convenient formula for the weight of the conductor per length l.

$$W = \frac{\lambda\,\theta\,C^2\,l^2\,\rho\,\phi}{7{\cdot}459 \times 10^9\,k\,\gamma} \quad . \quad . \quad . \quad \text{in C.-G.-S.}$$

Here ρ is the specific gravity of the copper used and ϕ the specific resistance per c.c. when heated by the average current C according to the previous formulation. It will be seen from this that the size of a conductor should be considerably dependent on such local conditions as the price of coal, or at all events on the cost of power in the special case. Such formulæ as this will be of great service when electric lighting becomes more universal, and large central stations and dynamos of economy and vast power allow plenty of margin in the energy supply. At present, however, the majority of machines demand rather unreasonable concessions to their many weaknesses, and when the cost of energy becomes a point for criticism the leads may be safely left to some rule depending on the minimum allowable efficiency of the circuit, and the attention turned to the more prolific sources of waste nearer home. Compare the loss by air-heating in machines with Gramme and Pacinotti type of armatures with that in the ironless Ferranti, and the range for one description of improvement will be apparent. In some armatures of the Pacinotti type the working temperature is some 120° F. above the surrounding air, or 10,000 odd foot-lbs. in each lb. of the iron ring, subject to dissipation by radiation and convection.

A very useful method of finding the size of any part of an electric light circuit is the one I have referred to above, namely, that the energy wasted on any part of the circuit must be the same percentage of the total energy flow through it as the total circuit waste is to the total energy in circuit. This at once points to the necessary resistance, but there is considerable difficulty in formulating the operation.

It has been already pointed out that the E.M.F. should be the same at the terminals of all the lamps. The margin of E.M.F. which must be supplied by the generator to allow for resistance of leads, must therefore be just expended in driving the lamp current up to each individual lamp; or, in other words, the resistance from the generator through any lamp and back to the generator must be constant in all cases; or if r = hot resistance of lamp, c = lamp current, and E the E.M.F. at generator terminals, then this constant resistance will be $R_o = (E - c\,r)/c$, the amount of excess of E over $c\,r$—the lamp E.M.F.—being determined beforehand by the theoretical circuit efficiency.

Now this resistance R_o will be made up of the lamp leads, sub-mains, and mains, and we have merely to determine the proportions in which we can distribute the spare E.M.F., $E - c\,r$, so as to give the best economy in copper. This must of course depend in a measure on the prices of different sizes of cable, but the most logical method seems to be to distribute the resistances in inverse proportion to the currents, that is to say, when the total resistance of leads through each lamp is $R_o = \frac{E}{c}$, the section of each lead will need to be, if the conductor be graded in n sizes between generator and lamps, $= s = \phi\,l\,c\,n/E$.

We can advantageously combine these methods into a suitable system for any particular work, but it is convenient to have formulæ for their values in terms of any of the portions which are known. Let us take α, β, γ as the resistances respectively of mains, sub-mains, and lamp leads. Then the sum of these we know "by construction" $l = \alpha + \beta + \gamma = \frac{1}{n-1} L$, the aggregate resistance of lamps being L and $n = \frac{L + l}{L}$.

The resistance of the mains α must be sufficiently low to carry the whole current c, while leaving sufficient E.M.F. for β and γ. That is to say, if c_1 and c_2 be the currents in the latter

$$\alpha = \frac{l\,c - (\beta\,c_1 + \gamma\,c_2)}{c}.$$

The current c_2 in γ being very small, the current needed for one or two lamps only, it is easy to assign a practicable value to it, such that too high sections shall not be necessitated in the other portions or too great temperature attained. Moveover, as the lengths may vary in different lamps, too small a section is liable to create an inequality of E.M.F. distribution. We can then treat γ as known.

Again, the same considerations affect both mains and submains, the difference being in degree only, varying as the current. We can therefore formulate β in terms of α, as $\beta = \frac{\alpha\,c_1}{c}$ which value inserted in the preceding equation gives us as the value of α

$$\alpha = \frac{c\,l - \gamma}{c - c_1},$$

and from this the value of β can be obtained as

$$\beta = l - (\alpha + \gamma).$$

From these resistances the values of sectional area or

Digitized by Google

weight per given length of a material of specific resistance ϕ and gravity ρ can be deduced by the formulæ (for C.-G.-S.)

$$W = \frac{\phi \rho l^2}{R} \qquad S = \sqrt{\frac{\phi W}{R \rho}}.$$

It should be remembered that the E.M.F. is generally to be considered as a fixed quantity. In increasing the length of any lead or main, therefore, its resistance must be kept constant by a proportionate increase of sectional area.

The "jointing" and piecing together of different portions of a circuit has, unless most carefully performed, usually the effect of increasing the resistance. I shall refer to the operation of jointing in a future part of this paper devoted to the practical portion of the subject. I merely mention this now as forming, together with unavoidable accidental mechanical stresses in erection and fixing, and other sources of increase in circuit resistance, an argument in favour of the allowance of a margin of, say, five per cent. on calculated data. This is, of course, with reference to exceedingly low resistance circuits, where a variation of ·0001 of an ohm makes an appreciable difference, as in low resistance dynamos running on large installations of low E.M.F. lamps all in parallel.

(TO BE CONTINUED.)

A GALVANOMETER AND BATTERY TEST.

The comparison of electrostatic capacities by De Sauty's W. B. method is effected as follows:—

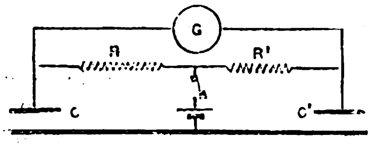

Fig. 1.

Where R and R′ are known and adjustable resistances, C a known and adjustable capacity, and C′ an unknown capacity. Then

$$R : R' :: C' : C, \text{ and } C' = \frac{R}{R'} C.$$

This test may be reversed, and by means of two known capacities and a known resistance, the value of an unknown resistance may be arrived at. Then if C, C′, and R be known and R′ unknown, once a balance has been obtained, one has

$$R' = \frac{C}{C'} R.$$

By developing the above facts, a convenient method is obtained for ascertaining the resistance of either battery or galvanometer. These two tests, it will be seen, bear a certain analogy to Mance's W.B. battery test, and to Thomson's W.B. galvanometer test.

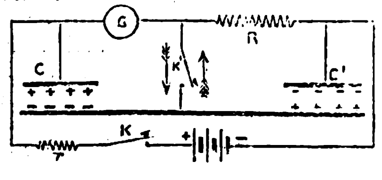

Fig. 2.—Galvanometer Test.

G = galvanometer of resistance unknown.

R = resistance known and adjustable.

r = convenient resistance inserted in battery circuit without influencing conditions of test.

C and C′ = two condensers, or one divided condenser of known and adjustable capacity.

Any one, or all, of the three values R, C, and C′ may be made adjustable.

Then the unknown resistance of G may be arrived at as follows:—Battery with instruments having been connected up, as shown in Fig. 2, K is depressed, a certain deflection, d, being thus obtained on G. R, C, and C′ are now adjusted until d remains undisturbed on the closing of K′. When this is the case,

$$G : R :: C' : C, \text{ and } G = R\frac{C'}{C}.$$

In practice it is convenient to make C and C′ equal, and to adjust R until a balance be obtained. Then

$$G = R.$$

It will be found that if the balance be *out* one way or the other—if, for instance, R be higher than G, the closing of K′ following upon the depression of K, with its accompanying deflection

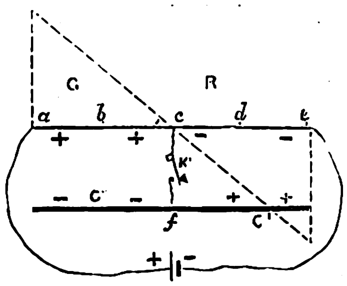

Fig. 3.

d, will cause a "*throw*" say to the right of the already deflected "*spot*." If, on the other hand, R be lower than G, the "*throw*" will be to the left of d, the "*spot*" in both cases immediately returning to position d. But when R = G, assuming that C = C′,

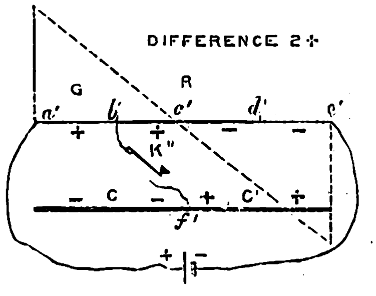

Fig. 4.

a balance is arrived at, and the closing of K′ in no way affects d, for the following reason:—

The closing of K′ completing, as it does, two inductive circuits, to both of which K′ is common—namely K′, G, and C

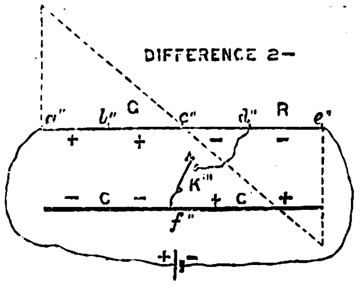

Fig. 5.

on one side, and K′ R, and C′ on the other, when a balance has been effected, that is to say when G : R :: C′ : C, K′ becomes attacked, so to speak, by two discharges, which being equal in potential, but contrary in direction, neutralise each other, and so in no way affect G. Whereas, when a balance does not exist, that is to say, when G is not to R :: C′ : C, one of the two discharges being of a higher potential than the other, the difference between the two is thus left un-neutralised, and is free to affect both inductive circuits, and thus to disturb G.

The direction of the consequent "*throw*" on G depends upon the *sign* of the discharge, which, in its turn, depends upon the nature of the adjustments of G, R, C, and C′. Assuming C

Digitized by Google

and C′ to be equal, if R be higher than G, the above-mentioned difference would be, say, *positive*, and the "*throw*" on G, say, to the right of *d*. On the other hand, if R were lower than G, the reverse would happen.

Figs. 3, 4, and 5 illustrate the *rationale* of this galvanometer test under three different conditions of things:—

1. Where a balance has been made, and G = R;
2. Where a balance does not exist, and where R > G;
3. Where a balance does not exist, and where R < G.

In all three examples C = C′.

a b c and *c d e* represent G and R respectively;

C and C′ represent two equal condensers, or what is the same thing, one condenser equally divided.

Here G = R and C = C′; so G : R : : C′ : C.

The distribution of electricity consequent upon such an arrangement is shown by + and − signs.

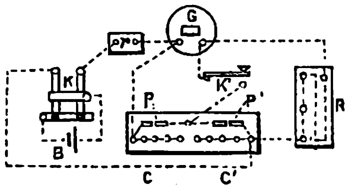

FIG. 6.

The closing of K′ connects points *c* and *f*, thereby not only forming two inductive circuits, but also producing two discharges in opposite directions, one neutralising the other. This neutralisation may be here represented by the equal number of + and − signs on either side of the points connected by K′. *a′ b′* and *b′ c′ d′ e′* = G and R respectively.

Here G = but $\frac{1}{3}$ R, whilst C = C′; so in this case a balance does not exist, and upon the closing of K″ and the consequent connecting of points *b′* and *f′*, one of the contrary discharges is at a higher potential than the other. So both inductive circuits are affected by the difference between these two potentials. In Fig. 4 this difference is represented by the two + *signs*, which are left un-neutralised on one side of points connected by K″.

This case is the reverse of Fig. 4.

Here G = 3 R, whilst C = C′, and the remaining un-neutralised *signs*, after closing of K‴ and consequent connection of points *d″* and *f″*, will be 2 −.

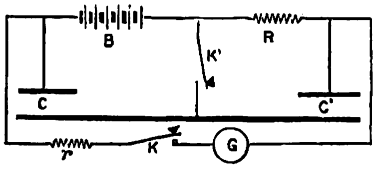

FIG. 7.

In Fig. 4, where R > G, the two inductive circuits, including the one containing G, are influenced by a discharge of 2 +.

In Fig. 5, where R < G, a discharge of 2 − is the disturbing agent.

So that in these two cases the "*throws*" on G are in opposite directions, and it is only when a balance exists, as in Fig. 3, that G remains undisturbed.

By the above method the writer has taken rapid tests of mirror galvanometers of a resistance ranging between 600$^{\omega}$ and 5,200$^{\omega}$. The results checked by ordinary bridge tests with a second galvanometer have proved correct within one or two units. For the testing of a mirror galvanometer of the "water," "dead beat," or ordinary "signalling" pattern, the only appliances necessary are an adjustable resistance and an office condenser, but when G is a sensitive testing galvanometer of the astatic pattern, an extra high resistance *r* (*vide* Fig. 2) inserted in the battery circuit becomes necessary for the producing of a convenient deflection within the limits of the scale.

It has been found requisite for both C and C′ to be short-circuited for an instant after each attempt at a balance, and before a fresh adjustment is made, in order to dissipate the residual charge.

The following shows the practical arrangement of the test:—

C and C′ an ordinary office condenser of say 20 micros, divided as convenient, each side being short-circuited at pleasure, at P and P′ (*vide* Fig. 6).

r extra resistance inserted if necessary, but in no way influencing conditions of test already explained.

B = convenient battery.
R = adjustable resistance.
G = galvanometer of unknown resistance.
K′ = make-and-break key. K battery key.

Battery Test.

By making G and B change places, the resistance of B may be calculated by the proportion—

$$B : R : : C' : C, \text{ or } B = R \frac{C'}{C},$$

a balance being obtained as before by adjusting R until no disturbance is noticed on G's deflected spot, when K′ is closed, *vide* Fig. 7.

If necessary for the obtaining of a convenient deflection, an extra resistance *r* may be inserted with G without altering conditions of test. A shunt also may be used on G.

E. RAYMOND BARKER, Madeira.

THE EDISON CENTRAL STATION IN MILAN.

During the past year great progress has been made in Italy towards the commercial introduction of the Edison system, the centre of activity being the enterprising city of Milan.

In August, 1882, the "Comitato Edison," a committee representing the leading banks of Milan, delegated Professor Colombo, of the Milan Polytechnic, to investigate the Edison Central Station system.

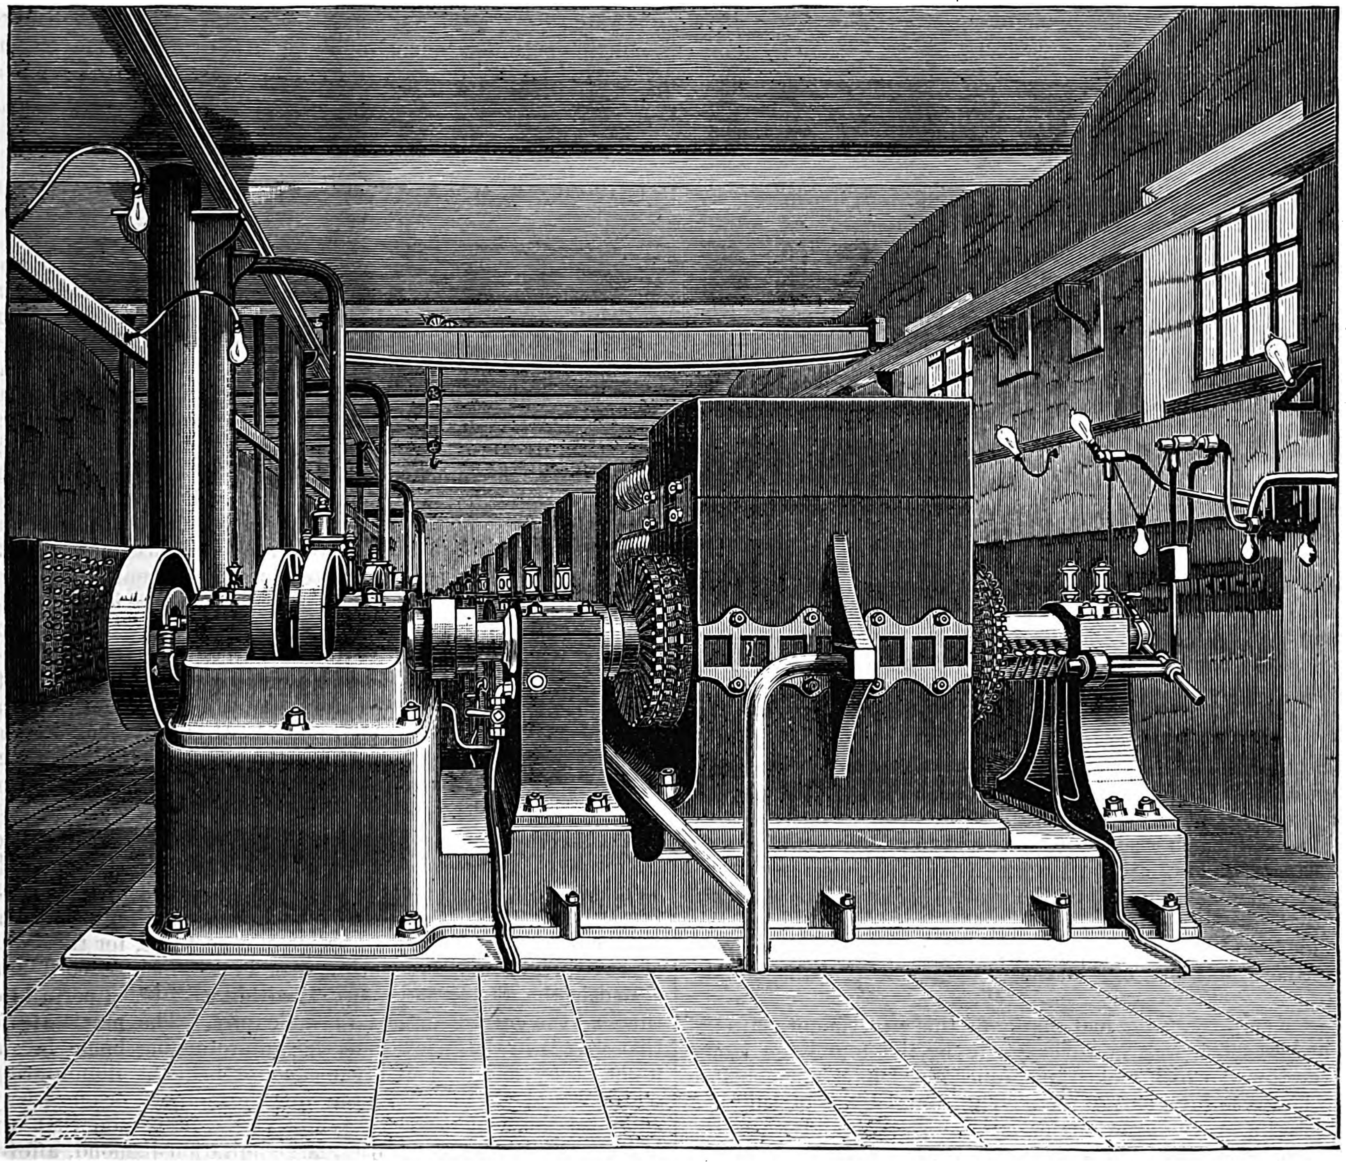
After visiting the stations in London and New York it was decided to undertake the installation of a central station plant for 3,000 lights, and towards the middle of October the construction of the station was begun. The station, which is a handsome three-story brick structure, was erected in accordance with the plans of Professor Colombo on the site of the old Teatro Santa Rodegonda, near the celebrated Duomo. The installation of the dynamos and the electrical plant was directed by Mr. John W. Lieb, formerly electrician of the Edison Central Station in New York. The first lights were supplied from the station in June, 1883, and they have been in constant operation ever since without any interruption. The generating plant then consisted of four Edison dynamos, type C, with a capacity of 1,200 lights each. Two of the dynamos are driven by Porter-Allen engines, and two have engines constructed by Messrs. Armington and Sims. These engines are connected direct, and run at 350 revolutions per minute, the Porter-Allen engines having cylinders 11 3-16 diameter and 16in. stroke; the Armington and Sims engines being 14½ diameter and 13in. stroke. The steam was furnished by four Babcock and Wilcox boilers of 160 horse-power each. In August, 1883, as a result of the action taken by the Municipality of Milan, the Edison Company closed a contract with the administrative board of the La Scala Theatre, for lighting it from their central station. It was therefore decided to increase the capacity of the station by the addition of two more dynamos and an additional boiler, making in all six dynamos and five boilers.

On the 22nd of September the Manzoni Theatre was added to the list of consumers, and it has been lighted every night since that date without the least accident or inconvenience. The installation at this theatre, while insignificant compared with that at La Scala, is yet of considerable importance, the total number of lamps supplied being about 400. The whole theatre, stage, vestibule, corridors, dressing rooms, &c., are lighted by Edison lamps, gas having been entirely excluded. The intensity of the lights in the auditorium and on the stage

Digitized by Google

is controlled by five regulators, giving any desired degree of illumination, from full 16 candle-power to total darkness.

Without doubt, the largest permanent installation of the electric light in the world is that just completed and now in operation at the Great Teatro a La Scala, and it may be of interest to present some details of this colossal installation. The total number of lamps is nearly 2,500, distributed as follows:—The stage, which is the largest in the world, requires for its illumination 1,000 lamps; the auditorium and orchestra, 400; vestibule, corridors, foyer, and boxes, 500; the remaining 600 are distributed among the offices, dressing rooms, and the different stage service apartments. The stage lights and those of the grand chandelier are controlled by sixteen regulators. The resistance bobbins are made from light T iron, faced with wood, upon which strands of galvanised iron wire are wound for interpolating resistances in the lamp circuits. The regulators are distributed as follows:—Eight for the overhead traverses, three for the side lights, two for the footlights, and three for the chandelier. Each resistance frame occupies a space of 2 metres high, 1 metre long, and half a metre wide. The lights supplied through these sixteen regulators can be manipulated separately or simultaneously by means of a common shaft carrying level gears, which engage with gears on the separate switches. In all, 1,316 lamps are controlled by regulators, all of type A (16 candles), and they are distributed as follows:—408 in the overhead traverses, 264 for the side lights, 80 on the reflectors, 120 for the movable stage footlights, and 100 in the fixed footlights. The grand chandelier alone contains 344 lamps, divided among three circuits, each circuit having its own regulator. To provide colour effects, the traverses footlights and sidelights are provided with blue and red glass globes, making it possible to instantly change from blue to red or white. The regulators are grouped in a room upon the stage, situated so as to command a good view, and from this regulator room all of the stage circuits are under full control. All the lamps in the theatre to the number of 2,500 are supplied from four services branching from the general underground network of the central station system, the theatre itself being situated some 450 metres from the central station. The construction of this vast installation was done under the direction of the general manager, Professor Colombo, by Mr. Lieb, electrician of the Italian Edison Company, and Mr. Bertini, of the electrical staff. The underground conductors of the district traverse the principal streets in the vicinty of the Piazza del Duomo, and they have at the present time a total length of nearly five kilometres. The most distant consumer is situated about 500 metres from the station. The total number of lamps now being supplied from the station is about 3,500, which number will be increased to 4,000 by the end of January.



Edison Central Lighting Station at Milan.

It is the intention of the company to increase the number of dynamos to ten during the coming summer, and to extend the network of conductors so as to be able to meet the supply of consumers out of reach of the present plant.

The contracts with consumers are made at a variable price per unit, depending upon the consumption. The charge is

Digitized by Google

made up of two parts, a constant for each lamp installed corresponding to the interest on investment, depreciation, &c., and a variable charge per lamp-hour corresponding to the cost of coal, attendance, &c. Upon this basis, proposed by Professor Colombo, the large consumers have the Edison light at a price equal to or even less than the cost of gas, while the small consumers who use the current but a small number of hours per day pay from 10 to 20 per cent. more than the cost of gas.

Since the 26th December the La Scala Theatre has been lighted regularly five nights per week without the least interruption or accident of any kind. Three dynamos at the Central Station supply the current to the theatre and all the other installations. The Italian press is very enthusiastic in praising the great success of this installation, unique for the difficulties overcome, and its vast proportions.

ELECTRIC LIGHT AT TURIN.

The following account of the electric light at Turin is translated from an article which appeared in one of the leading Italian newspapers:—

"It is impossible to keep our eyes shut any longer to the brilliant and numerous applications of electricity for illumination. The electric light as a source of illumination is undoubtedly destined to supersede gas. The incomparable superiority of this system of illumination over all others that are known to us up to the present time is just now beginning to be appreciated by us, and whilst remembering that it may be still further perfected by study and careful research, the experiment at Turin makes us now entirely in favour of lighting the establishments and streets of the town by this new method of illumination. At the instigation of G. Doll, Esq., director of the establishment Gruber, the large square of Turin is lighted magnificently by the electric light, to the general satisfaction and pleasure of the inhabitants. The Crompton dynamo machines, driven by two turbines, were placed in the weaving mills of Messrs. Gruber. Swan incandescent lamps, sixteen of 16 candle-power, were used to light the square, while Crompton lamps of a power of 6,000 candles each were affixed to the four corners of the tower of the municipal buildings. The light given by these lamps was most intense, white, and constant, and has been likened to a splendid full moon. Turin now appears to have shaken off the apathy and laziness which seemed to have grown upon it, and one may almost prognosticate that it is the future Manchester of Italy, which name was applied to Biella by Cavour. The plentiful supply of water-power favours immensely its development. It is understood that if Turin adopts the electric light to illuminate its streets and private houses, Biella will probably follow suit."

Mr. Kempster, who had charge of this experiment, says:—"The best effect was, however, made by the four large lamps on the tower, which looked magnificent. I have never before seen lamps so high as 120 feet. The consequence of this altitude is a very even light on the square, and that the rays are projected an immense distance. It is easy to read large type at a distance of about 600 metres (about 666ft.), and the reflection is thrown by the lamps all round the valley, a distance of ten or twelve miles. The Grand Square at Alexandria was illuminated when the King of Italy visited that city for the purpose of unveiling the statue recently erected to the lamented Batazzi, the illustrious Italian statesman."

Writing home at the date of the installation, Mr. Kempster says:—"The first night of lighting up we had not time to finish some joints in the wire at the bottom of some lamp-posts; we therefore joined it temporarily. A gendarme was standing with others at the bottom of one of the posts, and with natural officiousness he took hold of one of the wires, remarking to the bystanders that he could always stand a good deal of electricity. As he did not feel anything very particular he took hold with both hands, gave a little pull, then a great one, when lo and behold! the wire parted between his hands and the entire current rushed though his unlucky body. The unfortunate fellow was thrown a distance of over two yards, and fell senseless to the ground. He was taken to a neighbouring house, but was some time before he recovered his senses, and then could not speak. For a long time his arms and hands were paralysed, and two black marks on the palms of his hands showed where the current had entered. He had to keep his bed for several days, and is now undergoing fourteen days' imprisonment for touching the wires. I do not think he will try again how much electricity he can stand.

"On the mountains around the peasants are gathering olives in the evening when the lamps are burning, and a landowner who lives several miles away says that he has no need now to set watch for thieves, as the strong light would effectually prevent their coming. The night we first lit up the mayor sent a band of music to serenade Mr. Doll on his arrival home at midnight."

ELECTRIC JEWELLERY AND PORTABLE LAMPS.

In the early days of his electrical career that fertile inventor, Gustave Trouvé, of Paris, made some small jewels that executed various rapid movements at the pleasure of the wearer. Flies, butterflies, and humming birds flapped their wings; a lilliputian rabbit beat a microscopic drum, a death's head rolled its eyes and ground its teeth, &c., the movement being caused by a small electro-magnet, the current of which was supplied by a hermetically sealed battery carried in the pocket. But as the serious applications of electricity claimed more and more of M. Trouvé's attention, he could no longer superintend the construction of these scientific toys, and it was difficult to find workmen who would give the necessary care to their manufacture. Turning his attention more recently to electric lighting by incandescence M. Trouvé conceived the idea of enclosing minute lamps in various articles of jewellery, the imitation gems of which are so cut as to intensify the rays of light projected through them. We should not devote so much space to this subject, but that we see more than one useful and practical application of the idea; and, indeed, M. Trouvé has himself brought out a development of the principle which is calculated to render great service in entering an explosive atmosphere, while keeping both hands at liberty.

The accompanying illustration (Fig. 1) shows various articles of jewellery, each containing a small incandescent lamp, a full-sized sketch of which is appended. No. 1 is a hair-pin; 2 and 3, breast-pins; 4, the head of a cane; 5, a diadem for tiara; and 6, a large gem, intended to be set in a necklace, for theatrical effects. The leads are enclosed in a small supple cord concealed in the dress; and a switch within easy reach permits of turning the current on or off at pleasure. The practical use that we see in these jewels is that, in returning home late at night, they afford a ready means of brilliant illumination, which would aid in the finding of a lost object, or one's way, and also the way to the keyhole, &c. It is said that the walking stick, provided with a large imitation diamond, affords sufficient light to read a newspaper by. If set with, say, a white gem on one side and a red one on the other, it may be used for signalling to a distance, while the switch would enable a communication to be carried on by means of the Morse alphabet.

The neck of the lamp is luted into a small metal collar, so that a new lamp may be readily inserted in case one should break (Fig. 2). The battery, which is shown partly in section, was last year brought by M. Moncel before the Academy of Science, Paris. The ebonite case A (Fig. 3) is divided by compartments into three cells, two-thirds of their space containing a super-saturated solution of bichromate of potash. The cover B, also of ebonite, carries the elements D and D^1, and is attached to the case by two india rubber bands, E and E^1, a sheet of india rubber, C, forming a tight joint. To prevent any possibility of the liquid escaping, the whole is enclosed in

Digitized by Google

two thin ebonite covers, F and G, fitting after the manner of a cigar case. H and H¹ are the binding screws for the conducting wires. The duration of incandescence varies nearly in the ratio of the capacity of the battery. The smallest, shown full size in the cut, is capable of maintaining illumination for twenty or twenty-five minutes; while one twice the size, which may be carried by a belt attached to the outside cover, will maintain it for an hour. For theatrical effects of short duration, the size No. 3 will maintain incandescence in eight lamps at once; indeed, as many as twenty-five have been kept going at the same time. The battery can also be recharged in a few minutes by renewing the solution.

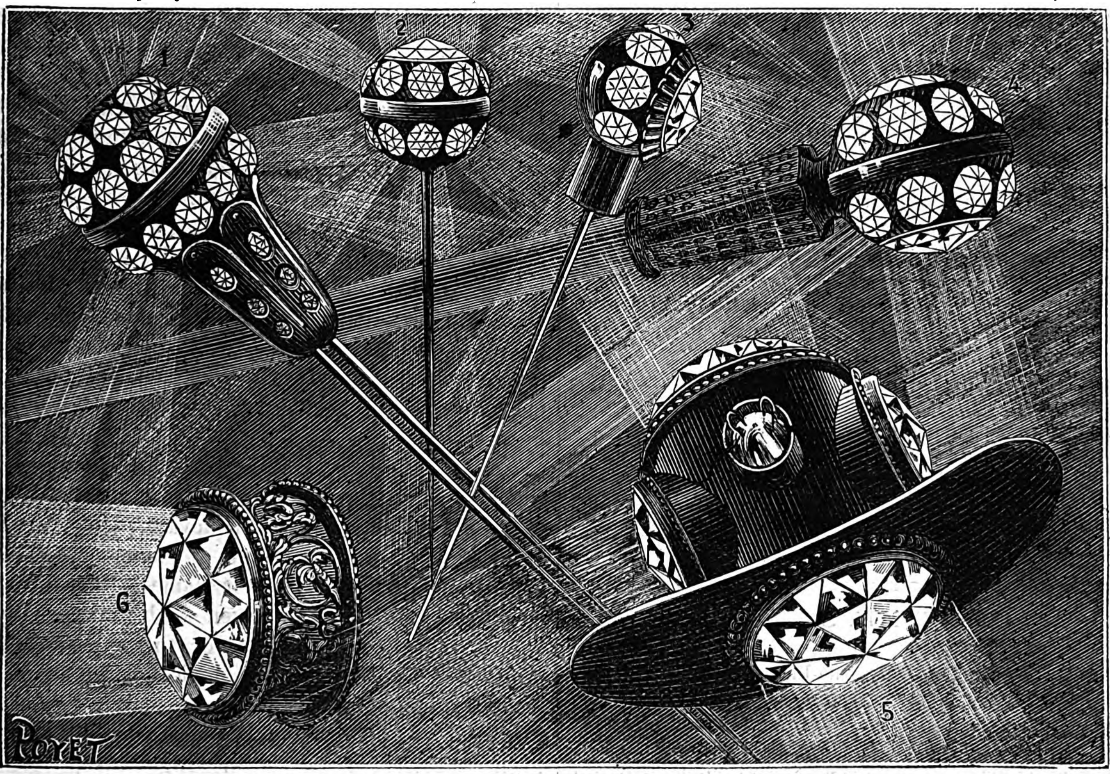


Fig. 1.—Collection of Trouvé's Electric Jewellery.

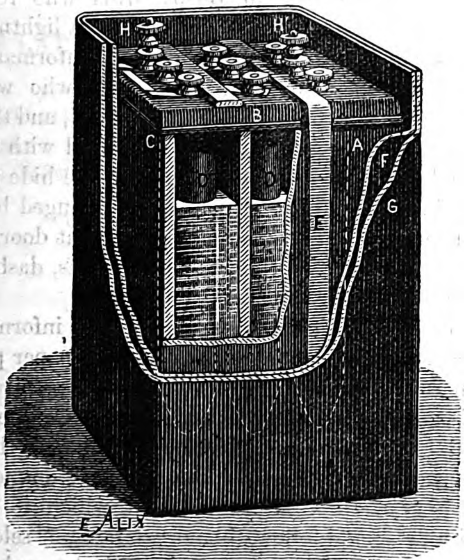

Fig. 3.—Trouvé's Battery.

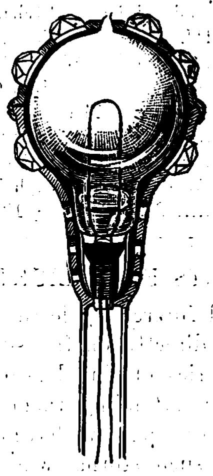

Fig. 2.—Trouvé's Scarf-pin.

The latest and most practical application of this system is that by means of which an *employé* of the Compagnie Parisienne du Goz is provided with one of these lamps attached to his head, so as to leave both arms at liberty for stopping a leak in a gas pipe without fear of igniting the explosive mixture of air and escaping gas. The battery is carried by a belt at his side; and the rays of light, intensified by a lens, are directed on to the work. His mate is provided with a modification resembling a miner's safety lamp; but both have the advantage of being self-contained, and not dependent on long conductors from a fixed battery. Both forms have been used successfully by the Paris Gas Company for about a year, the inside of gas-holders having been frequently inspected in this way. They are used by more than one manufacturer of dyes prepared with very volatile fluids, such as ether, benzine, sulphate of carbon, &c. Having recently been brought before the notice of the Société de Physique, these lamps are now adopted at the Paris Observatory for taking the readings of various instruments during the hours of darkness.

ACCIDENTS FROM LIGHTNING.

Following on several interesting lectures delivered recently bearing more or less directly on the subject of this article there have been a series of thunderstorms, the severity of which and the fatality attending them being almost unprecedented. For some years past we have done our best to give a careful record of all such storms wherever any damage to property or life has resulted; and wherever ascertainable we have added full details of the accident with reference to the situation and character of the structure when the object damaged was a building, and the nature of the injuries sustained when the victim was a human being. But in furnishing these records we have been painfully conscious of the meagreness and inutility of our labours, the sum total leaving us pretty much in the same state of ignorance as when we begun. Looking back at our notes on this subject from week to week they remind us of a barren list of casualties at sea, without the least clue to their origin or warning as to how they might have been prevented.

This being the case, we are anxious to see some amendment in the record of casualties due to physical causes which the electrical world ought certainly to be better informed about than it actually is. A record of accidents from lightning is all very well as far as it goes, but it goes a very little way. What we require to know for scientific purposes is something quite different, and for the prevention of such accidents something far more complete. As long ago as 1855, in a Report of the Academy of Sciences, quoted by the current number of the *Edinburgh Review*, in an article on "Lightning Conductors," it was pointed out that continued and minute observation and study of the effects of thunderstorms was imperatively necessary, with a view alike to ascertain what it is that lightning spares as well as what it strikes. Nearly thirty years have elapsed since that appeal was made, and made apparently in vain. "It is," continues the Report, "of the utmost importance for the advance of man's knowledge in this branch of physical investigation that all instances of injury from lightning should be immediately examined and tested, and that all facts ascertained should be accurately described and placed upon record."

Now, what are "all" the facts which are ever vouchsafed the student in this region of inquiry? Usually they consist of the fullest details on all irrelevant points, but of no details at all on the important points. A man is "seriously injured," another one "killed;" their names, their occupations, and sometimes their ages are given with praiseworthy exactitude, but the nature of the injury, or the appearances after death, much less the actual physiological cause of death, are not deemed worthy of mention. At one place a "valuable milch cow was killed"—just as if the value of the cow added something to the severity of the shock. Eight sheep were killed at one place, and a ninth had to be afterwards destroyed. We should like to know why; more particularly should we like to know more about the three girls in Busby Mills who fell into a trance for several hours from the effects of a lightning flash. Now and again we get a useful bit of casual information, such as that of the unfortunate man at Arisaig, who was found dead with a mark like a bullet-hole on his head, and that of the cow while grazing in a field being stricken dead with no visible marks of violence, save a slight singeing of the hide; but as a rule their value is of a kind which may be gauged by the following:—The lightning came in at the front door, went up the chimney, and after visiting the bed rooms, dashed out of the attic window, doing considerable damage!

The simple fact is, that the sources of our information are not such as are likely to help us. The newspaper paragraph writer is naturally more concerned with the picturesque and the sensational than with the scientific. When the storm is over the local incident has no further interest for the outside world, and we hear nothing of the coroner's inquest which follows, or the *post mortem* examination, which it would be highly desirable should follow, though we fancy it seldom does. Perhaps an appeal to the press on this subject may be of some use, and such lectures as that of Professor Tait, which we published not long ago, and Dr. Stone's address, more recently at the Health Exhibition, may be of service in directing attention to the really useful items of information that might be added to almost all reports of accidents due to lightning. But the difficulty of obtaining what is wanted at present was well illustrated in the case of Dr. Stone, who, though the cases are all recent, and he had made special application for information respecting them, could tell his audience very little indeed

about the accidents which had occurred in connection with electric lighting.

It seems to us, however, that if any facts useful for science are ever to be got together they must be collected under scientific supervision. Some society ought to be formed for the purpose; or what would be preferable, because more immediately practicable, some existing society should take up this matter in earnest, following the clue furnished in the newspapers whenever an accident to human life occurs through lightning, and obtaining, either by personal investigation on the spot or by correspondence, precisely those particulars in which we are at present so deficient. Some extensive and valuable data have been gathered by individual observers; but it is obvious that such a work should not be left to the chance efforts of personal enthusiasm. That it has been so long neglected would seem to indicate that scientists are not altogether free from the common superstition that accidents from lightning in the open country are wholly unpreventable, the only note of warning uttered by the scientific world and heard of the people being that during a thunderstorm it is dangerous to take refuge under a tree. Whether the danger is in the situation itself or in the possibly falling tree authorities are still not wholly agreed. But lightning plays much havoc in the open, it would seem from the reports; and before we can formulate some means of protection for our flocks and herds, to say nothing of the human beings who are tending them, or are overtaken by storm before shelter can be reached—shelter itself affording doubtful safety—we must have more exact information as to the locality, the configuration of the country, its general characteristics, and any peculiarities of the particular spot that may account for the pent up forces of electricity selecting it for their discharge. We shall obviously never get what we require from the ordinary channels of information.

CORRESPONDENCE.

CALCULATING THE RELATION OF DYNAMO RESISTANCES.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: In the report of the British Association, 1881, p. 528, Sir William Thomson gives the following equations for a series dynamo:—

$$\frac{\text{Waste}}{\text{Total work}} = \frac{R_M + R_A}{R_M + R_A + R_X},$$

and

$$\frac{\text{Useful work}}{\text{Total work}} = \frac{R_X}{R_m + R_A + R_X}.$$

In what units do you represent the terms on the left-hand sides of the equations? Do they only represent percentage as $\frac{93}{100}$ for the second equation?—Yours, &c.,

Bristol. A. T. B.

HAWKER'S SINE PHOTOMETER.

TO THE EDITOR OF THE ELECTRICIAN.

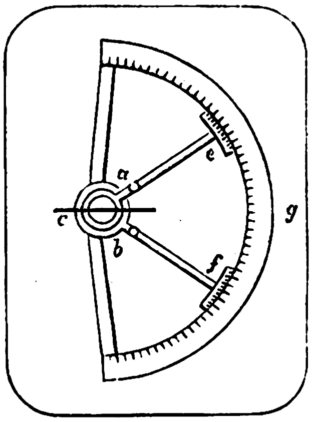
SIR: In the ordinary shadow photometers, depending for their action on the relative distances at which two luminous sources give equal intensities, there are many points which in practice render their manipulation difficult, especially to an unpractised operator, and especially when a slight difference of colour exists. A skill of eye and judgment are necessary to ensure correctness which are not at all common.

In proof of this, we have the sometimes ludicrous difference of results obtained by independent observers in identical cases; and this is naturally very noticeable in the comparison of the richly chromatic electric light with ordinary standards.

Doubtless in the future these measurements will be much simplified by the use of standard power electric lamps in such comparisons; but in the meanwhile we can but do our best to minimise the sources of error, and the writer has been led, therefore, to design a simple and yet effective instrument suitable for every day work, in which he has endeavoured to attain the desiderata of portability, rapid adjustment to any possible fluctuations in the lamp under measurement, and the direct reading off of luminous intensity in candle-power without calculation.

As shown in the accompanying plan, the instrument consists of a rectangular baseboard about 6ft. by 4in., at the centre of which is a brass sconce or short tube screwed into a circular brass plate at its lower end.

On this, as a centre, move two radial arms, each carrying a vernier seal at its extremity, and a pointed gnomon, *a b*, at a radius of about an inch from the centre. Inside the tube fits the pivot of a semicircular frame carrying a graduated arc, *g*, and supporting just above the common axis a small screen of thin translucent paper, spotted with paraffin wax. The plane of the screen coincides with a zero mark on the graduated arc, and on either side of this the graduations represent a scale of natural sines. It will be seen that the screen and graduated circle move together, while the two vernier arms which move along the edge of the graduated arc are mutually independent. The latter can, moreover, be fixed in any position by clamping screws without interfering with the freedom of movement of the screen and graduated arc.



Hawker's Sine Photometer.

c represents Screen; *a b*, Gnomons; *e f*, Vernier Indices; *g*, Graduated Arc.

To use the instrument, the two luminous sources are placed at equal distances from the centre of the screen, and separated by such an angle relative to the instrument that their lights fall on opposite sides of the screen.

Both the lamp to be measured and the standard can now be fixed, for all further adjustment is in the instrument itself.

The radial arms are now moved until the shadows of their respective gnomons fall coincidently on the central portion of the screen, and are then clamped in this position.

It will be obvious that illumination will be greatest on that side of the screen facing the most intense light in practice, and the spots of grease will then show *bright* on the opposite side.

If, however, the lights be equal, the illumination will be greatest on that side which is most directly facing the light, and least on the side most oblique to the radiations.

In other words, the brightness of the sides will be proportional to their respective areas projected normal to the light rays.

Hence, turn the screen and its attached arc on the axis until a point is attained at which the grease spots disappear, and then read off the respective angles made with the screen and vernier arms. The intensities of the luminous sources will then be inversely as the cosines of the angles.

In order to avoid the trouble of consulting tables of natural sines it is best to use sine graduation on the arcs, and in order to further simplify rapid measurements it is advisable

Digitized by Google

to arrange so that the standard shall be normal to the screen. A single reference is then sufficient to give the relative power of the test lamp at once, without any calculation.

The compact form of the instrument enables it to be very easily boxed in free from extraneous light.

It is of course essential that the luminous sources shall be on the same plane as the instrument, but this need not be necessarily horizontal.

A very excellent screen may be made by pasting together two thin opaque gelatine films, previously shaded in lines on the inner sides.—Yours, &c., T. H. SEYMOUR HAWKER.

LAMPS WITH DYNAMOS v. BATTERIES.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: I notice in your impression of 12th July two allusions to the working of some lamps which we put up on the occasion of the *conversazione* at the King's College.

While not fearing that your readers will consider Mr. O. C. D. Ross has proved the superior steadiness of primary batteries over dynamo machines by the comparison he makes between the lamps as supplied by his batteries and those exhibited by the Edison and Swan Company, I think it only fair to us and to the believers in dynamos generally to say that we had such short notice given us that our men were only able to begin work on the day the *conversazione* opened. This, however, would not alone have prevented our keeping up the credit which electrical engineers so justly claim of doing work with almost any required rapidity had it not been that at the last moment, when a start had to be made, the gas engine belonging to the college, though nominally easily able to do the work, was found to be in such bad condition as to be almost useless; indeed, had I not been obliged to be an absentee on the occasion of the *conversazione* I have very little doubt that Mr. Ross would have had no chance of making his unfavourable comparison, nor would you in your article referring to the occasion have had an opportunity of making the remarks you did. I may add that the lamps used were Swan and not Edison. Apologising for intruding on your valuable space on such a question of detail.—Yours, &c., J. F. ALBRIGHT, Resident Engineer.

The Edison and Swan United Electric Light Co.,
57, Holborn-viaduct, E.C., July 18, 1884.

THE HEALTH EXHIBITION.—III.

It is necessary that the electrician should know all about the external resistances, because he uses wire and other forms of metal in his dynamo, and the total resistances of the materials of which he makes his machine must bear a certain ratio to the total external resistance in order to give the best results. So far we have only looked at the terminals of the dynamo; we will look a little more closely into the parts of the machine and try to find out how it acts. Perhaps the better way will be to build up an elementary machine. The toy shops have made us familiar with a magnet, but because we are familiar with a toy magnet it does not follow that we understand the magnet as used in dynamo machines. If we take a bar of soft iron, AB (Fig. 1), and wind around it a piece of insulated wire, CD, we obtain part of the requisites of what is termed an electro-magnet. If we pass the blade of a knife backwards and forwards close in front of the ends A or B of the bar AB, the knife passes just as it would through air at any other point; but now, if we join the ends of the wire CD to the terminals of an electric battery so as to get a current of electricity through the wire, we find certain changes take place, not only in the wire but in the iron around which the wire is wound. Passing the knife again backwards and forwards in front of A or B we find that it is not so easy to move the knife, in fact it seems as if we have really to cut through something. The iron seems to have thrown out in every direction a number of invisible tendrils, which have to be cut before the knife gets through. These invisible tendrils have been termed "lines of force," and the whole apparatus an electro-magnet. The ends of the iron core are termed the "poles" of the magnet. Generally the iron core is bent into a U shape, so that the poles are much nearer each other than in the straight form. We shall assume that the reader has some knowledge of magnets, knowing for example that the two poles are known as the north pole and the south pole respectively, and also that the north pole of one magnet seems to repel another north pole and attract a south pole.

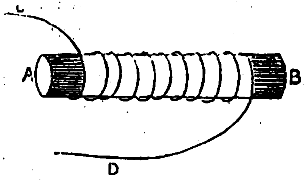


FIG. 1.

It has been found that if a wire—a copper wire, for example—is passed backwards and forwards in close proximity to the poles of a magnet, a current of electricity is generated in the wire so moved. In order easily to obtain indications of such a current, the wire must form part of a complete conductive circuit. Now suppose one part of this circuit to consist of a carbon filament, the current passing to and fro through the filament as the wire was moved backwards and forwards in front of the pole would make the carbon hotter than the copper wire, and, indeed, if the current were sufficiently powerful, would render it incandescent. This fact is made use of in the dynamo, which, indeed, is a machine for passing a wire or wires backwards and forwards in front of the magnet poles. A rough diagram will show this. AB represents the horseshoe magnet with pole pieces fashioned as at CD (Fig. 2). These pole pieces are called the field magnets, and that portion of space which contains the lines of force of the field magnets is called the "magnetic field." We ought to have stated that the lines of force starting from one pole find their end at the other pole, so that each line of force may be looked upon as a closed curve, the curve going partly through the iron and partly through the air. Any conductor interfering with these curves, that is, breaking through them or cutting them, undergoes change and is said to be electrified. If, as we have said, a closed wire is the interfering substance, we get indicated in it a current, and this current is proportional to the number of lines cut by the wire.

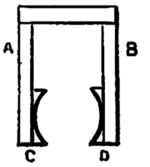

FIG. 2.
Field Magnets of Dynamos.

The lines of force commence say at C and end at D, going across the air space pretty well straight. If we take a cylinder (Fig. 3) and wind wires around it, W W W, fixing the axis of the cylinder so that the wires can be rotated in front of C and D, we get a current in the wire when the electro-magnet is excited by a current and the cylinder rotated. This rotating part is called the "armature." The wire of the armature and the wire and lamps external to the machine in reality form one continuous circuit. It would not be very economical, however, to have a machine made in this elementary manner. Dynamos may be classified according to the winding of the field magnets or the construction of the armature. All machines give a current first in one direction, then in the opposite or alternate current. With some machines the alternate currents are used, and these are called alternate current machines; while to others is added an arrangement whereby the alternate currents are so directed that the currents used are in one direction only. These latter are called direct current machines.

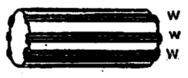

FIG. 3.
Elementary Armature.

Let us consider the various ways which have been suggested as regards the winding of the field magnets.

1st. THE SERIES METHOD.—We have explained that the current is generated in the rotating armature coils. From the coils it may be said to go to one of the collectors or brushes, from the brushes to the + terminal, and from this terminal through the external circuit to the other terminal, then to the other brush, and so completing the round. This explanation may not be altogether scientific, but for the moment it will help us in getting a fair idea of what goes on. In the series

Digitized by Google

method of winding, the main wire goes from the + terminal round first one and then the other arm of the electro-magnet, thence to the lamp circuit, and so to the other terminal. Fig. 4 shows this. T and T' represent respectively the + and − terminals; M M the arms of the electro-magnet.

2nd. THE SIMPLE SHUNT METHOD.—The current round the arms of the field magnets is taken not from the main but by means of a branch wire. The total current generated

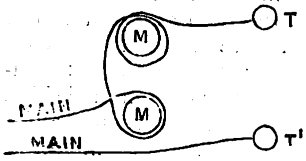

FIG. 4.
Series Method of Winding.

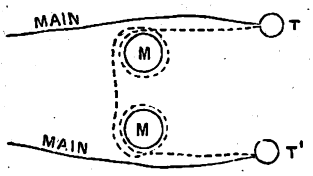

FIG. 5.
Simple Shunt Method.

divides itself between the main and branch wires inversely as the resistances of these wires. Thus, if the resistances be represented by x and $2x$, the current will be represented by 2 and 1 respectively. Fig. 5 shows this system. As before T and T' represent the terminals. The main wire is shown by a thick line, the shunt wire by a dotted line round the magnet arms M M.

3rd. THE COMPOUND METHOD.—In this system, as shown by Fig. 6, the magnet arms are wound with both a shunt and the main wire.

4th. THE COMPOUND SHUNT.—We do not know that any of the machines in the market are constructed upon this plan, but it will easily be seen that the number of branches or shunts is not limited to one. It has been suggested, then, that

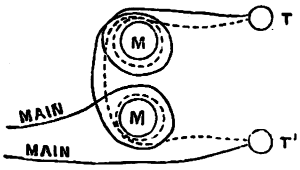

FIG. 6.
Compound Method.

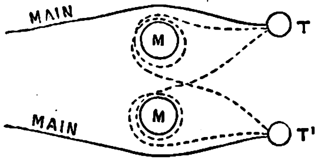

FIG. 7.
Compound Shunt Method.

there shall be a branch or shunt for each arm of the magnet. Two shunts thus used can be used either to make one ordinary machine, two ordinary machines, two unipolar machines, or a more perfect machine of a type similar to the Jurgensen. So far as we know this is the only direct way of getting a unipolar machine. The method is shown by Fig. 7, where T T' represent the terminals, the dotted lines represent the two shunt wires, the thick line the main wires. Making the resistances of the shunts equal the effect of each wire will be the same, and according to the direction of winding the poles can assist or oppose each other. If the resistances are unequal, either assistance or opposition can be obtained by the manner of winding, and by this means a good deal of governing can be done.

The above are the various ways of winding the field magnets. The current through the field magnet wires is not always obtained from the armature of the machine, but ofttimes a separate small machine is used to generate the current for these wires. The machine so used is termed the "exciter," the machine so excited is called the "generator."

LIGHTNING AND TELEGRAPH MATERIAL.—An interesting return has been made of the injuries sustained by telegraphic apparatus in France during 1883. The following ratios of damages are per 1,000 of the various articles in use:—

EXPERIMENTS ON THE EFFICIENCY OF INCANDESCENT ELECTRIC LAMPS.*

BY HORACE B. GALE.

These experiments were made by the writer in April and May, 1883, when a student in mechanical engineering at the Massachusetts Institute of Technology, and furnished the material for a thesis, from which what follows is selected for publication.

The object of the tests was to ascertain the efficiency of each of the principal forms of incandescent lamps when run at various candle-powers. The efficiency, as the term is here employed, is measured by the number of candle lights produced per horse-power of electrical energy expended in the lamps themselves.

As much of the work as possible, including the calibration of the instruments used, was done in the laboratories of the institute. The other experiments were made at one of the lighting stations of the New England Western Electric Light Company in Boston, as the necessary dynamo power could be more readily obtained there than elsewhere. It should be stated, however, that this company had no part in the experiments, and no knowledge of the results, except what was gained afterwards by inspection of the diagrams presented herewith. The forms of lamp tested were the Maxim, the Edison, and the Bernstein. Measurements of the Swan lamp, which it was intended also to include, had to be omitted on account of the limited time which could be spared for the work.

Before describing the experiments, a few words may be devoted to the

General Principles

which govern the efficiency of an incandescent lamp. Each of the lamps mentioned consists essentially of a filament of carbon enclosed in a glass globe, from which the air has been exhausted, the ends of the filament being joined to two platinum wires, which pass through, and are sealed into the glass. These wires form the connections by means of which a current of electricity is sent through the carbon. The energy which must be expended to force the electricity through the resisting substance of the filament is transformed into heat, which shows itself by raising the carbon to incandescence.

The heat escapes from the carbon filament in three ways: first, a little is conducted away by the connecting wires; second, a still smaller amount, probably, is transferred to the glass by the rarefied gas left in the globe; third, the remainder, which represents practically the whole energy expended in the lamp, escapes from the carbon by radiation. This radiation consists partly of invisible heat, and partly of light; and it is clear that the most efficient lamp is the one in which the largest part of the radiant energy is in the desirable form of light. In other words, the efficiency of an incandescent lamp depends solely upon the proportion between the quantity of energy which is given off as light and that which is wasted as invisible heat.

Now the ratio between the quantity of light radiated and the quantity of heat radiated by any solid body depends upon its temperature. The shape or structure of a body, or the extent of its surface, though influencing the total amount of radiation, cannot affect the proportion of the light and the heat.

By adjusting the strength of the current passing through the carbon of an incandescent lamp, we may heat it as hot as we please. We may raise it to a moderately high temperature without getting any light at all, all the energy expended being wasted in the form of heat; increase the quantity of electricity passing through the filament, and we can bring it to a dull red; again augment the current, and it glows with a feeble yellow light; and now, if the current is made a little stronger, without adding much to the amount of *heat* radiated, the intensity of the *light* becomes enormously increased. The way in which the candle-power rises, as the current strength is augmented, may be seen in the following table, based on a

* Reprinted from *Van Nostrand's Engineering Magazine.*

Digitized by Google

series of measurements made upon a Maxim "B lamp," designed to give about nine candle-power.

The efficiency of a lamp—that is, the return we get in light for a given amount of electrical energy, being greater the higher the degree of incandescence to which the carbon is brought, it follows that by varying the candle-power of any incandescent lamp, we may, within certain limits, make its

Current strength in amperes.	Candle power.	Increments of current strength.	Increments of candle-power.

2·5	55·0	0·5	38·0
3·0	120·0	0·5	65·0

efficiency as high, or as low, as we choose. On the other hand, the hotter the carbon is heated the sooner it is disintegrated and destroyed. A gradual transfer of particles of carbon takes place from the filament to the inner surface of the glass globe; the latter becomes darkened, the resistance of the carbon is raised, and finally the filament breaks at its weakest point.

It is worth noting in this connection, that in the experiment referred to above, the Maxim lamp was run for about 15 minutes at more than 10 times its normal candle-power without apparent injury, a fact which speaks well for the endurance of this form of lamp.

While the *efficiency* of an incandescent lamp is thus a matter of temperature chiefly, being greater the higher the temperature, its *durability* depends both upon the temperature and upon the form, structure, and density of the carbon, as well as upon the perfection of the vacuum obtained in the globe. The *relative economical importance* of the efficiency and the durability of a lamp will vary, of course, in different circumstances, according as the cost of the power or the cost of renewing the lamp is the greater; and if we can discover the law connecting the efficiency, length of life, and candle-power of a given form of lamp, we can determine, for each special case, at what candle-power the lamps should be run in order to obtain the greatest economy.

Description of Lamps.

The peculiarites of the various types of incandescent lamps depend mainly upon differences in the carbon filament.

The carbon of the Maxim lamp is made from paper, cut with a die to a shape somewhat like a letter M with its angles rounded. After carbonisation, the filament is placed in a rarefied atmosphere of hydro-carbon vapour, and heated by the current. The vapour is decomposed, and its carbon is precipitated upon the filament in such a way as to obliterate all inequalities in it.

Three styles of Maxim lamp were used in these experiments, rated respectively at 12, 24, and 16 candle-power. They were obtained at the Stanhope-street electric light station in Boston, and were taken at random by the writer from a large stock on hand at that place.

The carbon of the Edison lamp is a long, fine filament, made from Japanese bamboo wood, cut to the requisite size in a gauge, and bent into the shape of a U. Three varieties of Edison lamps were experimented upon, rated as 8, 10, and 16 candle-power. These lamps were sent from the factory of the Edison Company at Newark.

The Bernstein lamps used in these tests were peculiar in many respects, perhaps the most striking peculiarity being their very low resistance. The carbon consisted of a straight hollow tube, about an inch and a quarter long, of the size of a straw, and terminated by two knobs or bulbs of carbon about a quarter of an inch in diameter, into which the ends of the connecting wires entered. These lamps were obtained by the writer from the factory in Boston. They were rated at 30 candle-power. As they had scarcely passed their experimental stage, and have since been improved, the results obtained from them are not presented here as fully as are those obtained from the Edison and Maxim lamps.

Resistance Cold.

The following table shows the resistance of the various lamps when cold. The numbers here given were marked on the bases of the individual lamps to identify them. The resistances were measured with a large new Wheatstone bridge, made by Williams, of Boston, which was used as a standard of resistances throughout the work. Before using it the coils were tested by comparison with those in the Physical Laboratory at Harvard College. The galvanometer used in the bridge was a Thomson double coil reflecting instrument of 5,000 ohms resistance, made by Elliott Brothers, London. It was mounted on a pier of masonry, and furnished with a compensating magnet and shunt coils, so that it could be made as sensitive as desired.

The Photometer.

The measurements of candle-power were made upon a photometer of the ordinary Bunsen type, having a bar 100 inches long. The disc was enclosed in a box about a foot long, having an opening in each end to admit light, and two mirrors so arranged that both sides of the disc could be viewed at once from an opening in front. The box carrying the disc could be rolled on wheels along a horizontal track, and a

pointer projecting downward opposite the disc indicated on a graduated scale the ratio of the intensities of the two lights at the two ends of the bar. The whole was placed in a dark room, the interior of the room, and also the apparatus itself, being painted a dull black.

Illumination at Different Angles.

On account of the shape of the carbon filament, incandescent lamps generally give more light in certain directions than in others; and it is important to know exactly what the variation is, so that we may calculate, from a single measurement of the intensity of the light in a given direction, what is the true average candle-power of the lamp. This point was accordingly investigated for each one of the lamps. The method used was to place two lamps of the same kind, connected either in series or in multiple arc, at opposite ends of the photometer bar, and send a current from the same source through both. One of the lamps was then turned about its vertical axis through ten degrees, or less, at a time, as indicated on a graduated circle, and the intensity of the light given off at each angle was compared with that of the other lamp, which remained fixed, and served as a standard.

The principal advantage of this method is, that if any accidental variation in the current should cause the candle-power of the lamp tested to vary slightly from its normal value, the brightness of the standard lamp will vary in the same way, so that the ratio of the candle-powers will not be affected. It was found that in this way these experiments could be carried on equally well with a current of variable intensity as with a steady current. In all the tests here described, however, the current was kept perfectly steady, by a method which will be described further on.

The values of the illumination of each lamp at the different angles were laid off graphically from a centre, and a curve drawn through the points thus found. The area of each curve was then measured with a planimeter, and the ratio of the true candle-power to the candle-power as measured on the face of the carbon loop (*i.e.*, perpendicularly to its plane) was computed for each lamp. The average results for each class of lamps were also plotted in the same way.

The photometric measurements were made only in a horizontal plane, because that is the usual method of measuring candle-power, though perhaps a fairer comparison of the different lamps would be arrived at by taking the average spherical illumination.

Referring to diagram No. 1, the outer curve represents the illumination of the old style, or 24 candle-power, Maxim lamp; and the inner curve that of the Maxim lamp as improved by Mr. Weston, which is the style at present made by the United States Electric Lighting Company, and rated at 16 average candle-power. The curves are drawn so that if one imagines the lamp placed in the centre, the plane of the carbon filament being represented by the line 0-0, all points on the curve will be equally illuminated. The carbon of the Maxim lamp being made from paper is several times as broad as it is thick; hence we see that the illumination opposite the face, or flat, of the carbon is considerably greater than that on the edge. The variation in brilliancy, as we go from the edge (marked 0) round to the face, is extremely regular for the Maxim lamps, the curves of the individual lamps being almost identical.

Diagram No. 6 shows the same thing for the Edison lamps. Here the carbon filament has its greatest breadth in the direction perpendicular to the plane of the loop, so that the illumination is feeblest on the face, and increases as we go towards the edge. Just in the plane of the loop, however, there is a sudden falling off in the intensity of the light, because when the two arms of the U are exactly in line one cuts off the light of the other. Though these curves, each showing the average of five lamps, are tolerably regular, the curves for the individual Edison lamps are quite irregular, owing to the carbon being more or less twisted.

The illumination of the Swan lamp, one of which was tested at this time, was found to be the most uniform, being practically the same in all directions. It is claimed, however, that a uniform illumination is not always an advantage, as it is often desirable to be able to throw more light in certain directions than in others.

In each of the diagrams a circle is drawn, whose area is equal to the area of the irregular figure bounded by the curve of equal illumination, and the intersection of the circle with that curve gives us the angle at which we should measure the light of the lamp in order to get its true average candle-power. A better way, however, and that here adopted, is to measure the candle-power of each lamp on the face, and compute its average candle-power by referring to the curve for that individual lamp.

Source of Current.

For experimenting upon incandescent lamps, it is desirable to be able to maintain, for any length of time, a perfectly uniform and steady current of electricity. The available sources of current were in this case a Weston fifteen arc light dynamo machine, having the field in derived circuit, and a Kabath secondary battery of seventy-two cells. The current of the dynamo machine, though tolerably steady, was not perfectly so, on account of slight variations in the speed; and that from the storage batteries, though not subject to fluctuations, would nevertheless run down gradually as the cells became discharged. By using the machine and the battery in combination, however, it was found possible to maintain a current of a perfectly uniform intensity for any desired time. The batteries were connected in series, so that any number of them might be placed in the circuit of the dynamo machine, in derivation with the loop supplying the lamps. The current passing through the lamps could be regulated by means of an adjustable resistance, or by varying the number of cells of the battery in circuit; and a variable resistance was also interposed in the field circuit of the dynamo, so that its electromotive force could be adjusted to just balance that of the battery. The dynamo thus supplied the current to the lamps without exhausting the battery, which merely served to keep the electromotive force on the lamps constant, and absorb any fluctuations that might exist in the current of the dynamo. When the lamps were turned off, the dynamo merely supplied the loss due to leakage and local action in the cells. This arrangement of balanced electromotive forces is, of course, not possible with a dynamo having the field coils in direct circuit.

The Measurements of Current

were made by means of one of Ayrton and Perry's ammeters, which was carefully calibrated at intervals during the progress of the tests by comparison with a tangent galvanometer. The constant of this galvanometer was computed from the number and diameter of the coils, and the value of the horizontal component of the earth's magnetism as determined at Cambridge, and was also ascertained directly by the electrolysis of a solution of pure sulphate of copper. The results of the two methods were found to differ by less than one per cent.

Determination of Galvanometer Constant.

In the determination by the deposition of copper, three large Daniell cells, whose joint resistance in parallel circuit was about ·08 of an ohm, were used as a source of current; the circuit was completed through the galvanometer, a resistance box, and a depositing cell with a copper anode and a platinum cathode, the liquid being a saturated solution of chemically pure sulphate of copper. The resistance was first adjusted to obtain a deflection of the galvanometer needle of a little more than 30°. The platinum cathode was then removed from the cell, washed with distilled water and alcohol, dried, and weighed. The circuit was again closed by lowering the cathode into the solution, and the deflection of the galvanometer was kept constant for about an hour and a half, when the circuit was broken by taking out the cathode, which was washed, dried, and weighed, as before. The data for calculating the galvanometer constant were as follow :—

Increase in weight of the cathode.........	0·22208 gram.
Time during which the current passed ...	5095· seconds
Deflection of galvanometer	34·675 degrees.
Tangent of deflection	0·6918.

Digitized by Google

Assuming that one ampere of current deposits ·00033 gram of copper per second, as given by Prof. S. P. Thompson in his "Electricity and Magnetism," we have—

$$C = \frac{0{\cdot}22208}{5095 \cdot \times {\cdot}00033} = 0{\cdot}132 \text{ ampere.}$$

Hence the galvanometer constant

$$= \frac{0{\cdot}132}{{\cdot}6918} = 0{\cdot}19.$$

The galvanometer had 36 coils, whose mean diameter was 52 centimetres. Computing from these data the value of the horizontal component of the earth's magnetism, we obtain H = 0·165. The value of H, as determined at Cambridge in 1882, was 0·164.

Calibration of Ammeter.

To calibrate the ammeter it was put in circuit with the Daniell battery, a resistance box, and galvanometer, the current being divided between the latter and a shunt of No, 12 copper wire. The multiplying power of this shunt was 13·29. By adjusting the resistance the reading of the ammeter was varied by one degree at a time from 0° to 22°, deflections being taken both to the right and left, and simultaneous readings made of the galvanometer. The deflection of the ammeter was found to be proportional to the current, as far as the test could be carried, after making correction for a permanent displacement of the zero point of 0·14°, which was allowed for in all the subsequent work. The ammeter was again calibrated near the middle, and again at the close of the experiments, the results agreeing with the first calibration; thus showing that the strength of the permanent magnet had not altered perceptibly while the work was in progress.

Second Series of Tests.

The object of the next series of observations was to obtain the data from which curves could be constructed for each lamp, showing the variation in candle-power and current strength as the electromotive force is increased. The method consisted in varying the candle-power of each lamp by a succession of steps, from zero to as high a point as it could safely be carried, and taking simultaneous measurements of the electromotive force, current, and candle-power at every point.

Determination of Electromotive Force.

The current passing through the lamp could be ascertained directly by means of the ammeter; but the resistance of the lamp when hot being unknown, to find the electromotive force it was necessary to place the lamp in derivation with a coil of wire of known resistance, and measure at the same time the current passing through this coil. The electromotive force was then found by multiplying together the values of the current and resistance.

ERNEST VOLCKMAR.

It is always a matter of regret to lose from among the votaries of science one whose name has become familiar, either from being engaged in experimental work or as a man of business performing duties most distasteful to the pure experimentalist. It is a matter of deeper regret when the loss is not altogether in the ordinary course of nature. Mr. Ernest Volckmar (whose body was recently found in the Seine) first became known in the electrical world in his connection with secondary batteries. He was born at Kiel, in Germany, on 31st July, 1847. In 1866 he went to Paris, and two years after to South America, where in 1871 he became managing partner to Messrs. Dorado and Volckmar. It was in the works of this firm that he first occupied himself with the study of electricity. He returned to Europe in 1876, and during the early stages of secondary-battery work was associated with the Faure Company, in Paris. He afterwards became a director of the Storage Company in England, that company working, among others, his patents.

ELECTRO-DYNAMICS*.

BY JOHN W. NYSTROM.

The object of this paper is to criticise the electro-dynamics advanced by Count Du Moncel in his work on "Electricity as a Motive Power," page 297, English edition, and to show the confusion in which that subject is yet involved.

The Count Du Moncel gives three formulas on page 299 intended to express the quantity of work accomplished by an electric current, namely as follows:—

$$W = RC^2 \quad \ldots \quad (1)$$

$$W = \frac{E^2}{R} \quad \ldots \quad (2)$$

$$W = EC \quad \ldots \quad (3)$$

W = work expressed in kilogrammetres.
R = resistance in the conductor expressed in ohms.
C = intensity of current expressed in amperes.
E = electromotive force expressed in volts.

No formulas can express quantity of work without representing the three simple elements—*force*, *velocity*, and *time*, and as the time is wanting in Count Du Moncel's formulas, they cannot express work.

In the simplest formula for work, namely W = FS, or the product of force and space, the time is included in the space S, which is the product of velocity and time. No work can be accomplished without time.

Work is transformed into power by eliminating the time, and the power is thus expressed "work per unit of time." And therefore no work can be transformed into power without dividing it with the time in which it is accomplished; but the Count divides work by the acceleratrix of gravity, and calls the quotient *power*, namely, as follows:—

$$P = \frac{R\,C^2}{g} \quad \ldots \quad (4)$$

$$P = \frac{E^2}{gR} \quad \ldots \quad (5)$$

$$P = \frac{EC}{g} \quad \ldots \quad (6)$$

P = power in effects, which is expressed in kilogrammetres per second.

To divide work with the constant acceleratrix of gravity, $g = 9{\cdot}81$ metres per second, which is velocity, will give a quotient of momentum of time FT, when a force F acts for a time T upon a mass free to move. Therefore the formulas 4, 5, and 6 cannot express power, or the work done per unit of time, when formulas 1, 2, and 3 mean work. It appears that the first three formulas mean *power*, which multiplied by time T seconds will give work.

The term *intensity* of current is evidently intended to mean a definite physical quantity, which should have a definite unit of measure; but *intensity* is applied to heat, light, and other phenomena without a definite meaning.

It is evident from the formulas, and also by the mode of measuring *intensity* of current by a galvanometer, that *intensity* means velocity of the electric current, and can, consequently, be expressed by any unit of length per unit of time. Ampere is the unit of measure of *intensity* of current, which can be expressed by a unit of velocity. The present value of one ampere is, or should be, a velocity of 1,000 kilometres per second. Therefore, the term *intensity* should be abolished in that connection, and it should be called what it really is, namely, *velocity* of current, and denoted by V instead of C, which would make the expression intelligible and definite.

Electromotive force is an expression of a definite physical quantity, which can be measured by any unit of weight, but the unit *volt* does not convey an idea of a definite unit of weight or force. The electromotive force of one *volt* is a weight or force of about one milligram. The term *volt* should therefore be

* Paper read before the Electrical Section of the Franklin Institute, June 13th, 1884.

Digitized by Google

abolished in that connection, and it should be called what it really is, namely, *milligram*, and the electromotive force should be denoted by *f*, which means force. These proposed changes would make the subject intelligible and definite, as in mechanics, where we have the well-known physical elements *force*, *velocity*, and *time*, the combination of which gives the functions *power*, *space*, and *work*.

The old and new forms of electro-dynamics would compare as follows:—

	Old Form.		*New Form.*
Power	$P=\frac{RC^2}{g}$.	......	$P=V^2$.
	$P=\frac{E^2}{gR}$.	......	$P=\frac{F^2}{R}$.
	$P=\frac{EC}{g}$.	......	$P=FV$.
Work	$K=RC^2$.	......	$K=RV^2T$.
	$K=\frac{E^2}{R}$.	......	$K=\frac{F^2T}{R}$.
	$K=EC$.	......	$K=FVT$.
Resistance	$R=\frac{E}{C}$.	......	$R=\frac{F}{V}$.
	$R=\frac{gP}{C^2}$.	......	$R=\frac{P}{V^2}$.
	$R=\frac{E^2}{gP}$.	......	$R=\frac{F^2}{P}$.
Electromotive force.	$E=RC$.	......	$F=RV$.
	$E=\sqrt{gRP}$.	......	$F=\sqrt{PR}$.
	$E=\frac{gP}{C}$.	......	$F=\frac{P}{V}$.
Velocity of current.	$C=\frac{E}{R}$.	......	$V=\frac{F}{R}$.
	$C=\sqrt{\frac{gP}{R}}$.	......	$V=\sqrt{\frac{P}{R}}$.
	$C=\frac{gP}{E}$.	......	$V=\frac{P}{F}$.

Time of operation in seconds .... $T=\frac{W}{RV^2}$, $T=\frac{WR}{F^2}$, $T=\frac{W}{FV}$.

P = power in effects, which is expressed by kilogrammetres per second.

R = resistance of conductor in ohms.

E = F, the electromotive force expressed in milligrams.

C = V, the velocity of the electric current in thousands of kilometres per second; that is, when V = 1, the velocity is 1,000 kilometres per second.

T = time of operation in seconds.

W = work in kilogrammetres.

There are 75 French effects per horse-power.

There is a discrepancy between the old and new formulas for power, which is caused by Count Du Moncel dividing the work by the acceleratrix *g*, and calling the quotient *power*. Therefore his formulas for work do not agree with his formulas for *power*.

The new form gives the *power* ten times greater than the old form, on account of the unit of electromotive force being assumed to be one milligram, and the unit of *velocity* 1,000 kilometres per second, which ought to be the units of these quantities.

Comparison of French and English units of power and work.

English.		French.	
Effects P.	HP.	Effects P.	HP.
1	0·001818	0·1382	0·00184
550	1	76·2	1·0136
7·2334	0·00178	1	0·01333
542·47	0·9863	75	1

The numbers which express units of power are equal to the numbers which express units of work done per unit of time, but the quantities, power, and work are different from one another, as explained above.

I beg leave to repeat what I have stated many times within the last twenty years, namely, that the science of electricity can never be cleared up before the electrical savants learn to understand dynamics. The greatest difficulty they have to encounter appears to be the distinction between *force*, *power*, and *work*, which quantities they now confound with one another.

The difference between *force*, *power*, and *work* is respectively the same as that between *length*, *surface*, and *volume*.

DYNAMO-ELECTRIC GENERATORS.

(CONTINUED FROM PAGE 234.)

Classification.

Let us now consider the classification of machines. Briefly, an electric generator is composed in the main of three parts: 1st, the magnets, for producing the necessary magnetic field; 2nd, the moving armature, for the generation of the current; and 3rd, the apparatus for collecting the current. Most of the modern machines giving a continuous current have two free poles only, and generally these poles may be regarded as the union of two like poles—that is, a core of iron is wound with two sets of wire, the middle being left free, and the two coils so joined that the current passes in opposite directions at the two ends of the core, thus producing a pole in the centre, and if the ends are free two opposite and simple poles at these ends.

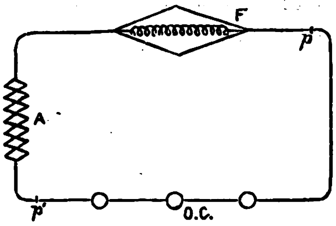

Fig. 1.—Series Arrangement.

A second core being wound so as to form a pole of opposite character, the four free ends are joined, thus forming a closed iron ring of irregular shape with two poles. These cores may be either of cast iron or soft iron—the latter, leaving out the question of cost, being of course preferable. Several machines, generally those giving an alternating current, have several field magnets. To both these rules, however, there are marked exceptions, some of which will be noticed later, for these are continuous current machines which have more than two free poles, and alternating machines with only two. The earlier machines used permanent steel magnets, and there are powerful machines, notably the De Meritens, which are still made with them. Ordinarily, however, an electro-magnet may be made more easily and quickly, and its magnetic field is more intense.

To excite the electro-magnets there are several ways.

1st (Fig. 1), by the series arrangement. In this the armature system of coils, the field-magnets, and the lamp, or external circuit, are joined in one complete circuit, so that the whole current generated flows over all parts. Starting with the residual magnetism in the iron, a very light current is

Digitized by Google

formed; this flowing through the field coils intensifies the magnetic field, which in turn strengthens the current, and so on, the augmentation of current increasing until the magnets are saturated. This point of saturation is very quickly reached.

2nd (Fig. 2), the shunt method. This was proposed by Wheatstone, and brought into prominence by Siemens. In this the current from the armature system divides, a part flowing through the lamp circuit and a part through the field coils. If now the resistance of the external circuit is increased, instead of lessening the current in the field coils it is increased, the magnets become stronger, and the current in the lamp circuit is kept up to its proper strength, or nearly so. Siemens used a shunt of moderate resistance.

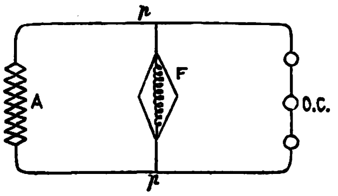

FIG. 2.—Shunt Method.

For the purposes of supplying currents which will vary inversely as the external resistance, Edison has introduced the high resistance shunt and the use of very heavy fixed magnets. By the use of large masses of iron the saturation point is less quickly reached and a more powerful machine made with a given armature, construction, and speed. It must be noticed that the characteristic curves vary a good deal with different relative normal resistance of armature, field, and external circuit, and differently dimensioned field magnets.

By the arrangement shown in Fig. 3 it is probable that very satisfactory results would be obtained. Here the field coils are in two sets, one at least being of low resistance. Through this whole armature current flows, then dividing so that part flows through the second system and the remainder through the lamp or external circuit. Another method of exciting the field magnets is by means of a second continuous current machine, this latter being a self-exciter; or a generator may have two independent systems of armature coils and two commutators, the current from one system feeding the field, and from the other the lamp circuit. In both arrangements the field is practically independent of all fluctuations of the main current due to the changes in the external resistance. I say practically independent, for the field is somewhat affected

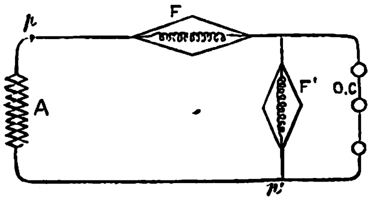

FIG. 3.

by the strength of the poles in the armature. Alternate current generators are usually excited by a second machine, although two or more systems of armature coils have been used. The armatures of electric generators may be divided into four classes—drum, ring, disc, and pole armatures.

1. *Drum.*—In this class the coils of wire are wound longitudinally—that is, along the element of a cylindrical drum. This drum may be either hollow or solid, magnetic or non-magnetic. The coils may or may not be wound in diametrically opposite divisions. They are generally so wound, and the drum rotates in close proximity to wide polar surfaces, the current generated, which is taken off by a commutator, being continuous.

2. *Ring.*—To this class belong all which have an iron ring or cylinder, which is enclosed by a series of coils. The ring may be perfectly regular, and entirely enclosed by the coils, or its surface may be broken up by projections, the coils being wound in the spaces between. There may be either one ring or several, the coils being connected in series, so that a continuous current is generated. This ring is rotated usually between two wide polar extensions, although more than two poles have been used.

3. *Disc.*—These may be described as having the active portion distributed in a thin disc or wheel, the axes of the cores being parallel to the shaft. Several field magnets generally obtain, the poles being ranged in an alternating opposition and but a short distance apart. These machines may be either continuous or alternate current generators.

4. *Pole.*—This is a very numerous class, embracing all the earlier machines, as well as a number of the modern ones. The Elias machine, although having a ring armature, depends for its action on the polar principle—that is, on the change of state, relative or absolute, of iron or steel magnet cores. Generally speaking, the machines of this class are not so efficient as those belonging to the other classes, especially when used for continuous currents. There are, however, one or two notable exceptions.

The other classes, as well as the fourth, generally use soft iron in the construction of the armature, and in some this is absolutely necessary for any efficient work. The more especially must it be used where the poles of the field magnets are far removed for the purpose of intensifying and directing the magnetic field, and where the wire is so wound that some portion must be screened from the magnetic field to prevent a counter electromotive force being generated, to the detriment of the machine's efficiency. In some of the disc armature machines, the poles being close together, iron is unnecessary between them, and the coils are so wound that the inactive parts are out of the magnetic field, or cut it in a lineal direction. In all cases where iron masses are rotated in a magnetic field they behave as any other conductor—that is, currents are generated, and these currents, circulating in the iron, rapidly heat it. Not only is a considerable amount of work thus absorbed, but the heat generated injures the wire conductors, and generally lessens the efficiency of the machine as a converter of mechanical into electrical energy. If the iron is not soft the change of magnetic state is opposed; it is not really magnetised, nor does it easily lose or reverse its magnetisation.

All these qualities are objectionable, but the use of iron being often necessary, whenever it must be rotated it should be as pure as possible, and well broken up, in which case the work is much lessened.

Of the particular action of iron screens and cores, and the means used to lessen their adverse influence, I will speak more at length in dealing with particular machines.

Machines Exhibited.

I have now to speak in detail of the principal machines exhibited, and of the theory and practice of their operation. Although some of these were exhibited by several companies, I will associate each with one only.

The generators were as follow:—

1. RING.

Gramme—British Electric Light Company.
Brush—Anglo-American Brush Electric Light Company.
Schuckert—Rowatt and Fyfe.
Maxim—Electric Light and Power Generator Company.
Bürgin—R. E. Crompton and Co.

2. DRUM.

Siemens (continuous current)—Siemens Bros.
Edison (wire armature)—T. A. Edison.
Edison (bar armature)—T. A. Edison.
Weston—Electric Light and Power Generator Company.

3. DISC.

Arago Disc (continuous current)—White House Mills.
Arago Disc (alternate current)—White House Mills.
Siemens (alternate current)—Siemens Bros.

4. POLE.

Lontin—Electric Light and Power Generator Company.
Lachaussée—Gerard and Co.

5. POLE AND RING.

Gramme Auto-Exciting—Compagnie Générale.

(TO BE CONTINUED.)

THE ELECTRICAL DEPARTMENT OF ST. BARTHOLOMEW'S HOSPITAL.*

BY W. E. STEAVENSON, M.B.

The importance which electricity has acquired in its application to medicine induced the Governors of the Hospital, at the suggestion of the medical staff, to appoint a qualified medical man to organise and undertake the management of a complete electrical department. This appointment was made in October, 1882, and I was so far honoured as to be selected for the post. The formation of such a department involved a considerable outlay, and therefore careful consideration and inquiry, so that the money expended might be used to the best advantage. A sub-committee of the staff was appointed to consider the matter, and to advise and assist me in its arrangement. The plan has developed so far at the present time as to justify me in giving an account of what has been accomplished, and also an outline of the electrical work which has been done in the hospital during the past year.

The exigencies of electricity demanded that the place selected for it should be warm and dry, that there should be space for the electrical machines and apparatus, and that these should not be subject to continual movement and disturbance, as would be the case if the room was used for any other purpose, and that there should be accommodation for the patients while waiting for treatment and for dressing and undressing, so that the whole business of the department should not be unnecessarily retarded.

It was ultimately decided to convert the room until recently used as the Coroner's Court into several compartments in which the different forms of electricity as used in medicine might be applied. One feature is the estabishment of a workshop in which all the minor repairs of the electrical apparatus used in the hospital will be carried out. It is hoped that great saving both in time and money will result from this arrangement. The man employed to make these repairs will also have the custody of the building in the absence of the medical officer. He will receive notices from the wards of patients requiring electrical treatment by the electrician, and supply and receive back again the batteries used in the wards by other medical officers. He will also prepare the galvano-cautery batteries when they are required, and take them to that part of the hospital in which they may be wanted. In the room I have marked as No. 1 there will be a frictional machine for producing statical electricity, and an insulated couch and benches; also a small table for operating. The electricity for this purpose will be conducted from the cellar below, in which will be placed a powerful Bunsen's galvano-cautery battery of six cells. The necessary operating instruments will be kept in this room. There will also be an element board connected with sixty modified Leclanché elements (also in the cellar) for producing a continuous current for galvanic purposes. An additional tray of six cells will be used to work an induction coil for producing an interrupted current. A couch will be placed under this element board on which the patient can recline, and it will be possible to use the galvanic or faradic current at will. In room No. 2 will be a similar element board connected with the same number of cells and worked in a similar manner, but it will also be possible to use the current for the electric bath in the adjoining compartment. The portable batteries for use in the department and for lending to the wards will also be kept in this room, and also the electro-magnets belonging to the hospital. In the centre of the building a lobby has been formed, provided with benches for the patients while waiting for treatment.

I can best show the amount of electrical work done by myself in the hospital during the year by a tabular arrangement. I have given in each case the reason why electricity was employed, and also appended a few remarks and a record of the result of the treatment. I almost invariably used one of Coxeter's portable combined batteries, so that I had with me either current which might be required.

[Here comes the list, which we do not think it necessary to publish.]

The preceding list does not represent a tithe of the number of patients in the wards on whom electricity was used for one purpose or another during the year, but only includes those for whom my assistance was asked. Several patients, who had been treated by the house surgeons or dressers, were referred to me to continue their treatment as out-patients.

In those cases in which electricity was used for treatment, I think I can show pretty fair success. The first case after my appointment was a woman who suffered from paralysis of the left leg after confinement. She was discharged almost well. The only case of lead palsy I had to treat as an in-patient improved under galvanism. One case of hysteria recovered; the other two did not improve. Of four cases of facial paralysis, two recovered; of one I was only asked to test the condition of the muscles, and the fourth case is still under treatment by the dresser. . . . Of the four cases of infantile paralysis in my list, I was only asked to undertake the treatment of one. This case improved considerably. A second case was treated, after I had seen it once, by the dresser; and of the two other cases I was only asked to test the electro-excitability of the muscles. The two cases of sciatica recovered completely.

In the cases in which electricity was used in the medical wards for diagnostic purposes, it, as a rule, only corroborated the opinion which had been formed from other symptoms, but was most useful in determining cases of supposed or real malingering. But in the surgical wards, where there was paralysis of a limb or part of a limb consequent upon an injury, in some cases, I believe, electricity was of great use in determining, for instance, whether a nerve was completely divided or not, and in other cases in helping to arrive at a decision whether an operation should be performed. I had seven such cases of paralysis following an injury.

In the practice of this department, I have found my former medical and surgical experience of the greatest use, for I have been called upon to examine or treat cases of all descriptions.

For the first few months after my appointment the organisation of the department was under consideration. I therefore did not take under my charge the treatment of the out-patients, except a few cases I was especially asked to attend to. These I find amounted to 74. I shall only give the number treated and the result, as far as I am able to state it, of some of the cases, noting those of more especial interest.

1. *Drop wrist* (13 cases).—Only one could be clearly traceable to lead poisoning. Eight were from pressure on the nerve during sleep, several occurring while the patient was in a state of intoxication. Six of these cases improved. Of the four cases for which no cause could be assigned only one improved. It is impossible to give a very certain opinion as to the result of treatment. Several of the cases had improved considerably and then ceased to attend; I believe they were fairly on the road to recovery.

2. *Loss of power and pain in arms* (12 cases).—Seven of these improved, and in three no benefit was derived. Of the cases which improved, several appeared to be associated with disorder of the menstrual function. One woman, aged 48, sent to me by Dr. Farre, who was passing through her climacteric period, had had pain in both her arms, especially the left, for eighteen months, and had been unable to follow her employment as a needlewomen. After several months' treatment with electricity, she can now do needlework, and the pain has almost disappeared. This woman is still attending as an out-patient; she was induced to attend regularly for so long a time because she had faith in the remedy, and felt better after each application. My experience with these cases leads me to believe that they are certain to be relieved by treatment; and yet I think there is no doubt they suffer the pain of which they complain.

Electricity seems to be particularly useful in all those cases of vague pains and neuralgia which afflict women, and are often called hysterical, and certainly for which no obvious cause can be discovered. The pain appears to be caused merely by some

* We insert this report to show that electrical methods are being carefully examined by those whose privilege it is to attempt the cure of the diseases to which the human frame is liable. There is, we believe, a very large field for the use of electrical apparatus in surgery, and we are glad to chronicle these experiments and results.—*Ed. E.*

Digitized by Google

functional derangement, and by no organic lesion, and the application of electricity produces that beneficial change which is repuired to make the organ or its nerves perform their proper function without giving rise to this undue pain.

3. *Facial palsy* (6 cases).—Four cases improved. It was the same with these cases as with others; when they had slightly improved they ceased to attend. In two cases I did not get any beneficial result.

4. *Infantile paralysis* (11 cases).—Six appeared to improve under treatment, five did not. Several that I only saw once I have not counted. The remark with which Sir William Gull commences his article "On the Value of Electricity as a Remedial Agent," in the Guy's Hospital Reports for 1852, is most applicable to these cases, and it shows the difficulty with which an out-patient electrical-department has to contend. He says, with regard to the number of cases he has reported, "They would have been far more numerous had we been able to enforce upon our patients a more regular attendance; but after having carefully recorded the details of their history, progress, and present state, our labour has in more than half the cases been lost by their non-attendance, or by their attending so irregularly, or for so short a time, that no practical inference could be drawn."

5. *Enuresis* (9 cases).—Four were cured, and the other five improved, and would have been cured I believe if they had not, from one reason or another, ceased to come. One woman was pregnant, and I therefore advised her to desist from coming, dreading that I might bring on a miscarriage. One young girl was brought up from the country twice. After the first galvanising she was much better, and I suppose after the second her mother thought there was no more necessity for treatment. In the case of one boy I declined to continue the treatment as he was covered with scabies. I am now treating the scabies.

I have had no cases of amenorrhœa sent to me expressly for treatment, so cannot confirm the good opinion formed by Dr. Golding Bird* and Sir William Gull† as to the effect of electricity in relieving this condition, but several cases I have had to treat in which amenorrhœa was present. The catamenia appeared during the course of treatment, and was marked in several instances by a relief of the paralytic or hysterical symptoms.

6. *Duchenne's paralysis* (1 case).—Did not improve, but got gradually worse; in fact the child, who was about eight years old, became so very weak that I advised the mother not to bring him. He attended for many months, and said he felt better and stronger after each attendance, the relief lasting over the succeeding day.

7. *Paralysis of the serratus magnus* (1 case).—Did not improve. Patient only attended a few times.

8. *Paralysis from division of nerve* (7 cases).—One of these cases was only sent to me to test the muscles, when I was able to show that the median nerve had been completely divided just above the wrist, and the ulnar most likely also partially divided. The other six patients all expressed themselves as benefited by the electricity; but I only saw marked improvement in one.

9. *Paralysis of deltoid* (1 case).—This was produced by a fall on the shoulder. The patient was a sailor, and the accident had taken place on board H.M.S. "Superb" on January 22, 1883. When the patient came to me in August, the deltoid was much wasted. He now (October) can raise the arm with ease and the muscle is recovering its bulk.

10. *Sciatica* (2 cases).—Both cured.

11. *Tic douloureux* (1 case).—This case was sent to me by Mr. Coleman. The pain had been of a most persistent character, and nearly everything had been tried to relieve it but electricity. He improved from the first time he was galvanised, and as he has now ceased to attend, I believe he is cured.

I have made the above selection of the most interesting cases which occurred among the out-patients, but I had numerous others of weakness and numbness, and loss of power in different parts of the body, together with one lunatic and a sprained ankle.

* Guy's Hospital Reports, 1841, p. 114 seq.
† *Ibid.*, 1852-53, p. 137 seq.

LEGAL.

The Jablochkoff Electric Light and Power Company v. Howard and Wyndham.

In the Court of Session at Edinburgh, before Lord Kinnear, evidence was heard on the 16th and 17th instant in this action, which was taken by the Jablochkoff Electric Light and Power Company (Limited) against Messrs. Howard and Wyndham, of the Edinburgh Lyceum Theatre. The purpose of the action was to recover the sum of £1,732 5s. 4d., being the amount said to be due for supplying and fitting up an installation of machinery and fittings for electric lighting at the Lyceum. In defence it was explained that the plaintiffs took over the contract entered into by defendants with the Electric Carbon Storage Company, which went into liquidation. By the contract it was provided that in the event of the apparatus not working satisfactorily, the Electric Company should be bound to remove the machinery at their own cost, and make good any damage. The machinery erected by the plaintiff company was said to be defective, and not in conformity with the contract. Frequent attempts had been made to work the installation, but without success, and the attempts had now been given up as hopeless, the installation being quite unworkable and useless in its present condition. In these circumstances it was pleaded that defendants were not liable in payment of the account. On the other hand, the plaintiffs denied these allegations, and alleged that the installation was complete and in full working order in November, 1883, when it was taken over by defendants without complaint. Several witnesses were called to give evidence as to the insufficiency of the light and as to several failures which had occurred from "earths" being formed, and the case was then adjourned.—Counsel for plaintiffs—Mr. Mackintosh and Mr. Fleming. Agents—Davidson and Syme, W.S. Counsel for defendants—Mr. Trayner and Mr. Lang. Agents—Paterson, Cameron and Co., S.S.C.

The Brush Midland Electric Light and Power Company (Limited).

In the Chancery Division on Tuesday—before Mr. Justice Pearson—Mr. Bucknell supported a petition for the reduction of the company's capital, in accordance with a special resolution passed by the shareholders in November, and confirmed in December last, when it was resolved that in the opinion of the meeting the present nominal capital of the company was in excess of the requirements, and that it should be reduced from £250,000 to £70,500. His lordship, after hearing what was proposed to be done, refused for the present to accede to the petition, but allowed the matter to stand over generally, with liberty to apply to have it restored to the paper.

COMPANIES' MEETINGS & REPORTS.

West Coast of America Telegraph Company (Limited).

The ordinary general meeting of the shareholders was held at the City Terminus Hotel, Cannon-street, on Thursday, Mr. Robinson Kendal (the chairman of the Company) presiding.

The notice convening the meeting was read by Mr. F. L. Robinson (the secretary), and the report and accounts were taken as read.

The Chairman said: Gentlemen—It is now my duty and my pleasure to move the adoption of the report and accounts which you have taken as read, but which I have no doubt have been read elsewhere with satisfaction by most if not all of the shareholders. The Board are pleased to think that they present to the shareholders to-day the most satisfactory and improving balance-sheet the Company has ever had, and whilst we are able to present this balance-sheet we are able at the same time to announce that the Company is still steadily and surely gaining ground, and that good as is last year's report, our receipts for this year show so far an increase of some £7,000. As the report says our earnings for the last year were £57,338 12s. 1d., against the sum of £38,908 2s. 10d. for the previous year—or an increase of £18,430 9s. 3d., and leaving a nett balance, after paying debenture interest and all other charges, of £23,314 9s. 7d.—a result which has fully realised the anticipations of the Board, and firmly established the position of the Company as a dividend paying concern. The significance of this result, and the gratification of the Board, and my own gratification in being able to report it, will be best understood by a reference to our past reports and balance-sheets. Two years ago, owing to the war between China and Peru, and owing to the Chilian Government having cut our cables to prevent the possible transmission of intelligence, our position was far from encouraging, and our prospects far from bright. To meet our engagements we had to mortgage our steamer for between £12,000 and £13,000, and we had a balance on the wrong side of some £20,000. To-day I have the pleasure to say that we have not only paid off the mortgage on our steamer, and extinguished all our indebtedness, but that we have paid in dividends a sum of £12,000, and we are now ready to pay a further sum of £6,000, besides having formed a reserve of some £10,000. These are results which have not been accomplished without much care and anxiety; but

Digitized by Google

they are results on which we may fairly and reasonably congratulate the shareholders who have retained their interest in the property, and reaped the reward of their confidence. It will be noted that there is an increase in our expenditure, but the increase in one item, the item which includes the passage out of an extra number of clerks to cope with our increased business, will explain the other increases, which as a consequence follow, and even these increases are unimportant when compared with the increase in our income. Without impairing the efficiency of our service, I hope there will be a diminution rather than an increase in our expenditure as a whole this year; but on this point I would prefer to await the issue and not venture to prophecy. At the moment trade is deplorably bad on the coast, but with the termination of the war, which seems to be approaching, it may be hoped that trade will revive and our Company share in the consequent and general return of business and prosperity. In the ordinary course of things a resumption of trade and business enterprise ought to bring us a still further increase in our income, and help still further to augment our resources, and enhance the reputation of the Company as a solid, successful, and prosperous concern. Our cables are in good condition; they are, in fact, reported to be in as good a condition as when they left the manufacturers. Our staff is efficient for our work, and it will not be the fault of the Board if the Company does not reap the advantage of the future which ought now to be before us. I have pleasure in moving the adoption of the report and accounts.

Mr. T. F. CAMPBELL seconded the motion, and in doing so congratulated the shareholders on the improved position of their affairs.

Mr. LAMONT asked whether the Board had formed any idea as to what amount of reserve was necessary?

The CHAIRMAN replied that the question of reserve had been a matter of calculation and thought on the part of the directors over and over again, and it would still continue to receive their attention. The amount of the reserve would largely depend upon the income of the Company and other matters; but the directors would do all they could to build up the concern on a solid and successful basis, and this could not be done unless they had an adequate reserve.

The motion was then put, and carried unanimously.

Mr. CAMPBELL moved the re-election of the retiring directors, Messrs. Robinson Kendal and Henry Roberts.

Mr. W. E. MACANDREW seconded the motion, which was carried.

On the motion of Mr. TAYLOR, seconded by Mr. LAMONT, Mr. J. Weise (of the firm of Messrs. Turquand, Youngs, and Co.) was re-appointed auditor.

Mr. MASON said that, as the representative of a considerable number of the shareholders, he had much pleasure in moving a vote of thanks to the chairman and directors for their management of the business of the Company during the past year. Their gratitude was especially due to the chairman for his unremitting care and attention to the interests of the Company, for there was little doubt that but for that care and attention the Company would not be in the dividend-paying position which it now occupied. The position of the Company was now very different to what it was in 1879, when Mr. Kendal joined the Board; but although in the interval the amount of business had so very largely increased, the expenses of management were only £500 larger at the present time than they were five years ago. Under the circumstances it was only just that some recognition should be made of the services rendered to the Company by the chairman and his colleagues; and he therefore moved:—"That the best thanks of the shareholders be given to the chairman and directors for their constant attention and devotion to the interests of the Company, and that in view of the inadequate remuneration received by them in the past, the sum of £500 be placed at their disposal out of the funds of the Company."

Mr. TAYLOR, in seconding the motion, remarked that as the original proposer of Mr. Kendal for a seat at the Board, he had watched with the utmost satisfaction the progress which the Company had since made.

Mr. WILKINSON cordially supported the proposition, but suggested that the amount to be voted should be £1,000 instead of £500.

The CHAIRMAN said there had always been the most perfect concord and harmony at the Board, and he had been most ably assisted by his colleagues. Of course the directors would take no part in the discussion of the proposition, and whether or not any money grant was made to them they would feel grateful to the shareholders for their hearty appreciation of the services rendered to the Company by himself and his colleagues.

In the course of some further conversation,

Mr. TAYLOR remarked that since the present chairman joined the Board the market value of their property had advanced from £60,000 to £180,000.

Mr. WILKINSON's suggestion that the amount to be voted should be £1,000 instead of £500 was accepted, and the proposition thus amended was unanimously adopted.

The CHAIRMAN acknowledged the compliment, and the meeting then closed.

Telegraph Construction and Maintenance Company (Limited).

A half-yearly general meeting of the shareholders of this Company was held at the Company's offices, 38, Old Broad-street, E.C., on Tuesday last, under the presidency of Sir Daniel Gooch, Bart., M.P.

The MANAGING DIRECTOR (Mr. Shuter) having read the notice convening the meeting,

The CHAIRMAN said: Gentlemen, these meetings are merely for the purpose of informing you what progress has been made in our work during the past half year. We have manufactured during the last six months 4,322 miles of cable. We have laid the French cable between Saigon and Tonquin, 785 miles in length, and also the Brazilian Company's duplicate cables between Madeira, St. Vincent, and Pernambuco, amounting to 3,030 miles; and we have effected two repairs in that company's original cables. The steamship "Scotia" is now engaged on a third repair on her way home from the completion of the duplicate lines. The Direct Spanish Company's duplicate cable, 473 miles in length, has been laid between the Lizard and Bilbao. A cable about 40 miles long has been laid across the Strait of Sunda, and sundry lengths have been laid in the Australian and China Seas, amounting to 560 miles. The total lengths laid have been over 4,800 miles. Of course, that has been done under considerable pressure, in order to get it finished in the summer, and you must not expect that the work will continue during the next half year. The year's work is embraced very much in what you have heard me read. With regard to electric lighting, we are now hard at work endeavouring to complete the electric lighting of the Paddington Station. The wires are laid, and it is hoped that by November or December the work will be accomplished. It will enable us to judge how far it corresponds with the estimates that have been made. It is a new line of business entirely for us, and the experiments made there will enable us to draw conclusions as to how far the calculations that have been guiding not only ourselves, but other electric companies, are worthy of trust. I have nothing further to say beyond this, that everything appears to be in satisfactory state.

Subsequently, in reply to a shareholder, the CHAIRMAN said that the accounts were presented at the meeting held in the spring. The present meeting was convened out of deference to the wishes of the shareholders to merely give a statement as to the Company's business.

Mr. WM. ABBOTT reminded the meeting that the suggestion emanated from him that the shareholders should meet every half year with the view of dispelling the rumours that were circulated from time to time by people outside by way of disparaging the Company's property. He thought that every announcement that the chairman made at these half-yearly meetings justified the wisdom of the policy they adopted. He concluded by saying that the shareholders, considering the extraordinary times of depression which they had passed through, could not but express their entire satisfaction as to the condition of the Company and their warm acknowledgments to the Board for the admirable manner in which the affairs of the Company were managed, and he would therefore move:—"That the statement of the chairman to this meeting is satisfactory to the shareholders, and that the best thanks of the meeting be given to the chairman, directors, and the officers of the Company, for their attention to the business of the Company during the past half year."

A SHAREHOLDER seconded the motion, which was cordially agreed to, and

The CHAIRMAN having briefly returned thanks, the proceedings terminated.

The India Rubber, Gutta Percha, and Telegraph Works Company (Limited).

A half-yearly general meeting of the shareholders of this Company was held at the City Terminus Hotel, Cannon-street, on Tuesday last, Mr. S. W. Silver presiding.

The SECRETARY (Mr. Wm. J. Tyler) having read the notice calling the meeting,

The CHAIRMAN said: Gentlemen, our business is very short. We call you together for the purpose of confirming the recommendation of an interim dividend. When we last met, you will remember perhaps that it was to obtain your sanction to apply to Parliament for a short Act to make the Company's memorandum of association clearer and more comprehensive, and I have now to inform you that it received the Royal assent on the 3rd of the present month. Well, now, the chairman—who, I am sorry to say, is at present unwell—told us at the last annual meeting in February that the year had begun satisfactorily. That report I can confirm. The general business done this half year exceeds to some extent that done in any corresponding period of former years. As to our cable orders we have been fairly well employed. We have had several contracts for the Government departments, and for the Western and Brazilian Telegraph Company, which our steamer, the "Dacia," is now, under hire, carrying to the ground. You will be glad to know, with reference to the Spanish National Company's cables, that the obstacles that have hitherto stood in the way are removed by an agreement having been come to between the French and Spanish Governments as to the landing of the Senegal cable at the Canaries; and they have both made us payments under their contracts, and the work is now being gone on with. Well, now, I would remind you that we live in difficult times. The results that I have mentioned have not been arrived at without considerable efforts. As regards general sales, we are well represented in the chief manufacturing centres and at all the leading ports in the United Kingdom. With these few remarks I will now move that an interim dividend of 5 per cent. (or 10s. a share), free of income tax, payable on and after the 23rd inst., be now declared.

Mr. NEIL BANNATYNE: I second that.

The CHAIRMAN, in reply to Mr. Lamont, said that the Company was as well represented in China as it was in any other part of the world, and that the development of the China trade was carefully watched and cultivated by the manager.

The motion was then carried unanimously, and a vote of thanks having been accorded to the chairman and directors for their conduct of the Company's business for the half-year, the proceedings terminated.

Digitized by Google

West Middlesex Electric Light Company.

The secretary has forwarded us the following report of the second annual general meeting of this Company, which was held at the Company's offices, Hammersmith, a few days since. As we were not advised of this meeting it was impossible to send a reporter, and we give the following report simply to keep up the continuity of our Companies' Meetings:—Mr. C. Cordingley occupied the chair. He congratulated the shareholders upon the success of the Company in obtaining a provisional order for the Fulham district. The Royal assent was given to the Bill on Monday last, and it now remained for the Company to proceed to carry out the provisions of the order, which were of an extremely satisfactory character. The order practically included the whole of the Fulham district, containing over forty miles of roads. The first installation was not a large one, yet extensions would be made from time to time until the whole district was covered, and this would be carried out under the present order without the expense of applying to Parliament for fresh powers. The first section of the work to be carried out would be from Addison-road railway bridge, through the Broadway and King-street to Rivercourt, with some of the lateral streets; the Cedars estate and Brook-green road. The works for this section were estimated to cost £16,000, and a deposit of £800 only would have to be made to the Board of Trade. Two years was allowed for carrying out this scheme. These were extremely favourable terms, and had been obtained at a moderate cost. Nearly every other provisional order obtained by other metropolitan companies had lapsed, occasioned in many instances by the enormous deposits required by the local authorities. Thus, one company undertook an installation estimated to cost £50,000, and they were required to deposit £25,000. This was fatal to companies. They had numerous applications for the supply of electric light, and with the improvement effected in appliances, tending to economy of production and storage, he believed that the electric light would emerge from the cloud in which it was at present shrouded, and would prove an effective and economical, a healthy and safe light for domestic and other purposes. It was necessary to fill one vacancy upon the board of directors, as Mr. W. H. Lefevre had left the neighbourhood, and did not offer himself for re-election.

Mr. Cosh, in moving that the vacancy upon the Board should not be filled up at present, said that he believed a gentleman of considerable influence would shortly offer himself for a seat upon the Board, and as he was the representative of a large *clientèle* of capitalists, it might be an advantage to the Company to keep the vacancy open. He spoke of the labours of the directors during the past two years, and considered that they had acted wisely in not squandering the capital of the Company in the purchase of patents, many of which had cost other companies thousands of pounds, and were not to-day worth sixpence. They were quite free and unfettered, and could negotiate for the application of the very best system invented up to the present time. The directors had made trials and installations, and examined all the electric light systems in this country. Within a few days they were going to Colchester, in company with Mr. Preece, well known as chief electrician to the Post Office, to inspect the storage system by which that town was lighted, and he hoped that when the works of the Company were complete they would supply Fulham and Hammersmith with an electric light which should be second to none. He traced the difficulties they had had to contend with during the two years of the existence of the Company, commencing with the original agreement with the Board of Works, then the almost insurmountable difficulties which arose through the passing of the Electric Light Act, with the obtaining of the licence, and finally the provisional order. He paid a high compliment to the courtesy of the officials of the Board of Trade, but yet difficulties were daily cropping up in interpreting a new Act of Parliament. These had been boldly met and surmounted. The local authority, from the chairman downwards, had also assisted them in every way, being strongly of opinion that the electric light would prove a great boon to the district.

Mr. Parker seconded the proposition, and stated that the shareholders were well satisfied with the business tact and indefatigable exertions of the Board.

The resolution was unanimously carried, and after some formal business the meeting concluded with a vote of thanks to the directors and chairman.

The Globe Telegraph and Trust Company (Limited).

Report of directors to be presented at the eleventh general meeting on July 29:—The balance-sheet and accounts for the year ending 18th July, 1884, with statement of stocks and shares held by the Company at that date are herewith submitted. The net revenue of the Company for the year, after deduction of expenses, amounts to £189,663 4s., which, with the balance of £1,365 9s. 10d. brought forward, makes a total of £191,028 13s. 10d. From this amount there has been distributed the sum of £131,385 15s. in interim dividends, leaving an available balance of £59,642 18s. 10d. The directors recommend payment of a final dividend for the year of 3s. per share on the preference shares, and of 3s. 6d. per share on the ordinary shares making with the former distributions a total dividend for the year of 6 per cent. upon the preference and 4¾ per cent. upon the ordinary shares, carrying forward a balance of £2,088 3s. 4d. In order to provide the £130,130 to pay required 11,830 new shares of the Eastern Extension Company, taken up last year, and the £15,000 Telegraph Construction and Maintenance Company's 6 per cent. Debentures allotted to this Company, the directors have issued 5,655 preference shares, and 5,655 ordinary shares, and they have also transferred 3,182 of the Eastern Extension shares. The company's balance-sheet is now free from liability of any kind. Forty-four of the shares of the German-Norwegian Company have been drawn and paid off at par, and the proceeds carried to the credit of the capital account. In conformity with the Articles of Association, Mr. William Ford and Sir Daniel Gooch, Bart., M.P., two of the directors, retire, but being eligible offer themselves for re-election. The auditors, Mr. John George Griffiths, F.C.A. (Messrs. Deloitte, Dever, Griffiths, and Co.), and Mr. William Griffith, B.A., barrister-at-law, also retire at the meeting, and offer themselves for re-election.

WANTED at once, an intelligent MAN, experienced in manufacture of electric light carbons, to take charge of a small Carbon Plant in a factory near London, S.E. district. State experience and wages required.—Address replies, "Coppered Carbon," care of *Electrician*, 1, Salisbury-court, Fleet-street, London.

YOUNG ELECTRICIAN or STUDENT wanted to look after Testing Lamps, &c. Small salary. Hours from 7:30 in summer and 8 in winter.—Apply 36 and 37, Bermondsey-street, S.E.

WANTED.—Steady, sober, LINE MAN, accustomed to Gower-Bell Telephones and Running Wires.—Apply, with references, Engineer, Telephone Exchange Company, Swansea.

CIVIL SERVICE COMMISSION.—EXAMINATION for ASSISTANT EXAMINERSHIPS in the Patent Office (21-25), 29th August. Salary £250 to £400.
The date specified is the latest at which applications can be received. They must be made on forms to be obtained with particulars from the Secretary, Civil Service Commission, London, S.W.

TO ELECTRICAL COMPANIES.—LARGE OFFICES to LET in grand building. Steam, gas, and hydraulic power on the premises. Enquire of G. F. Brooke, Leadenhall Market, London, E.C.

Digitized by Google

NOTES.

Book Received.—"La Chaleur et le froid," par L. C. E. Vial. Published by J. Michelet, Paris.

Earthquakes in England.—*Longman's Magazine* contains an article on this subject from the pen of Mr. Richard A. Proctor.

Western and Brazilian Telegraph Company.—The traffic receipts of this company for the week ended 25th July were £2,241.

Brazilian Submarine Telegraph Company.—The traffic receipts of this company for the week ending the 25th inst. amounted to £2,832.

Electric Lighting in Theatres.—The Edison system is now in use on the stage of the Opera House in Paris. Its use was inaugurated a few days since.

Ship Lighting.—It is stated that the lighting of the ss. "Umbria," the new Cunarder, has been entrusted to Mr. Andrews, of Glasgow. The incandescent system will be employed.

Personal.—We are glad to be able to state that Mr. W. H. Preece, F.R.S., has been appointed one of the visitors of Cooper's Hill College, in the place of the late Sir William Siemens.

A Physics Demonstrator Wanted.—The Council of University College, Bristol, want a demonstrator of experimental physics. Applications should be sent in before the 16th August.

Electrical Propulsion of Tramcars.—We understand that the Ryde (Isle of Wight) Pier Company are about to make experiments on the propulsion of their tramcars by electrical energy.

French Electrical Power Storage Company.—A petition for the winding up of this company was presented on the 22nd July by the Faure Electric Accumulator Company, and will be heard by Vice-Chancellor Bacon to-day (Saturday).

Eastern Telegraph Company.—This company announce that the coupons on the Five per Cent. Debentures due on the 1st August will be paid by Messrs. Glyn, Mills, Currie, and Co. Coupons should be left three clear days for examination.

The Sanitas Company.—The directors of this company have declared an interim dividend for the half year ended 30th June last at the rate of 10 per cent. per annum. The business of the company is said to be proceeding most satisfactorily.

Electric Lighting in Belfast.—On Saturday night some experiments were made in the Queen's College, Belfast, in connection with the illumination of the entire buildings with the electric light during the sittings of the British Medical Association.

A Coincidence.—In the "Deaths" column of the *Standard* for the 30th July we noticed the deaths of Mr. John *Lightning* Morgue and the wife of Captain George *Thunder*, a coincidence of two unusual names which we think well worthy of a passing note.

The Telephone in France.—The Minister of Posts and Telegraphs has appointed a commission, composed of ten gentlemen well up in financial matters, to examine into the finances and capabilities of all persons or companies applying to the State for telephonic concessions.

Electric Lighting at Walham Green.—We are requested to state that the arc lamps used at the *fête* of the Butchers' Charitable Institute at Walham Green on the 15th inst., the steadiness of which was commented on, were hired from the Pilsen Electric Light Company.

British Electric Light Company.—A petition for the winding up of this company was presented, in the High Court of Justice, on the 24th July, by Mr. M. W. W. Mackie, of Gracechurch-street, E.C., and is directed to be heard before Vice-Chancellor Bacon to-day (Saturday).

Electric Lighting at Dover.—The arrangements for fitting electric lights in the armour-plated turret on Dover Pier are ordered to be carried out under the superintendence of Captain P. Cardew, principal instructor in telegraphy at the School of Military Engineering, Brompton.

Wimbledon.—The winners in the Telegraph Clerks' Handicap competition at the Wimbledon Rifle Meeting were as follow:—Serg. Kemp, first, 31 points; Serg. Smith, second, 30 points. The first prize consisted of £5, and the second of a cup and £3. The conditions were seven shots at 200 yards.

Domestic Electric Lighting.—We have received a quarto pamphlet entitled "Notes on Domestic Electric Lighting" from the author, Mr. T. Taylor Smith. It contains a description and some excellent illustrations of Mr. Smith's ingenious fittings for domestic electric lighting exhibited at the Health Exhibition.

Earthquake at Massowah.—According to telegrams from Suakin, on July 25, an earthquake had occurred at Massowah. It is stated that nearly all the houses in the town have been destroyed or damaged by the shock. The ships in the harbour were seen to rock violently. The inhabitants were greatly alarmed, and fled to the mainland.

Business Notice.—We understand that Mr. Harry South, who, until recently, was associated with the Hammond Electric Light and Power Storage Company, and at various times had charge of several of their most important installations, has commenced business as an engineer and electric light contractor, at 169, Queen Victoria-street, London, E.C.

Post Office Telegraphs.—Examinations for female telegraph learners in the General Post Office at London and Dublin will shortly take place; that for London on the 17th Sept., and for Dublin on the 9th August. The ages of candidates must be between 14 and 18. Further particulars can be had of the secretary, Civil Service Commission, London, S.W.

Telegraphic Extension in Scotland.—The new line from Lochboisdale to Barra was commenced last week. A number of men are busily engaged erecting the poles between Dalibrog and Polashar. The steamer for laying down the cable between the farm of Kilbride and Bravig Bay—a small bay some two miles north of Castle Bay, Barra—arrived on Saturday.

Electrical Transmission of Power.—A French contemporary says that the preparations for M. Deprez's experiments on the transmission of power between Creil and Paris are being actively carried on. The preliminary work is finished, and the two engines which are to supply the motive power are already in place at Creil. The collectors of the electrical machines are being constructed by the firm of Gottendorf.

Electric Railways in America.—The *Standard's* New York correspondent, telegraphing on Tuesday, said:—"Litiga-

Digitized by Google

tion in respect to patent rights has hitherto impeded the development of electric railways. The Patent Office has now decided in favour of S. D. Field against Edison and Siemens. The first railway was opened at Cleveland, Ohio, on Saturday, and others are expected to be constructed now in quick succession."

THE MAGAZINES.—We have on our table *Cassell's Magazine* for August, and the same firm's "Technical Educator," Part 6. The former contains the continuation of several interesting stories, and the columns of "The Gatherer" include many electrical items. The latter has instructive and well-illustrated articles on "Notable Inventions and Inventors," "Technical Drawing," "Building Construction," "Applied Mechanics," "The Electric Telegraph," &c.

TELEPHONY.—Servia boasts 1 telephone line 1 kilometre long, connecting the Ministry of the Interior and the Prefecture at Belgrade. Bulgaria and Luxembourg do not believe in the telephone; at all events, they have not a yard of line at work at present. Turkey has three lines, one used by the Administration of Telegraphs, the second used at a life-saving station on the Black Sea, and the third belonging to the Eastern Telegraph Company and the Ottoman Bank. The above lines represent a total length of wire of 41 kilometres.

EXHIBITION AT VIENNA.—An international exhibition of motors and tools has been opened at Vienna. Its object is to promote improvements and the development of small trades by showing how they can compete with large manufacturers. All the new appliances in lighting will be exhibited, including two great Siemens regenerators. Gas burners of 2,000 candle-power each are placed in the gallery of the main hall, and other rooms will be illuminated by incandescent and arc lamps, and by gas lamps of various construction. Several English firms are among the exhibitors.

THE LATE SIR WILLIAM SIEMENS.—The executors under the will of the late Sir William Siemens, F.R.S., &c., announce that they have arranged for the continuance of Sir William Siemens's practice as consulting engineer, by transferring his obligations and rights, including his patents for regenerative gas furnaces, and iron, steel, and glass processes, to his brother, Mr. Frederick Siemens. They add that the business will be conducted on precisely the same lines as heretofore, and Mr. John Head, who was the representative and principal assistant to Sir William Siemens, will continue to act in the same capacity for his brother.

A MULTIPLYING SEISMOGRAPH.—At the last meeting of the French Academy of Sciences M. Bouquet de la Grye communicated the results he had obtained at Puebla with a multiplying seismograph. The friction of the parts of this apparatus is so small that the heat of the hand produces a movement of the indicating needle. Results obtained during November and December, 1882, show that the sun and the moon have a direct action on the pendulum. The moon attracts it, the sun has an inverse effect. By its means 22 abnormal movements were noted during one month, which were probably due to seismic causes. One of them only was felt in the town of Puebla.

REDUCTION OF PATENT FEES.—The Board of Trade, with the consent of the Treasury, have made the following reduction relating to certain fees prescribed by the Second Schedule of the Patents, Designs, and Trade Marks Act, 1883:—In the case of patents granted before the commencement of the said Act a patentee who has paid the prescribed fee of £50 before the end of four years from the date of his patent may, in lieu of the prescribed fee of £100, payable before the end of seven years from such date, pay the following annual fees:—Before the end of the seventh year from the date of the patent, £10; eighth, £10; ninth, £10; tenth, £15; eleventh, £15; twelfth, £20; and thirteenth, £20. This reduction came into operation on the 1st of this month, viz., Friday.

THE CLAIMS OF THE TELEPHONE COMPANIES.—In the House of Commons on Thursday week Mr. Fawcett said, in answer to Mr. Jacob Bright, that the United Telephone Company and another company had submitted to him proposals involving very complicated and difficult details. It was of great importance that these should be considered in all their bearings. Although he had personally devoted all the time he could spare to it, the investigation was not yet completed. Several companies had not yet sent in proposals, and they had been informed that if they did not do so he would give his decision without them. No one could be more anxious than he was that a speedy settlement of the question between the Post Office and the telephone companies should be speedily settled.

HONOURS FOR AN ELECTRICIAN.—The Paris correspondent of the *Daily News* says:—"English electricians who were connected with the Paris Electrical Exhibition organised by Dr. Cornelius Herz in 1881 will hear with pleasure that he has been, upon the proposition of the Minister of Posts and Telegraphs, raised to the grade of Commander of the Legion of Honour for services rendered to electrical science. Dr. Herz is known in France, and has supplied for a number of years the funds required for making costly experiments in the transmission of power by electricity and enabling inventors to carry out their conceptions. He founded *La Lumière Electrique*, the leading specialist organ in France. Dr. Herz, though born in France, is of American nationality, and the only foreign scientific man who has ever been made Commander of the Legion of Honour."

TELEGRAPHING MONEY ORDERS.—Great improvements in the money order system of India will, says *The Times*' Calcutta correspondent, be introduced on October 11, the German system being closely followed. Coupons will be added to the orders, on which the remitters may communicate their wishes to the payees. Payment at the payee's residence will also be arranged for; and telegraphic money orders will be introduced at a charge of 1 per cent., plus the cost of the telegram.—Mr. K. B. Murray takes the opportunity afforded by the publication of the news to write to the *Daily Chronicle*, pointing out that, although such a system has been mooted several times at the General Post Office, it has always, up to the present, been regarded with disfavour. He hopes that the example of India may spur our own authorities to try and overcome the technical difficulties surrounding the matter.

COST OF ELECTRIC LIGHTING.—The *Bulletin* of the Compagnie Internationale des Téléphones says:—"We have received a communication, giving the working cost of the electric lighting installed by the Société Edison in the grocery shop of Felix Potin. This lighting cost for one month, 6th March to 6th April, 1884, 367·15f., distributed as follows:—Wages, 150f.; lubrication, 1 kilo of olive oil per diem, or 26 kilos per month, at 2·66f., 69·15f.; eight lamps, at 6f., 48f.; coal, 100f. —total, 367·15f. The installation comprises 71 incandescent lamps, burning 12 hours per day. The number of hours of lighting was therefore 852 per day, or 28,152 for the month. The lamp hour costs, therefore, 1·7 cent. Further, 3,102 cubic metres of gas were saved, the amount consumed in the same month of the previous year, which at ·30f. would have

Digitized by Google

cost 930·60f. Deducting from this sum the 367·15f. expended on the Edison light we have an actual saving of 563·45f.

OVERHEAD WIRES IN LONDON.—Sir H. Tyler has made an interesting calculation, from which he finds that no less than 230 overhead wires may be counted between the Royal Exchange and St. Michael's Church, Cornhill, and 200, more or less, between the Mansion House and Queen-street, the latter being stretched across Queen Victoria-street. A few days since he called the attention of the Secretary of the Local Government Board to these figures. In his reply this gentleman pointed out that out of the 230 only six belonged to the Post Office, and out of the 200 only four. He further stated that it was under consideration whether a Select Committee of the House of Commons should be moved for next Session, to inquire into and report upon the subject of overhead wires. We have recently seen it stated in a contemporary that "overhead wires serve to dissipate the electricity in the atmosphere, and thus protect cities from lightning." Do they ? We should be glad if the paper in question would kindly substantiate its statement.

THE NANTUCKET CABLE.—The Boston (Massachusetts) *Herald* of July 16 says :—The appropriation of 20,000 dols. by Congress for the establishment of a signal station at Nantucket and the laying of a cable connecting the island with the main land causes great rejoicing. It is believed that in the fall an additional appropriation will be secured, and that before the winter is over the island will enjoy the blessing of direct communication with the Continent. No place of similar size on the Continent is so isolated from the outside world during the winter season. The boats from Woods Holl run irregularly, owing to the uncertainty of the weather, and many a person who has ventured to go to the island in the winter season has remained a prisoner there for a week or more, deprived not only of means to get away from there, but of means to communicate with his family and friends. There are many wrecks off the shore of the island, and oftentimes a long time must elapse before the details are known. The value of a cable as a means of transmitting shipping news can hardly be overestimated.

LONDON LOCAL AUTHORITIES AND OVERHEAD WIRES.—The Parliamentary Committee of the Lambeth Vestry reported at the last meeting of that authority that they had considered the application received from the Board of Works for Wandsworth, asking that the vestry should contribute towards the expense of appealing to the House of Lords against the judgment of the Court of Appeal in the action brought by the Wandsworth District Board of Works against the United Telephone Company for erecting overhead wires in the Wandsworth district. The Court of Appeal having given a unanimous judgment against the rights of the local authority to restrain (except where actual danger was shown to be likely to arise) wires being placed across the streets of the parish, the committee did not advise the vestry to contribute towards the costs of the appeal or to support the Wands worth Board ; but the committee recommended the vestry to join with the Marylebone Vestry in urging the Government to pass a Bill through Parliament conferring upon the local authorities the control over the erection and maintenance of overhead wires. The recommendation was carried.

THE TELEPHONE AND THE POST OFFICE.—In the House of Commons on Tuesday last Mr. Gray asked the First Lord of the Treasury whether he was aware that, although the House had refused to give to the Post Office control over the telephones, the department obtained a legal decision on a technical point, to the effect that a telephonic message was a telegraph message and within the meaning of the Act of 1869, although at the time the Act was passed the telephone was not in existence ; and whether he was aware that since that date the Post Office had levied a tax upon the use of the telephone, and had imposed constantly increasing restrictions, eventually amounting to practical prohibition of its use for exchange purposes ?—Mr. Gladstone stated that a judgment had been taken in the courts as to the sufficiency of the existing law for the protection of the Post Office, and according to the legal advisers of the Government that decision by no means rested on a technical point, but upon the substance of the matter. It was to the effect that the Crown was in possession of certain rights by the existing law, and, that being so, it was the duty of the department to assert those rights. As to the amount of the tax, he was not prepared to say what should be the proper position of the Government, but his right hon. friend the Postmaster-General was engaged in considering whether, with justice to the Crown, he could relax the rules now in force.

OUR TORPEDO SERVICE.—The following notification has been published :—The Admiralty are giving increased attention to the importance of torpedoes in naval warfare, whether carried in independent small craft or on board of men-of-war, and have just issued an order for the purpose of securing uniformity in the arrangements of all torpedo fittings and electric apparatus in Her Majesty's ships. As the only place possessing torpedo schools ashore as well as afloat, and an electrical workshop and a staff of officers, Portsmouth has been very properly converted into the head-quarters for the torpedo branch of the service. There all the patterns and drawings of approved fittings are for the future to be prepared, whence, with the necessary instructions, they are to be forwarded to the other dockyards for the guidance of the officers concerned. The dockyard officers at Portsmouth are to confer with the captain of the "Vernon" on all questions relating to changes of existing patterns and to the introduction of fittings for new classes of ships and boats, and once every week the latter is instructed to attend the *levée* of the Admiral-Superintendent for the purpose of considering any matter which may arise in relation to torpedo and electric fittings. It is also ordered that the position of all electric batteries and machines, projectors, and directors, and the stowage of torpedo stores, &c., are to be arranged in consultation with an officer from the department of the Director of Naval Ordnance, the fittings being carried out by the dockyard. Tracings of all proposals are to be forwarded to the Admiralty for approval before being undertaken, and after the work has been supervised by an Admiralty official and tested when completed by another, previous to the ships being passed into the first division of the steam reserve, no alteration is to be made without the sanction of their lordships.

EARTH CURRENTS.—The *Journal Télégraphique* gives a translation of an article from No. 5 of the *Maanblad voor Telegraphie* for 1884, by Mr. Hissink, of the Dutch Indian Telegraph Service, from which we take the following :—"We observed very strong earth currents on the 17th, 20th, and 21st April, 1882, traversing the line which unites Lahat (Island of Sumatra) and Benkoelen by way of Tebing Tinggi. The length of this line is 220·73 kilom., and its resistance 970 ohms. On the 17th April the earth current appeared directly the daily work was begun, at 8:55 a.m., and from time to time telegraphic communication was interrupted up to 4 p.m. The currents were particularly strong from noon to one o'clock. The needle of the Siemens sine galvanometer included in the circuit to

Digitized by Google

Lahat gave all kinds of deflections, now − 65°, now + 45°. The current varied at long intervals and each time changed direction. The two other lines going from Lahat to Moearadoea and Palembang, which ran in a different direction, were only traversed by weak earth currents. On the 20th April we again observed more or less strong earth currents traversing the same line between Lahat and Benkoelen. The galvanometer indicated from 9 a.m. to 9:15 a.m. a deflection of + 15 to + 25; at 11:25 this became − 37; at 11:50, + 27; at 12:8 noon, + 15; at 12:10, − 5; at 12:14, + 3. Later on the current varied every moment; the greatest deflection, that of − 49, was observed between 2:30 and 3 o'clock. The current then flowed without interruption in a direction from Benkoelen to Lahat. Communication with Tebing Tinggi office was occasionally interrupted. On the morrow we made similar observations up to 3 o'clock. Later on we found that the wire between Benkoelen and Tebing Tinggi had been broken at eight leagues from Benkoelen; but the deflections of the needle and the other observations made enabled us to ascertain that the line was affected by earth currents."

Gas and Electricity.—We think the following extract from an address delivered last week by Mr. F. T. Linton, engineer to the Edinburgh and Leith Gasworks, as president of the North British Association of Gas Managers, well worthy of a place in our "Notes." Speaking of the prospects of gas lighting, he said:—"How far other sources, and notably electricity, might come into use as competitors for illuminating purposes with coal gas they need not discuss. The hard logic of facts had shown how impossible in present circumstances it was for electric lighting to compete commercially with gas, and it was difficult to conceive any probability of those circumstances being materially altered. Meanwhile they, as humble fellow-workers in the same field of adapting the forces of nature to the use and benefit of mankind, might well express their unfeigned admiration for that most beautiful and striking example of it which the genius and patient labour of many eminent men had produced in the various forms of electric lighting, and especially in the incandescent lamp. They had no jealousy of the electric light. They wished it every success in the many special uses to which it was admirably adapted. They did regret, however, that, owing to the action of unprincipled speculators, and, it must be added, to the way in which the public press in too many instances lent itself to the publication of extravagant and misleading statements, the legitimate extension of the use of electric lighting had been hindered for probably many years, and the money of a number of credulous persons, to the extent of millions of pounds, absolutely squandered. It seemed to him that gas manufacturers, who were threatened, somewhat jubilantly on the part of some people, with total extinction by electric lighting, were, after all, those whom it had chiefly benefited. They must confess that it was largely due to the threatened competition by electric lighting that their profession had been thoroughly roused from a condition of use and wont to one of activity and progress, and that spirit of inquiry induced which had already led to such beneficial results." We are glad also to be able to record the fact that Mr. Linton's sentiments were most cordially received by his audience.

Electric Lighting in London.—The Board of Trade have decided to proceed at once to revoke no fewer than 25 of the provisional orders which were granted by them last year, and subsequently confirmed by Parliament, for the electric lighting of London and its suburbs. Of this number 23 are orders which were obtained by the Metropolitan Brush Electric Light and Power Company, which has since gone into liquidation. These orders relate to the electric lighting of Barnes, Mortlake, Bermondsey, Chelsea, Chiswick, Clerkenwell, Finchley, Greenwich, Hackney, Holborn, Hornsey, Islington, Limehouse, Poplar, Rotherhithe, St. George's-in-the-East, St. George the Martyr, portions of the parish of St. Giles, the parishes of St. Luke's, St. Olave, St. Saviour's, Southwark, Shoreditch, Whitechapel, and an order known as the Wandsworth order, which, however, relates to portions only of the parish of Clapham. Of the other two orders which will be revoked one relates to the lighting of Kensington, and the other is an order granted to the Pilsen-Joel Electric Lighting Company, with powers to light those portions of the parish of St. Giles not granted to the Metropolitan Brush Company. So far as London is concerned, the result, therefore, of the numerous electric lighting orders which have been granted during the past two years is that only eight now remain in force, namely, the St. James's and St. Martin's order, which, with the Hanover-square, Strand, and Victoria district orders, are now held by the Edison and Swan United Electric Lighting Company; the Hampstead order, granted to the Hampstead Electric Lighting Company; the St. Pancras order, granted to the Vestry; the order for the lighting of Fulham, which was granted only last May to the West Middlesex Electric Lighting Company; and the order, also granted in May last, to the West London Electric Lighting Company, for lighting portions of the parishes of St. George's, Hanover-square, St. James's, Westminster, and St. Martin-in-the-Fields. Of these eight orders, the first five have already had their time extended within which to comply with the provisions of the orders, and unless these provisions are complied with before the 15th October next, the powers will be lost, unless a further extension of time is granted.

Thunderstorms.—The latter end of last week was marked by a series of more or less severe thunderstorms in the British Isles. At Burwell, near Whitney, Oxon., on Thursday, the 24th July, a cow was killed. A thunderstorm also passed over Oxford on the same afternoon, but without, so far as we know, doing any damage. A storm visited London on the same date, and was remarkable for its severity and short duration, although no damage appears to have been done. At Sunderland a clerk of Messrs. Austin and Son, shipbuilders, was struck by lightning while listening to a telephonic message. He fell to the ground and was seized with violent hysterical fits. He was subsequently seen by Drs. Morgan and Horan and conveyed to the infirmary, where he is reported to be going on well. At Nottingham, James Harris, a milkman, whilst selling milk to some men employed upon a new sewer at the east end of the town, was struck by lightning, which set fire to his hair and passed down the left side of his body as far as his heel, causing instant death. At Dedisham Farm, in the parish of Slinfold, five valuable cart horses were struck by lightning and knocked down. Three of them were killed, another was struck blind, and the fifth was injured, but not permanently. Two boys were knocked down at the same time, but escaped serious injury. At Tunstall (Staffs.) a chimney of the manufactory of Mr. Holcroft was struck by lightning, which passed into a workshop where several women were employed. The windows were smashed, but the women were not injured. At Warminster 12 cows, standing near some iron fencing on the farm of Mr. George Pickford, of Monckton Deverill, were struck dead by the lightning, and two others were also so badly mutilated that they had to be slaughtered. Scotland was also visited on the same day, viz., Thursday, the

Digitized by Google

24th July, by severe storms. At Arbroath the tower of the Memorial Chapel, just erected in the cemetery by Mr. Allan Fraser, of Hospital Field, was struck by lightning, but the damage done was trifling. Two masons were standing in the main doorway at the time, and were stunned. The lightning was attracted by a steel rope of a tramway used for the carriage of building materials up Keptie Hill to the new water works. It passed along the rope, and Mr. Archd. Anderson, contractor for the works, who was standing near, was stunned, temporarily losing the power of one of his hands. He soon recovered, however, as did also the two men at the cemetery. All the reports speak of the storms as having been accompanied by unusually large hailstones. On Saturday, the 26th of July, during a slight thunderstorms which passed over the Lake district the corning-house at the Black Peck Powder Mills, near Ulverston, was struck by lightning. A terrific explosion ensued, completely wrecking the building and killing three men who were inside at the time instantaneously. Another, named George Gosten, was standing outside, and the flames from the explosion set fire to his clothing, but by throwing himself into an adjoining brook he escaped with a severe scorching. Those killed were John Woodend, aged 60, single; Reuben Stephenson, aged 35, married, four children; and William Phillips, aged 23, married, one child.

THE ELECTRIC LIGHTING ACT.—Our very enterprising contemporary, the *Pall Mall Gazette*, has been interviewing Mr. Arnold White, late of the Edison Company, on the subject of the Electric Lighting Act. Mr. White has already made our readers aware of his sentiments in this matter, and we shall therefore make only a few extracts from the report of this interview. The failure of the Act, Mr. White thinks, "arises primarily from comparing the gas burner, which consumes something physical—namely, gas—with the incandescent lamp, which gives something infinitely more subtle—namely, a form of energy. The cardinal principle running through the Act, and which vitiates it, in my opinion, is the treatment of electricity as though it were treacle or butter; as though it were powderable, and could be sold in quantity, while it is obvious that electricity is only known by its effects in light, heat, or power." When asked by the *Pall Mall* reporter if he had ever made an analysis of how the millions subscribed for electric lighting have been spent, Mr. White replied, "Yes. In 1882 there were sixty-two companies founded, the paid-up capital on which was £4,951,575. Since then about £400,000 has been called up, giving a total of £5,351,575 as the amount actually invested since 1882 in the electric lighting enterprise under the Joint Stock Companies Act. I estimate the expenditure of this amount during the past thirty months to have been as follows:—

	£
Promoters, including "patents"	800,000
Inventors	115,000
Law and Parliamentary charges	160,000
Directors' fees	130,000
Expended on exhibitions and free lighting, undertaken for advertisement	300,000
Expended on machinery and plant, now mostly obsolete	270,000
Expended on installations and ship lighting, undertaken mainly at a loss	1,000,000
Fixed charges, *i.e.*, clerks, secretaries, office rent, advertising, and sundries	1,250,000
Cash in hand	500,000
Factories, plant, and stock	826,575
	5,331,575

I do not believe that as a going concern the electric light interests now in the hands of the joint stock companies are worth in the aggregate more than a million sterling, and I question whether the profits on the business as a whole would yield 5 per cent. dividend on that amount. In support of this opinion I may mention that the paid-up capital of those electrical companies which have obtained a quotation on the London Stock Exchange amounts to £1,289,000, while, at the price quoted in the official list of Saturday last the whole could be bought for £221,880."

ELECTRIC LIGHTING FOR LAMBETH.—At the last meeting of the Lambeth Vestry, Mr. Fowler brought forward a report of the Electric Lighting Committee, stating that, after waiting several months, in lieu of the draft licence settled by counsel on behalf of the Vestry and submitted to the Board of Trade for their approval, the Board had written sending to the Vestry a form which had been settled for Colchester, and suggesting that the vestry clerk should alter the form to make it applicable for Lambeth. To this the clerk replied that the form for Colchester was not a form for the local authorities at Colchester, but for a private company; that the form did not appear applicable to a local authority taking a licence; and suggested that the Board of Trade should consider the form already before them settled by counsel for Lambeth. In the result an interview had taken place at the Board of Trade between the vestry clerk and Mr. Calcraft, the Board's secretary, accompanied by the Board's counsel, Mr. Meysey Thompson, at which Mr. Calcraft produced a print of a new form of licence for Lambeth, which was given to the vestry clerk for him to consider, and it was at the same time arranged that should the Vestry not accept the licence in the new form, the counsel of the Board and the counsel of the Vestry should meet to see whether the differences could not be adjusted. On referring to the new form it was found that it was word for word the same with the licence given to the private company for Colchester, making only the necessary alterations, except that the form gave to the Metropolitan Board of Works the powers as a local authority, which, by the Colchester form, was given to the local authority for Colchester, although in Lambeth the Vestry and not the Metropolitan Board is, by the 31st section of the Electric Lighting Act, made the local authority. In the form the stringent provisions which might be properly imposed on a private company, but which were not required, and were quite inapplicable in a licence given to the local authority, were all retained. The committee, after fully considering the matter, recommended that the Vestry should send to the Board of Trade a memorial, praying that the licence might be granted in its original form; that the Board might receive a deputation from the Vestry in support of the memorial; and that the borough members be asked to attend the Board with the deputation in support of the views of the Vestry. Mr. Fowler, in moving the adoption of the report, said the committee had been very anxious to obtain a licence, because they felt that a great improvement might be made in the lighting of the parish; and if not universally adopted, there were portions of the parish which would readily accept the light. The Board of Trade, however, sent back the licence, and presented them in its stead with a licence prepared for a public company, with very stringent conditions attached. These it was impossible for them to accept. Therefore the committee wished to appeal to the Board of Trade by deputation, because they were convinced the Vestry would regret that the light should be carried out by stealth, as in the Brixton-road, rather than under the direct surveillance of the Vestry. The resolution was carried, only one hand being held up in opposition.

THE ELEMENTS OF ELECTRIC LIGHT ENGINEERING.

BY E. C. RIMINGTON.

Before commencing to set up a dynamo machine and arrange a circuit it is necessary that the reader should be acquainted with the various forms of instruments for measuring current and electromotive force.

In putting up a circuit the current flowing through it, or, in the case of a multiple circuit, through each branch of it, should be known.

Most instruments for measuring strong currents as produced by dynamo machines are simply modifications of galvanometers, where the current is made to pass round a magnetised needle, which it deflects.

The simplest form of galvanometer, which gives readings proportional to the currents passing through it, is the tangent. This instrument is, in its ordinary form, fitted with two turns of thick copper rod to take large currents; it has to be placed in the magnetic meridian so that the needle remains at zero when no current is passing through it. The scale is generally divided into natural tangents, so that the current is proportional to the number of divisions indicated by the pointer or needle; when, however, the scale is only divided into ordinary degrees of arc, the current is proportional to the natural tangent of these degrees.

Other forms of measures for strong currents are made after the manner of ordinary galvanometers, but the magnetic needle is placed between the poles of a very strong permanent magnet, thus allowing the instrument to be employed in any position. The number of degrees indicated by the pointer are read off, and are given in amperes by reference to a table, usually supplied with the instrument. Among these may be mentioned M. Deprez's ampere meter and Messrs. Ayrton and Perry's modification of Deprez's instrument.

Another and different form of current meter is Siemens's electro-dynamometer, which acts by the well-known law that currents flowing in parallel wires in the same direction attract one another, the force with which they attract one another being neutralised by the torsion of a fine brass spring. The last instrument can be employed with alternating currents, an advantage which none of the before-mentioned instruments possess; its great disadvantage being that it is a zero instrument, and therefore only suitable for a fairly steady current.

Instruments for measuring E.M.F. are similar in form to those for current, the difference being that, while the latter are wound so as to have as low a resistance as possible, the former have a resistance of from 2,000 to 10,000 or more ohms, so that a *very* small current flows through them.

Dynamos may be divided into five classes, viz.,

(1) Magneto dynamos.
(2) Separately excited dynamos.
(3) Series dynamos.
(4) Shunt dynamos.
(5) Compound dynamos.

The first class consists of an armature rotating between the poles of one or more permanent magnets; but, as this form of dynamo is now so seldom seen or used, we shall say no further concerning it.

We will now give a description of the series dynamo (3) as related to the external circuit, leaving the separately excited machine for future consideration:—

The Series Dynamo.

This machine is the cheapest and most generally employed form of dynamo, especially in the case of arc lighting. It is essentially composed of an armature, A, Fig. 1, wound with insulated copper wire, and provided with a collector, C; this armature is rotated in the magnetic field produced by the field-magnets F M.

The current generated in the armature by its rotation is collected by means of brushes, B B, of wire or slit metal, which press lightly against the collector C.

T and T_1 are the terminals of the machine, to which the external circuit is attached.

This form of dynamo is termed "series," because the armature, field-magnets, and external circuit are all in series with one another. Fig. 2 shows clearly how this is arranged, the letters representing the same parts as those in Fig. 1. From this it will easily will be seen that the armature A, the field-magnets F M, and the external resistance R form one unbroken circuit. The current generated in the armature A, by its rotation in the magnetic field, passes by the brush B, which we will call the + or positive brush, round the field-magnets F M, through the external circuit R, and back through the – or negative brush B, to the point whence it started.

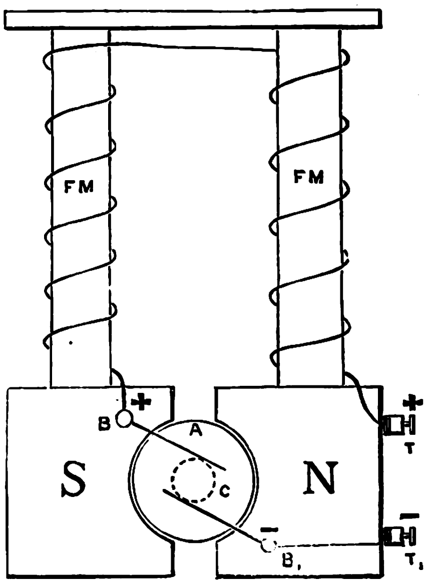

Fig. 1.

The series dynamo is self exciting—that is to say, on rotating the armature a very small current is started by the residual magnetism remaining in the field magnets (the iron of which they are made being never soft enough to completely lose all its magnetism). This small current, flowing round the field-magnets causes them to become more magnetic, and produce a stronger magnetic field, which in its turn produces a stronger current, thus making the field-magnets still stronger, and so on. This action, though it takes time to describe, occurs practically almost instantaneously. In running a new machine it sometimes happens that there is not sufficient residual magnetism in the field-magnets to start any currrent. In this case the machine should be circuited through a low resistance, say from ½ ohm to 1 ohm, or *very cautiously* short-circuited for a few seconds (in the latter case it is *advisable* to keep out of the way of the driving belt in case it should break from the sudden strain caused by the strong current produced). If there is no trace of residual magnetism in the magnets this method will fail, and it will then be necessary to stop the machine and connect a few battery cells to the terminals for a short time.

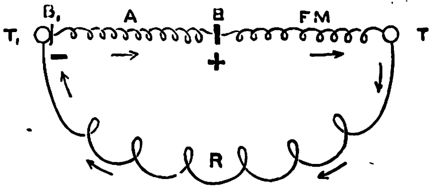

Fig. 2.

We shall now give a short description of the various forms of armatures employed in continuous current dynamo machines, but although they are given as related to the series machine they apply equally well to the armatures of any machine giving a continuous current, whether series, shunt, separately excited, or compound.

Armatures may be divided into three classes:—

(1) Ring armatures.
(2) Drum armatures.
(3) Pole armatures.

Digitized by Google

The last class of the three being seldom employed in continuous current machines we shall not yet touch upon it. Ring armatures are composed of wire coiled upon a ring, the principal armature of this type being the Gramme. In the case of the Gramme armature the ring is composed of iron wire, the insulated copper wire being coiled round and round it, as in Figs. 3 and 4, wires being brought from every few coils, as shown, to adjacent strips of the collector.* In practice the wire is not coiled all in one length, but in separate coils, one end of each of which is attached to one strip of the collector, and the other to the next strip, to which is also connected the first end of the next coil, as shown in Fig. 4. Each coil is, however, composed of several layers of wire, the number depending on the fineness of the wire employed in winding, dynamos for high electromotive force and small current having a large number of turns of fine wire in each coil, while those for low electromotive force and large current have fewer turns of thicker wire. There are various modifications of this method of winding, as regards the shape of the section of the ring, but the same principle is involved in all of them.

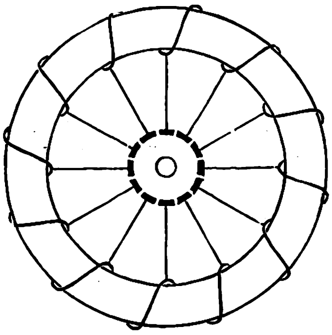

Fig. 3.

Drum armatures are composed of wire wound longitudinally round a drum made of wood or iron. One end of one coil is connected to one segment or slip of the collector (which is of the same form as that employed for the ring armature), the other to the next slip, to which is also connected one end of the next coil, and so on, as in the case of ring armatures. The drum armature is employed in the Siemens direct current, in Edison's, and in other machines.

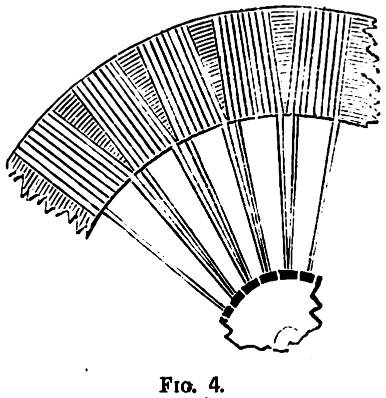

Fig. 4.

Although the field-magnets of a series dynamo are often arranged as in Fig. 1, this is by no means the only method of arrangement. The armature may come between the coils of the two field-magnets, as Fig. 5 and Fig. 6, where the current generated in the armature flows by the brush B through the field-magnet F M to the + terminal T, thence through the external circuit R and back, through the field-magnet F M, to the armature by the – brush B_1, as shown by the arrows in Fig. 6.

The first operation to be performed when we have a new and unknown dynamo to deal with is to measure its internal resistance—*i.e.*, the resistance through the terminals, and the resistance of the field-magnets and armature.

* Sometimes miscalled commutator. The Brush and the Weston-Plating dynamos are about the only machines that have a *commutator*.

To do this we employ a Wheatstone bridge, the principle of which will be found in any text-book on electricity.

The method of working a bridge to measure some fixed resistance is as follows:—

We have four terminals, D F E H; between D and F is connected a resistance A, between D and H another resistance B, between H and E another, R; between F and E is inserted the unknown resistance to be measured (in this case the dynamo machine, the terminals of which, T and T, are connected to F and E); between F and H is inserted a galvanometer, G, and a key, k, to connect or disconnect the galvanometer from H.

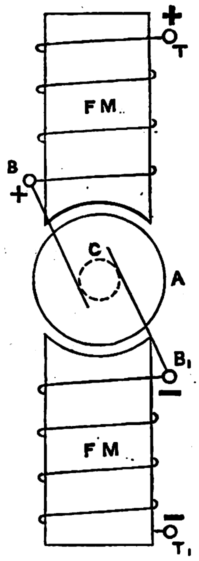

Fig. 5.

To D is attached one pole of a battery of two or three cells, while the other pole is connected to E through the key k.

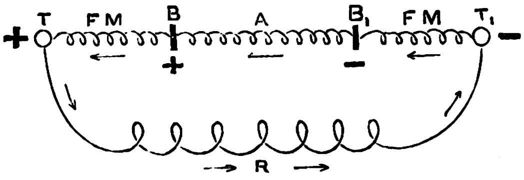

Fig 6.

The resistances A and B are kept constant, while R is varied. For measuring a series dynamo we may make A = 10 ohms, B = 100 ohms.

Suppose we have a bridge thus connected up. Unplug in R some resistance at random; depress the key k, then, after two or three seconds, depress k_1, keeping k still depressed. We shall now probably obtain a deflection on the galvanometer G either to the right or to the left, for it is improbable that we should have chosen R of exactly the right resistance; suppose we obtain a slight deflection to the right. Now, to find whether this deflection is due to R being too large or too small, make R infinite by pulling out the infinity plug, or by disconnecting it either from E or H, and again depress the key; there is now a violent deflection one way or the other, say to the right.

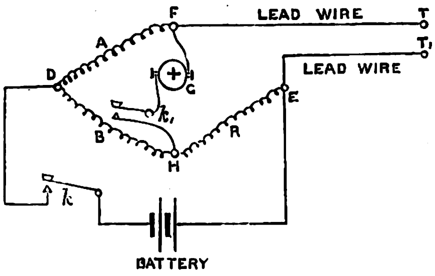

Fig. 7.

Digitized by Google

We therefore now know that a deflection to the right means that R is too large, and, *vice versâ*, one to the left shows it to be too small. Connect R again to E and G as before, but slightly lessen its resistance; depress the keys as before. Suppose we now obtain a smaller deflection to the right, we must decrease R until on depressing the keys no deflection is seen on the galvanometer; if, however, a deflection to the left is obtained, R must be increased.

When a balance is obtained—*i.e.*, when the galvanometer gives no deflection on depressing the keys, the resistance of R must be noted. Then the resistance of the dynamo and the leads, or whatever resistance was connected between the terminals F and E

$$= \frac{A}{B} \times R$$

Suppose there were 22 ohms unplugged in R when we obtained a balance, then as A = 10 ohms and B = 100 ohms, $\frac{A}{B} \times R = \frac{10}{100} \times 22 = 2{\cdot}2$ ohms, which is the resistance of the dynamo + the lead wires connecting F and E with T and T_1.

Disconnect the leads from T and T_1, and connect their ends together; now measure the resistance as before, and when a balance is obtained suppose R = 2 ohms, then

$$\frac{A}{B} \times R = \frac{10}{100} \times 2 = \quad {\cdot}2$$

Therefore the resistance of the dynamo = 2 ohms. When accuracy is required, the bridge should be "balanced" before use. That is, the terminals E and F are joined by a piece of thick copper strip or other conductor of practically no resistance, equal resistances are unplugged in A and B, and all resistance plugged in R. Then, since R = 0 and x, or the resistance between E and F = 0, when the keys are depressed there should be no deflection. If there should be any, look to all plugs and binding screws until the bad contact is found.

When putting in the plugs in order to obtain good contact the plug should be gently turned in the hole with a slight pressure until felt to "bite." It is, however, a very bad practice to force the plugs in, as it results in the breaking of the ebonite heads.

(TO BE CONTINUED.)

OLD CABLE STORIES RETOLD.—IV.

BY F. C. WEBB.

THE ATLANTIC EXPEDITION OF 1857.

On June the 5th, 1857, H.M.S. "Agamemnon," a 91-gun screw line of battle ship, arrived off Messrs. Glass and Elliot's works, Morden Wharf, Greenwich, to ship one half of the first Atlantic cable, a work which at that time was looked forward to with intense interest by the general public, as well as by the engineering profession.

The cable was by that time nearly all manufactured, one half (1,250 miles deep sea and 15 miles shore end) having been made by Messrs. Glass and Elliot, and the other half by Messrs. R. S. Newall, at temporary works in some warehouses at Birkenhead. The American Government had sent over their crack frigate the "Niagara," to carry half the cable, and that ship arrived at Gravesend in May, and on the 16th was visited by Messrs. C. Bright, Canning, and Woodhouse, and myself (engineers to the Atlantic Company), Messrs. Whitehouse (the electrician to the company), Statham (the manager of the Gutta Percha Company's works), and R. Glass. We found the ship greatly cut up by engines, decks, and bulkheads, and no holds to speak of. It was evident we must coil between decks, but then the finely-decorated ward room, of which the ship's officers were very proud, would have to be cut into. The captain and officers wanted us to coil the cable on the main deck in a kind of horseshoe form down two sides of the engine room hatch, and it was not until actual experiments were tried that they were convinced of the impracticability of this plan, and gave full permission to have their bulkheads cut away in all directions, and eventually the coils in her were as follow:—

In hold, forward of engines	352	miles	D.S.
On lower deck, exactly above this..............	182	„	D.S.
On main deck, exactly above this	294	„	D.S.
On main deck, between main and mizen masts	297	„	D.S.
On upper deck, above the last	130	„	D.S.
	1,255		
On upper deck, forward of foremast	10	„	S.E.
Total	1,265	miles.	

All these coils were in circular wooden structures, and had Newall's cones and rings fitted under Mr. Woodhouse's directions, who had before served on expeditions with Mr. Newall.

In the "Agamemnon" one large wooden tank of a peculiar shape was made in the hold, forward of the mainmast. It was nearly circular at its top and elliptical at its base. The cone had to be of a still more peculiar shape, for, to take the same number of thickness of cable in every direction at any flake between cone and sides of tank, it was made elliptical at bottom and nearly circular at top, and the top had to be less in diameter than the minor axis of the ellipse. A longitudinal section of it was like an exaggerated dumpy Eddystone Lighthouse, and a cross section was nearly like an ordinary cone. This was very cleverly worked out by Mr. (now Sir Samuel) Canning and Mr. Clifford. In this tank the whole of the 1,250 miles of deep sea cable was coiled, and 15 miles of shore-end was coiled on the orlop deck just forward of the main coil, thus leaving her lower main and upper decks quite clear of cable.

The paying-out gear in both ships consisted of four grooved wheels, on horizontal shafts, placed in series one behind the other, the two middle ones being a little higher than the others. These wheels overhung the frame. On each shaft was a spur wheel. These were geared in pairs, and between the two pairs was a pinion gearing into one wheel of each pair, and on the shaft of this pinion was a Prony brake and dynamometer. The cable fed on to top of No. 2 wheel, went three-quarters round and on to top of No. 1, then coming off bottom of No. 1, went straight to bottom of No. 4, off top of No. 4 to bottom of No. 3, then three-quarters round and off altogether at top of No. 3 to the stern sheave. But I am not going to discuss the machinery. A full drawing of this paying-out gear is given in my paper read at the Institution of Civil Engineers in February, 1858, and its merits and faults are there discussed. Coiling on board the "Agamemnon" began on June 16th. On the 28th (a Monday) it was found that the top flake of the coil in the yard, which had been standing all Sunday, showed signs of the gutta percha being melted. It was visible in little pimples (the size of a pea) outside the wires. The cable was cut 30 miles down, and tested by Mr. Whitehouse, and the portion below the cut passed. On the 16th of July places were found where the copper was quite through the gutta percha, and these were cut out.

The "Niagara" took her cable on board in the Mersey, as she could not enter the Birkenhead Dock, where Messrs. Newall and Co. were making the half of the cable that she was to carry. It was brought out in a small sailing ship. On the 20th of July a dinner was given at the Adelphi Hotel, Liverpool, to the officers of the United States frigates, "Niagara" and "Susquehana."

The "Agamemnon" was officered in a curious way, four masters—that is, what are termed staff commanders now—were appointed, one to do duty as captain, one as master, and the other two as lieutenants.

On July 24 we started in the "Agamemnon" from Greenwich. It was a very high tide, and as we passed Blackwall we seemed from the poop of the ship to tower up above the place, and had a bird's-eye view of the crowd on the wharf, that cheered us lustily. All the way down to Gravesend all passing ships cheered us. Now telegraph steamers are so common that notice is scarcely taken of them—at any rate, in the Thames. When we arrived off Gravesend it was strong ebb, and as the anchor was let go without first bringing the ship round head

Digitized by Google

to tide, she swung round with such a spin that it nearly took us off our legs on the poop. I had given up my poop cabin to some ladies—relations of Mr. Nodall, R.N., who commanded the ship—and took one of a row of temporary cabins erected on the main deck. The next morning, just at dawn, the ship was getting her anchor, and I was suddenly awoke by a tremendous noise, with cries of "Lie down, men, lie down," and then a crash against the door of my cabin. I got up, and with some difficulty got out of my cabin, as one of the large capstan bars had been hurled against it. The ship had been steamed ahead before the anchor was off the ground and the cable having "taken charge of the capstan," the capstan was dragged round reverse way at a fearful velocity, knocking all the men over. The swiftsure then broke, and all the capstan bars flew out and came crashing amongst the men, who were lying about in every direction stunned. Three had broken legs, and seventeen others had to be laid up in the sick ward, but there were many more that were merely stunned. It looked just as if a shell had burst. We sent the three serious cases back by a tug to Woolwich. We anchored in Sea Reach for this, and got into Sheerness at 4 p.m. We left Sheerness on 27th for Cove. When past Dover we tried the machinery by paying out a bit of cable and heaving it in again. The paying-out gear was made to haul in with. Again on the 28th we tried some experiments, and I have a note that slack accumulated between the two end sheaves of paying-out gear. On the 29th we paid out a piece of cable rove through a rough-made machine which Professor Thomson (now Sir William) proposed for catching the cable if it broke. We cut the cable, but the end flew through without being caught. I have a note, too, that the brakes put a great deal too much strain on even when they were "hard off"—that is, when entirely released. On the 29th we came into Cove, and found the "Niagara," the "Susquehana," and H.M.S. "Leopard" all there. The "Susquehana" played "God save the Queen" as we passed her. Crowds of people came on board both cable ships. On the 31st I left with Mr. Cyrus Field and the Knight of Kerry for Valentia to choose a landing place for the cable. On the 1st August Mr. Field and I selected a place, and a tent was rigged up. Batteries and clerks arrived in H.M.S. "Cyclops" and the steam tug "Advice." On the 3rd the Lord-Lieutenant arrived at Valentia, and the next day a grand *déjeuner* was given in his honour by the Knight of Kerry. The other ships arrived the same day, and on the 5th we landed the end of the cable from the "Niagara." For this we used the paddlebox boats of the paddle frigates, and also the "Willing Mind" tug. When the end was ashore there were prayers, and then a speech from the Lord-Lieutenant.

The "Agamemnon" had remained outside cruising about in the bay, and I went off at 10 p.m. to her in a tug with several clerks and luggage. She was rolling heavily, although it was fine weather, but a swell on. She lowered a cutter and took me on board, but would not take the unfortunate clerks. When I got alongside it was not an easy matter to get up her side, as one minute the side ropes were scarcely within reach, and the next minute her lower deck ports were in the water. I managed a grasp at the side ropes, and the next second the boat was thirty or forty feet below me. When I got on deck I found the commander, Mr. Nodall, in a towering rage at having to lower a cutter at that time of night, when the ship was rolling so heavily.

"Here we have been," he said, "rolling about to that extent, sir, that we have had to set up the rigging afresh twice, and then you come off at this time of night with a lot of clerks and luggage." I said I could not help it as it was Mr. Bright's orders. "It's my opinion, sir," he replied, "that Mr. Bright does not know whether he is standing on his head or his heels, sir." This was scarcely a polite remark, so I went below to the ward room, and had some supper. I was now on board the "Agamemnon," and all the three other engineers on board the "Niagara," it having been arranged that Mr. Canning, who was appointed at first to the "Agamemnon," should go with the "Niagara," so as to make three engineers in the "Niagara" during the time of her paying out her cable, leaving me in charge in the "Agamemnon." I can only relate, therefore, what I saw from my own ship, and indeed these articles are not intended as complete histories, but only one person's experience.

On the 6th the "Niagara" started paying out, and was soon seen to turn back, and then forward again, and then back into harbour; then out again, apparently dredging, and then in again. On the 7th we sent a boat ashore with letters; boat came back, and we learnt that in paying out "Niagara" had got shore end of cable foul round axle of break, and had broken it. Had now under run in paddle box boat to a mile out, and then cable was cut, and shore end handed to the "Leopard," and end from "Niagara" passed also to "Leopard," and splice made in "Leopard." She started again at about 5 p.m., and at night we saw her stationary for some time. On the 8th, at 2 a.m., "Niagara" was about two miles from land; at 8 a.m. the whole fleet, consisting of "Agamemnon," "Niagara," "Leopard," "Susquehana," and "Cyclops," twenty-four miles from land; at noon thirty-seven miles paid out. On the 9th, at 8 a.m., "Niagara" signalled "coil on quarter deck out." At noon we were ninety-eight miles from land, and "Niagara" signalled ninety-nine miles out. I have a note saying, according to agreement, this would be in last twenty-four hours. At night "Niagara" was going very fast. On 10th at noon we had run 112 miles since noon the day before, and "Niagara" had paid out 111 miles. Probably this discrepancy is due to errors of longitude. At 5 p.m. "Niagara" suddenly backed, then we saw a large bight go over, after which "Niagara" signalled "all right."

The next morning my servant, who had been with me in the old "Monarch," came to me with the awful words, "Cable parted, sir!" and sure enough when I looked out of my port I missed the familiar thin line that used to be streaming away over the stern of the "Niagara."

We then closed with the "Niagara" to try some experiments. We passed end of cable to "Niagara" and broke cable. Passed it afresh, got out five miles, and then broke it; strain by the dynamometer, about two tons. "Niagara" tried to haul in her five miles from stern and broke it also. Mr. Canning now came back to the "Agamemnon," and all the fleet started, the "Agamemnon" and "Niagara" for Plymouth, where we arrived much disappointed on the 14th. Thus ended the first Atlantic cable expedition of 1857.

THE HEALTH EXHIBITION.—IV.

This introductory or explanatory matter is almost at an end, and then the various exhibits will be described. The methods of winding the field-magnets have been mentioned, but a greater diversity will be noticed in the mechanical construction of the armature. In principle all armatures are alike, and consist of an arrangement by means of which a conductor is carried into and out of the magnetic field, due to the excitation of the field-magnets. If we like we can represent the strength of a magnetic field by the number of lines drawn in a given space. Suppose, for example, in Fig. 2, we draw ten lines across the space between the pole pieces C D, that might be taken to represent a magnetic field of strength x; while a field of strength $2x$ would be represented by twenty lines across the same space, a strength of $3x$ by thirty lines, and so on. It is customary very often to imagine a magnetic field made up of forces acting along certain lines or directions, and to call these "lines of force." The greater the number of lines of force in a given space the greater the strength of the field at that point. It has been the aim of designers of dynamos to concentrate the magnetic field so that the conductor of the armature may pass from the position of no field to the position of greatest magnetic strength with the smallest possible change of space. If we use an instrument to indicate the direction of a current, the

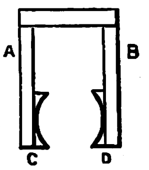

Fig. 2. Field Magnets of Dynamos.

Digitized by Google

needle or pointer of the instrument swings in one direction when the conductor enters the magnetic field, and in the opposite direction when the conductor leaves the field. Hence there seems to be phenomena of an opposite character taking place when the conductor enters and leaves the field. If the current in the one case is known as + or positive current, in the other case it is called − or negative current, and a machine which first sends a + current through the lamp and then a − current is, as we have previously said, called an alternate current machine. The alternate current is used for all lamps of the Jablochkoff type, and frequently with incandescent lamps. In the ordinary arc lamps, with the carbons in the same vertical or horizontal line, the alternate current has to be changed into a continuous current. It is easy to see that a push and a pull alternately may move a block of stone or a log of wood in one continuous direction. We have only to make the push at one end and the pull at the other to attain our object. In order to change an alternate current machine into a continuous current machine, it is necessary to use a piece of mechanism called a commutator (Fig. 8). A simple form of commutator is thus made:—Take a cylinder of insulating material, shown in section by A, two strips of conducting material, such as copper, fixed to A, as shown at C C′, two springs S S′, which press either on C C′ or on the insulator A; the springs are connected to the terminals T T′. The wire through which the current is to go continuously is shown by *x*.

The wire in which the current is generated is shown by *y*. Let the direction of current required be from left to right. Then when the current in *y* is generated by rotating the arma-

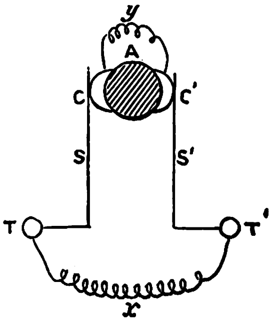

FIG. 8.—Elementary Commutator.

ture, the current passes as required with the apparatus as shown. If the current generated is in the opposite direction, then the spring S′ must be brought into contact with C and S with C′ in order that the current through *x* may be as required. All continuous current machines have some arrangement of this kind, and are therefore not so simple as alternate current machines. The reason why alternate currents are used with such candles as those of Jablochkoff and Wilde is that the carbon connected with the + terminal wears away twice as fast as that connected with the − terminal.

Thus, using two parallel or almost parallel carbons and alternate currents, the carbons consume at the same rate. It is this greater consumption of one carbon over that of the other that constitutes one of the difficulties of making a really perfect arc lamp. The one carbon, it will be seen, must be fed at twice the rate of the other. One word to visitors watching arc lamps may be useful, viz., to form no opinion as to the merits of one arc lamp over and above that of another unless the mechanism of the lamp is thoroughly investigated. The burning of a lamp may be an excellent test, it may, however, mislead. Frequently a good lamp burns badly, not from any fault except that of bad carbons. The carbons consumed nowadays are a wonderful improvement upon those used ten years back, but there is still much to be done before a perfect carbon is produced. With this preliminary information we may proceed to investigate the individual exhibits, without showing too much ignorance or being unable to follow the statements made.

(TO BE CONTINUED.)

ON THE MOST ECONOMICAL SIZE OF ELECTRICAL CONDUCTORS.

By W. L. HOOPER, Physical Laboratory, Tuft's College.

The problem of determining the most economical size of a conductor designed to transmit electrical energy for lighting, or as a source of power, is one of great importance and not difficult of solution.

Let E represent the difference of potential between the terminals of the main conductor at the dynamo, R the resistance of the conductor, *r* the combined resistance of the lamps, and C the total current, then by Ohm's law

$$E = C\,(R + r).$$

If P represent the energy of the current measured in horse-power, then

$$P = \frac{C\,E}{745} = \frac{C^2\,(R + r)}{745}.$$

The resistance is here composed of two parts; and since the heating effect of the current, or the loss of electrical energy in various parts of the circuit, varies directly with the resistance, the horse-power wasted upon the conductor is evidently expressed by the equation

$$P = \frac{C^2\,R}{745} \quad . \; . \; . \; . \; . \; . \; . \; . \quad (1).$$

Let *p* be the cost of an electrical horse-power transmitted to the conductor for one hour, and *n* the number of hours in a year that the current is used; then the cost of the current wasted in the conductors during the year will be

$$\text{Loss per year} = p\,n\,P.$$

Substituting value of P in (1),

$$\text{Loss per year} = \frac{p\,n\,C^2\,R}{745} \quad . \; . \; . \; . \quad (2).$$

Let R^{sp} be the specific resistance (the resistance of unit length of unit cross-section) of the material composing the conductor, *l* its length, and *l* its diameter, if round. Then the area of cross-section of the conductor will be expressed by

$$\square = \Pi \left(\frac{d}{2}\right)^2 = \frac{\Pi\,d^2}{4}.$$

The total resistance of the conductor will be

$$R = \frac{R^{sp}\,l}{\frac{\Pi\,d^2}{4}} = \frac{4\,l\,R^{sp}}{\Pi\,d^2} \quad . \; . \; . \; . \; . \; . \quad (3).$$

Substituting this value in (2) we have

$$\text{Loss per year} = \frac{p\,n\,C^2\,4\,l\,R^{sp}}{745\,\Pi\,d^2} \quad . \; . \; . \quad (4).$$

Let W represent the weight of unit length of unit cross-section of the conductor, then the

$$\text{Weight of conductor} = \frac{W\,l\,\Pi\,d^2}{4} \quad . \; . \; . \quad (5).$$

If the cost of unit weight *in situ* be *q*, then the

$$\text{Cost of conductor} = q\,\frac{W\,l\,\Pi\,d^2}{4} \quad . \; . \quad (6).$$

Let *i* be the current rate of interest, then

$$\text{Interest on cost of conductor} = \frac{i\,q\,W\,l\,\Pi\,d^2}{4} \quad . \; . \quad (7).$$

Now, the cost of the conductor, and consequently the interest on that amount, may be supposed to vary directly with its area of cross-section; but the resistance of the conductor, and consequently the waste of energy in it, will vary inversely with its cross-section. Hence the interest on the cost of conductor and the cost of the current wasted in a year will vary inversely with each other. Now, the sum of two quantities that vary inversely is a minimum when the two quantities are equal. The most economical size will

Digitized by Google

therefore be that with which *the cost of current wasted in a year will equal the interest on capital invested in the conductor.* Hence

$$\frac{4\,p\,n\,C^2\,l\,R^{sp}}{745\,\Pi\,d^2} = \frac{i\,q\,W\,l\,\Pi\,d^2}{4} \quad . \quad . \quad . \quad . \quad (8).$$

$$d^4 = \frac{16\,p\,n\,C^2\,R^{sp}}{745\,\Pi^2\,i\,q\,W} \quad . \quad . \quad . \quad . \quad . \quad . \quad (9).$$

It will be noticed that l cancels out of equation (8), therefore the size of conductor is independent of its length.

EXAMPLE.

Let p		$= \$\cdot03$
n	$= 365 \times 6$	$= 2190$ hours
C		$= 1000$ amperes
R^{sp} inch, copper pure, at 0° C.		$= \cdot00000064645$ ohms
i		$=$ 8%
q per lb., *in situ*		$=$ \$·30
W cubic inch		·32523lbs.

Log. 16	$= 1\cdot204120$	Log 745	$= 2\cdot872156$
„ ·03	$= \bar{2}\cdot477121$	„ Π^2	$= 0\cdot994302$
„ 2190	$= 3\cdot340444$	„ ·08	$\bar{2}\cdot903090$
„ 1000000	$= 6\cdot$	„ ·30	$\bar{1}\cdot477121$
„ ·00000064645	$= \bar{7}\cdot810538$	„ ·32523	$\bar{1}\cdot512192$
	2·831223		1·758861
	1·758861		
	4)1·072362		
Log d	$=$ ·268090		

d = 1·8539in.

From equation (9) it appears that the area of cross-section varies with the current, hence a copper conductor that carries 10 amperes under the conditions in the above example should have a diameter of

$$\frac{1\cdot8539}{\sqrt{\frac{1000}{10}}} = \cdot18539\text{in.}$$ No. 5 gauge would answer.

It is important now to determine the heat generated in the conductor by the current. The heat in water gramme centigrade degrees generated by any current in t seconds is expressed by the equation

$$H = \cdot24\,C^2\,R\,t \quad . \quad . \quad . \quad . \quad . \quad (10).$$

The ratio between the gramme centigrade and pound F. degree is $\frac{9}{5 \times 453\cdot54}$, which multiplied by ·24 gives ·00095251.

Hence the heat in pound F. units will be

$$H = \cdot00095251\,C^2\,R\,t \quad . \quad . \quad . \quad . \quad (11).$$

Substituting for R its value in (3)

$$H = \cdot00095251\,C^2\,t\,\frac{4\,l\,R^{sd}}{\Pi\,d^2} \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (12).$$

The temperature to which the conductor will be raised in any time, supposing no heat is radiated or conducted away, will be the quotient of the whole amount of heat divided by the weight of the conductor multiplied by the specific heat (H^{sp}) of the material composing it.

$$T = \frac{H}{\text{weight} \times H^{sp}}.$$

Substituting for weight its value in (5)

$$T = \frac{4\,H}{W\,l\,\Pi\,d^2\,H^{sp}} \quad . \quad . \quad . \quad . \quad . \quad (13).$$

Finally substituting for H its value in (12)

$$T = \cdot00095251 \times 16\,\frac{C^2\,t\,R^{sp}}{W\,\Pi^2\,d^4\,H^{sp}} \quad . \quad . \quad . \quad (14).$$

Since in the above equation C^2 and d^4 are the only variables, T is constant under the same conditions for wires of different sizes, each carrying its most economical current.

EXAMPLE.

The copper wire in the last example, current 1,000 amperes, t one hour or 3,600 seconds, H^{sp} of copper being ·09515.

Log ·00095251	$= \bar{4}\cdot978869$	Log ·32523	$= \bar{1}\cdot512192$
„ 16	$= 1\cdot204120$	„ Π^2	$= 0\cdot994302$
„ 1000000	6·	„ d^4	$= 1\cdot072362$
„ 3600	3·556303	„ ·09515	$= \bar{2}\cdot978409$
„ ·00000064645	$\bar{7}\cdot810538$		0·557265
	1·549830		
	·557265		
Log T. =	·992565		

T = 9°·8302 Fahrenheit.

In the above example it is assumed, as has been before stated, that no heat is lost by radiation or conduction. But it is evident that a conductor whose temperature rises only at the rate of 10° F. per hour would soon reach a point where the heat given off would equal that acquired; hence, it could never be many degrees hotter than surrounding objects, especially if Professor Forbes's suggestion of making the conductors flat was adopted. I have no data for computing what this final difference of temperature would be for a wire buried in the ground (the only way to dispose of conductors carrying large currents), and it would evidently vary in different localities, but it is safe to say that the difference would be so small that it would only be objectionable on account of slightly increasing the resistance of the conductor.—*New York Electrician.*

ANNUAL REPORT OF THE POSTMASTER-GENERAL.

We make the following extracts from the Postmaster-General's report for the year ended March 31 last:—The number of telegraph messages despatched in the year was 32,843,120, an increase of 640,055 over the previous year. The increase in that year over 1881-82 was 746,165. The number of messages despatched in London was 12,639,192, as compared with 12,374,707 in 1882-83, and of this number 1,772,125 were for delivery in London.

On the subject of sixpenny telegrams and telephonic communication, Mr. Fawcett remarks:—"Although the introduction of a reduced tariff for telegrams has been postponed till the 1st of August, 1885, considerable preparations have been made in anticipation of that event. Many new wires have been laid and main lines commenced. By Treasury minute of the 14th of June, 1883, a total sum of £500,000 was authorised to be expended in providing the necessary plant for the new tariff, and of this about £180,000 was spent between August and the 31st of March. By far the larger part of the telephonic communication of the country continues to be supplied by private companies who hold licences from the Post Office. Frequent representations have been made that if some of the conditions which have been inserted in these licences for the protection of the revenue could be relaxed, the public might enjoy greater facilities in reference to telephonic communication. As it would be very undesirable to impose any unnecessary restrictions upon the development of telephonic enterprise, I lately suggested to the telephone companies that they should meet, and if possible come to an understanding as to the changes which they consider necessary to be introduced in the existing licences in order that the public may enjoy the greatest possible facilities for telephonic communication that are compatible with the revenue being properly protected. Various proposals have been submitted to me which are now being carefully considered."

The balance-sheet shows that upon the entire business of the department there was in the twelve months a net revenue of £2,687,100, the expenditure being £7,208,953, and the receipts £9,896,053.

ELECTRIC LIGHT FOR OUTDOOR RECREATION.

One of the best, though probably unintentional, services rendered by the Health Exhibition to the cause of health has been the attention it has drawn to the possibilities of outdoor recreation for town populations after the toils of the daytime and its sunshine are over. An evening contemporary last week warmly endorsed and backed up the recommendations of Mrs. Ernest Hart a few weeks ago, when advocating the extension of popular ballad concerts for the people, and the cry has been promptly echoed in several other quarters since then. We make no apology, therefore, for dealing with the subject in these columns, although hardly anything can be added to the excellent article in the *St. James's Gazette* of yesterday week. We have never thought much of the several attempts made last year both in England and elsewhere to enlist the electric light into the services of football or cricket at night time. The light is ill adapted for such occasions considered from the player's point of view, and still worse from the spectator's. Games of that kind, moreover, although healthy, are recreative only in a secondary sense, and their healthfulness depends, or rather is greatly due to the daylight, fresh air, and sunshine in which they are played. Besides this, they are suburban or rural in their main features, and we are now dealing with a subject peculiarly urban, where, therefore, the advantages enjoyed or easily procured by residents in the country are altogether absent. What is wanted for the half-stifled toilers within the boundaries of our large towns and cities is some provision for affording fresh air combined with recreation after nightfall, both of which are beyond their reach in the daytime. We have plenty of open spaces; all that is needed is light to illuminate them, and this we are rejoiced to see is now acknowledged to have been found in the electric light.

To the singularly dry and genial weather which continued through the spring and ushered in the summer we owe, no doubt, a great deal of the success of the Healtheries; but the experience of the last two or three weeks, during which time St. Swithin has had sole charge of the elements, proves that outdoor recreation may be taken in spite of him. Several experiments have been successfully carried out in imitation of South Kensington, even the hazardous one of acting Shakespeare's plays in the open air. And if this can be done in the daytime it is no longer impossible to do it at night. The fact is we take our unsettled climate too much as a matter of course, yielding ourselves to its uncertainty, when in reality a little self confidence would very soon demonstrate that in the summer time at all events rainfall is seldom continuous, and often confined to small areas. It rained in torrents in some parts of London on "Demonstration Monday," but hardly a drop fell in Hyde Park, though Oxford-street was drenched. Politicians may opine that there was a special providence in this, but the same will hardly be said for South Kensington, where the outdoor bands have not been prevented playing more than two or three times during the whole season.

But what is needed, more even than confidence, is a place of recreation to go to, and suitable provision for it when we have got there. This is to be found in abundance in the grounds of the Health Exhibition, and novel as is the experiment it has attracted already more than a million of people, most of whom we may safely conjecture remain there long after the surrounding parks have been enveloped in darkness, and closed to all innocent enjoyment.

On this point we cannot do better than quote the words of Mrs. Hart, in the address before referred to:—"Well do I remember one sultry August evening, now three years ago, riding up to town from the country. The sun had set when we left Richmond, and it was quite dark as we reached London. I proposed we should take the road through the park, so that we might canter through the deserted 'Row;' but when I reached the park its black darkness was alarming, and I was afraid to venture out of the road. It was Sunday evening, and the streets were thronged with the dense moving crowd seeking some relief from hot rooms—the great park was silent and deserted, given over to deeds of darkness. All London, namely, the well-to-do, were away on the moors of Scotland, by the seaside, on the Alps; the greater London, that were left behind, had the streets in which to enjoy the summer evening. 'Some day,' I said to my husband, 'this park shall be lit by the electric light, and we shall have bands playing every night to the public; and the people shall rest instead of pacing the weary streets.'"

Precisely the same remarks, we need hardly say, are true of the other parks in the east, north, north-west, and south of

Digitized by Google

London, and the remedy is or might be precisely the same. Most of us have noticed with surprise and regret that in the very localities where open spaces least abound, and where the only available spot for open air exercise and recreation would be most appreciated, that one spot is ruthlessly closed at sunset. There are some obvious social reasons for this, it is true; but they would have been overcome before now if we had been in earnest in securing the benefits of outdoor enjoyment after dark, even on a limited scale. Imperfect illumination has no doubt had something to do with the restrictions; but this necessity exists no longer, for the electric light will give as much and as beautiful light as can be wanted at a cost which under such conditions would be far cheaper than gas, besides being infinitely more tasteful and more wholesome. Mrs. Hart's suggestions have been received with such warmth by the public that most probably some steps will be taken to fulfil her predictions before another summer comes round. We hope and believe that promoters of electric lighting will heartily co-operate in a movement which besides profiting them would effect a reformation much needed in the social life of the people.

CORRESPONDENCE.

DYNAMOS v. PRIMARY BATTERIES.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: Writing to you with reference to the comparative steadiness of the light of the lamps in the hall and in the reception rooms on the occasion of the recent *conversazione* at King's College, Mr. Albright, on behalf of the Edison and Swan United Electric Light Company, does not contest, but endeavours to account for the fact that the steadiness of the light which was supplied from my primary battery was "in marked superiority to that of his lamps" by explaining that his dynamo was worked with an inefficient gas engine. It may readily be granted that under Mr. Albright's personal superintendence the working of that gas engine would have been greatly improved, but I am under the impression that many of your readers must have experienced similar disappointments when using other gas engines. If such an expert as Mr. Gerald FitzGerald would kindly furnish you with his experience of the lighting of the School of Telegraphy in Prince's-street, Hanover-square, that point might be impartially determined.

I think it fair to add that I am as much a "believer in dynamos" as Mr. Albright himself, but with this distinction. Dynamos and batteries in electric lighting may be compared to the steam-horse and the four-footed animal. For 1,000 lights, or the transport of 1,000 passengers, give me the dynamo and the locomotive; for family, or domestic purposes, the primary battery and a pair of horses in my stable. Each invention has its appropriate place. Engines and dynamos in the outhouse or cellar are sometimes an intolerable nuisance, but a battery can be placed there without the slightest inconvenience.

Electric lighting can never become general until more attention is paid to the practical obstacles which have beset its path. Some of the "believers in dynamos" would now have the public wait for central stations to be everywhere established, forgetting that, for the supply of only one-quarter of the light now obtained from gas, London alone (as the late Sir William Siemens pointed out) would require 140 such stations, each with from ten to fifteen 500 horse-power engines, and innumerable noisy dynamos, erected at a cost of no less that fourteen millions sterling.

Householders who do not wish to wait "it may be for years, or it may be for ever," ask for an alternative, and if the Edison and Swan United Electric Light Company has found that they are not all satisfied with the expedient of a gas engine and dynamo in their own houses, surely no one, it seems to me, should be more interested than that company in the very practical improvements which have been established in primary batteries.—Yours, &c., O. C. D. Ross.

21, Austin Friars, E.C., July 28th, 1884.

SMALL GRAMME DYNAMO.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: I have made a Pacinotti armature of the cog pattern with 20 teeth in it, and wound it with 3lb. 18cc. wire, 20ft. in each coil, armature 5in. diameter 2in. wide $\frac{7}{8}$in. thick. And will any reader be good enough to give me sizes of arms of F.M., and a small sketch how to wind the F.M.s and connect up in parallel arc? I want it to light about six 10 candle-power Swan lamps. I have got 9lb. 16cc. wire for the field. Hoping you will find room for this.—Yours, &c., H. P.

ELECTRO-DYNAMICS.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: The object of the paper read before the Electrical Section of the Franklin Institute by Mr. John W. Nystrom, and recently reprinted in *The Electrician*, is said to be to show the confusion in which the subject of electro-dynamics is yet involved. This object is admirably attained and kept in view at every step, for there is hardly a formula or statement in the whole of the paper which is not faulty. How far the paper will clear up the subject in America I am not prepared to say, but the elucidation is not likely to be greatly appreciated in England.

To start with an early statement, "No formulas can express quantity of work without representing the three simple elements—*force*, *velocity*, and *time*; and as the time is wanting in Count du Moncel's formulas, they cannot express work." With generous assurance Mr. Nystrom immediately presents us with the product of force into linear space, as representing work, but hastens to add that linear space involves time, because it is the product of velocity into time. As if velocity were a simpler idea than space. What the author fails to appreciate is, not that the quantities occurring in dynamics and in electricity, considered as a branch of dynamics, can all be expressed in terms of three of them, for he himself tells us what he considers the three simple *elements*, viz., *force*, *velocity*, and *time*, but it is the much wider generalisation that we may choose as fundamental ideas *any three* of the ideas considered, and express all the others in terms of them, subject to the condition that no one of the ideas chosen involves merely the other two or one of them only.

Thus a system could not be supported only upon the three quantities, linear space, time, and velocity, because velocity can be formulated in terms of space and time only. Nor could a system be raised upon volume, area, and any other third, because area can be formulated in terms of volume. But subject to such restrictions, any three ideas may be considered fundamental. It is customary to take linear space, mass, and time as the basis of formulæ; but Mr. Nystrom is perfectly free to choose force, velocity, and time if he wishes to do so. They form a thoroughly sound basis, but having been chosen should then appear in the formulæ expressing the other ideas, unaccompanied by signs of any other ideas. But in Mr. Nystrom's new forms he constantly introduces the signs of power and work, besides those of velocity, force, and time, the fundamental ideas. Thus as simple formulæ the new forms break down in many cases. They might, however, be true, without being simple, but for the introduction into the fundamental considerations of vital errors. Mr. Nystrom has taken current to have a similar formula with velocity, and potential to have a similar formula with mechanical momentum-producing force.

Adopting his fundamental conceptions, the formula for current is $F^{\frac{1}{2}}$ where F is mechanical force, and potential is $v\ F^{\frac{1}{2}}$ where v is velocity, so that it would be hopeless to look for any truth in the new forms of Mr. Nystrom.

As to force, power, and work differing in the same way that length, surface, and volume do, that is a statement bearing no intelligible interpretation. I do not wish to defend the omission by Count du Moncel of his *time*, nor have I verified the

Digitized by Google

statement that he has omitted it. If he did, it was probably in a passage in which he felt his meaning would not be mistaken. The historian of "Scientific Ideas" occasionally uses the word *pressure* when he means *force*, but no one on this side of the Atlantic would accuse him of mental confusion on the point.—Yours, &c., THOMAS H. BLAKESLEY.

THE TRANSFORMATION OF ELECTRICAL ENERGY.

M. Hospitalier, at a conference at the Conservatoire des Arts et Métiers last month, read a paper dealing with the elementary facts of this subject. The following is a brief extract of the paper, which, although containing nothing new, may serve as a reminder of the constant "changes" which really constitute the tools of the world.

The text of the lecturer was the text upon which modern science is founded, "The Conservation of Matter and the Conservation of Energy." Change is everywhere, but nothing is lost, nothing created. The study of this law embraces all physical and chemical science, but we do not occupy ourselves here with the phenomena attaching themselves to any form of energy except that known as "electrical energy." The characteristic quality of electricity is in its transmission to a distance by means of a metallic conductor, the action being known under the name of electric current. The phenomena is not local, as with heat, nor is it necessary to attain a right line as with light, but we are able to direct the current as we please to the most convenient point of usage. The electric current is obtained by various means, chemical, mechanical, and otherwise, from apparatus designated as generators. On the contrary, any apparatus by which electrical energy is transformed into another form of energy—in virtue of the principle of reversibility—is a "receiver." Such are electric machines known as "motors," electric lamps, &c., which transform the electrical energy into work or heat.

If, on the other hand, the electricity re-appears on leaving the apparatus, but with different qualities to those it possessed on entering, the latter is known as a transformer. It is this class of apparatus, that we are about to study. From an industrial point of view their utility is not *a priori* evident. A transformer, whatever it be, is a costly intermediary; all agents, however employed, cost more or less for the service they render, and do not give out the whole of the energy put into them. By using transformers, therefore, a charge is burdened with a loss which varies according to the circumstances and the actual return—that is, the relation of the energy utilised to the total energy expended is subject in their case to the above impost. But the nature of each application of electricity necessitates a certain kind of current, having special qualities, which must be obtained to get the best result. If the generator at hand does not produce the current required, the employment of electricity necessitates a transformer which shall give to the current the necessary properties, and this may in certain cases be very advantageous in spite of the losses entailed. The better to understand this, let us compare the current which flows in a conductor to water circulating in a pipe. In the two cases the characteristics of the flow are:—(1) The force which produces the displacement; (2) the volume of delivery per unit of time; (3) the resistance to the flow. Water is displaced by virtue of pressure, difference of level, or height of fall; we express it in metres. Electrical motion is due to electromotive force or difference of potential, and we measure it in volts. The delivery of water, or volume flowing per second, is measured in litres per second, and of electricity in amperes. The unit of resistance offered to the propagation of the electric current is expressed by an ohm, whilst for water it is calculated by a fraction of the height of fall. Supposing we have three water-wheels working with a delivery of 1 litre falling from a height of 1 metre, we can arrange them in two different ways for the same expenditure of work, (1) by putting them one under the other, so that the water which has done work on the upper wheel shall fall on to the second and then the third. The characteristics of the fall will be 1 litre delivery with 3 metres of fall, a high fall and small volume. 2. We can arrange them side by side, so that each wheel shall receive 1 litre of water under a fall of 1 metre; the delivery will be 3 litres under a fall of 1 metre, large volume and small fall. With electricity the arrangements can be varied in the same way. If the current traverses all the machines successively, they are said to be arranged in tension, or in series, require high pressures, plenty of volts and few amperes. If, on the other hand, the current is divided between the various receivers or transformers, they are said to be arranged in quantity or derivation; in this case we require a large volume, plenty of amperes and little pressure, that is, few volts. If the generator at disposal does not produce the currents required by the arrangement of the machines, we must, in order to utilise it, have recourse to a transformer which will allow of variations according to our requirements.

Classification of Transformers.—If the transformed current has to be used at once, under penalty of losing the benefit of the operation, and if its form only is modified, the transformer is said to be *instantaneous*. If, on the contrary, a certain interval of time, more or less long, and theoretically unlimited, must elapse between the production and the utilisation of the current, the transformer is called a *deferred* machine. In each of these cases the result can be obtained directly by the effects of electrical actions solely, and the transformation is therefore direct; at other times another form of energy, work, or chemical action intervenes, according to circumstances, and the transformation is indirect. The following table, drawn up by M. Hospitalier, shows the different scientific and industrial applications of the numerous transformations of electrical energy. It shows at once what we shall ascertain later on by several experiments, that electrical energy has but one nature, but that this energy appears to us, according to circumstances, with very varied qualities of volume or pressure.

INSTANTANEOUS TRANSFORMERS.

DIRECT. *Induction.*	Interrupted c. into alternate c.—The Ruhmkorff coil. Undulatory c. into undulatory c.—The telephone. Alternate c. into alternate c.—Jablochkoff, Fuller, Gaulard and Gibbs. Continuous c. into continuous or alternate c. by commutation.—(Cabanellas). Extra currents.
INDIRECT. *Auxiliary use of mechanical energy.*	Continuous c. into continuous c.—Cabanellas. Manufacture of ozone. Continuous c. into alternate c.—Feeding Jablochkoff candles. Alternate c. into continuous c.

DEFERRED TRANSFORMERS.

DIRECT. *Electrostatic actions.*	Leyden jar. Jars. Condensers. Planté's rheostatic machine. Transformation by coupling up { + amperes − volts / − amperes + volts.
INDIRECT *auxiliary use of chemical energy.*	Maintenance of continuous work.—Electric flywheel. Convenient separation of work and time of production and consumption. Variable natural forces. Weak forces. Deferred utilisation. Modification of the qualities of the current. Splitting up and distribution.

INSTANTANEOUS DIRECT TRANSFORMERS.

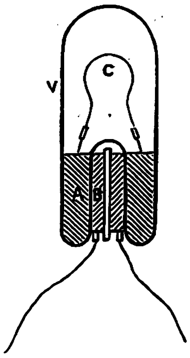
Interrupted Currents into Alternate Currents.—The best known example is that of Ruhmkorff's coil, so frequently used in scientific investigations and experiments, such as for the illumination of Geissler tubes, Crookes's experiments, and so on. In

Digitized by Google

this apparatus, generated at intervals, currents of low E.M.F. and large quantity are transformed into currents of very high E.M.F. and of small quantity. The product volts × amperes is the same, in virtue of the principle of the conservation of work. The qualities of the ultimate current depend upon the proportional lengths of the primary and secondary coils. Thus, causing the current from six accumulators, with an E.M.F. of about 12 volts, to traverse a Ruhmkorff primary, we are able to render incandescent an Edison lamp requiring an E.M.F. of 100 volts by means of the secondary. The lecturer also explained how a double transformation could be obtained by using two Ruhmkorff coils. In either case the increase in volts is at the expense of amperes, or the increase in amperes at the expense of volts.

Undulatory Currents into Undulatory Currents.—This method has received numerous practical applications in telephony. For feeble resistances—that is to say, with short lines, the transmitter is placed in the direct circuit; but with greater resistances a relay is employed. From 1877 to the present time this method has been applied to from 5 to 600,000 apparatus.

Alternate Currents into Alternate Currents.—The aim of this transformation is to modify the qualities of the current, and assist the distribution. It has been studied by Spottiswoode, by M. Jablochkoff in 1877, by Fuller in 1879, and by Messrs. Gaulard and Gibbs in 1883. These latter gentlemen have employed the method in electric light operations. Another



Diehl's Lamp.

original application is in the incandescent lamp of Diehl (1882), in which he has avoided the most delicate of all the points in incandescent lamps—the differential expansion of glass and platinum. In this case the lamp is entirely enclosed in a glass case of special form, as shown by the figure. In the interior of the case V is a coil, A, the ends of which are connected to the carbon filament C. Another coil, B, wound round a soft iron core is placed as shown, and connected to the source of electricity. The filament C is rendered incandescent by the current induced in A.

Continuous Currents into Continuous or Alternate.—The transformation into continuous currents is by means of commutators conveniently arranged. If continuous currents are obtained they must be transformed into alternate for such purposes as the feeding of Jablochkoff candles. The *extra current* is an example of instantaneous transformation.

Indirect Instantaneous Transformers.—This class of transformers are used in mechanical operations. If we utilise the initial current provided by a battery or a dynamo with a motor, we obtain a certain quantity of mechanical energy, which can be employed in setting in motion a second machine, to produce continuous currents or alternate currents of high or low E.M.F., of large or small quantity, according to the use for which it is designed.

Deferred Transformation.

Direct.—The apparatus used is generally of that class used in electro-statics, and has been known for many years. Examples may be given in the case of Leyden jars, the ordinary condenser, and so on. The Leyden jar, for example, receives and preserves during a certain time the electricity furnished by a statical machine, and gives it up as required in a series of discharges or otherwise, or may be used to drive a statical machine and produce work. The use of a number of such discharges enables us to vary the conditions of discharge. One of the principal applications of condensers is in submarine telegraphy, for duplexing, in fact, the cables. The extensive application of this method is restricted.

Indirect Transformation.—Chemical action is the auxiliary used in this method of transformation. For example, a current is used to decompose certain chemical combinations. After a time more or less lengthy, under certain conditions the elements separated will recombine and furnish a quantity of energy sensibly equivalent to that which caused the decomposition. The secondary battery of M. Planté (1860), to which the name of accumulator has lately been given, is the type of this form of apparatus and has been employed in industrial work by Messrs. Faure, Sellon, Volckmar, and others. They are able to preserve their charge for several months without much loss by the employment of a series of accumulators and modifying the connections, and by the grouping in quantity or in series are able to obtain varying effects. Generally the grouping is not the same during a period of charge and discharge. Monsieur Planté has designed an apparatus to alter the system of grouping at these times, and M. Hospitalier has rendered it auto matic by a commutator worked by the armature of an electromagnet which effects the same operations. For electric lighting, for instance, the accumulators will be grouped automatically in quantity for charge and in series for discharge. These batteries of M. Planté permit us to make experiments in order to show the analogies which exist between statical and dynamical electricities. If with two Bunsen cells, giving a maximum of 3 volts, we charge 800 Planté couples, we can, connecting these in series, obtain an E.M.F. of about 16 volts, each couple giving about two volts. If with these currents transformed we charge 50 condensers made of plates of mica and foils, we may obtain a discharge of 32,000 volts and several millionths of an ampere, the effects of which will be comparable with those of a statical machine, or we can charge a Leyden jar, and repeat the experiments previously referred to. In order to give more interest to this part of the subject M. Hospitalier made an experiment, by means of which a piece of carbon of 9 mm. diameter was made red hot by means of the current from six Faure-Sellon-Volckmar accumulators. He expatiated upon the contrast between the results obtained before and after transformation. On the one hand we get a current of low electromotive force, and after transformation very high electromotive force. Accumulators are often employed for the regulation of continuous currents. With a variable source it suffices to put the accumulator in a branch circuit; in fact, the uses of accumulators are enormous. We may thus utilise natural forces, storing up the energy, and this application presents a grand field of research. The special properties of accumulators render them superior to direct transport, for which the initial force would not under certain conditions be sufficient, and under other conditions would be far too powerful. Storage facilitated, distribution diminishes the inconvenience of high potentials and counteracts any accidental stoppage of the original source of energy; it permits the employment of the varying forces of nature, such as wind and tides, &c., which may be utilised by having windmills or turbines, &c., likewise continuous force may be utilised to store up energy, which would be utterly inadequate to carry on the work during the short time. Thus Monsieur Menier lights his house with 150 incandescent lamps with a four horse-power gas engine, used to charge accumulators during the day. M Hospitalier then alluded to many other ways in which accumulators could be used with advantage. He concluded by a protest against the use of the terms "static" and "dynamic" electricity, which, he thought, would only confuse electrical students.

Erratum.—Electric Lighting at Terni.—By an unfortunate error the name of the town of *Terni* was misprinted *Turin* in our last week's issue. We shall be glad if our readers will kindly alter Turin to Terni wherever the name occurs on p. 250. Terni is a town some 30 or 40 miles from Rome.

DYNAMO-ELECTRIC GENERATORS.

(CONTINUED FROM PAGE 260.)

DESCRIPTION OF DYNAMOS.

Gramme.

This is so well known that any lengthy description is not necessary; but, after noting the principle of its construction, I wish to consider the theory advanced by the late M. Antoine Breguet, and to advance a new one of my own.

In Figure 4 let R R be a soft ring enveloped by a continuous coil of insulated copper wire, *s s*. Suppose this ring mounted on an axis or spindle, and to be placed between the two poles of a permanent or electro-magnet, P P′. Opposite poles will be set up in the ring. Further, let the outer convolutions of the copper wire be denuded, and let two brushes, *c c*,′ rest in contact with the exposed parts. If the ring be rotated, currents will be induced in the upper and lower parts of the convolutions with reference to the central line A A, which will tend to flow in opposite directions. If the brushes were not in contact, such currents would not really be formed, for the two potentials set up being in opposition, and equal, and the circuit closed, precisely the same conditions would exist as if two equal batteries were joined, like poles to like—that is, in parallel circuit with the open terminal. If, however, the brushes are brought in contact with the denuded parts, and the circuit closed from one to the other, the two halves of the ring convolutions send a current through the external circuit, this current flowing in at one brush, *c*, and out of the other c^1—that is, one point is maintained at a high, and the other at a low potential. It is evident that by this arrangement low electromotive forces only would be

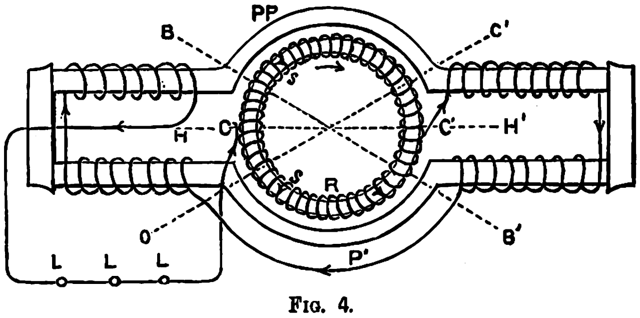

FIG. 4.

obtained, and the wires would soon be worn through. Then, too, if a solid iron ring were used, currents would be set up in the iron tending to heat it very much. To avoid these troubles M. Gramme replaced the iron ring by a hank of iron wire, which had first been drawn through a bituminous compound to cover it with an insulation, and instead of winding a continuous coil he replaced it by a series of coils—that is, the coils are much increased in number, crowded together, and theoretically every *n*th turn denuded. We have then a wire ring strung with a series of flat insulated coils. Then the bights of the coils, the connected ends, are joined to radial plates, and these plates in turn connected with wide strips of copper, there being as many strips as there are coils. The strips are built up into a circular range, which envelops the spindle, and is insulated from it.

The brushes are allowed to rest in contact with the range of copper strips, by means of which electrical contact is made with the external circuit. The contacts are at diametrically opposite points.

As the ring rotates the position of the coils with reference to the middle line and the field magnet poles is changed regularly and continuously, any particular coil passing successively into, through, and out of one field; into, through, and out of the opposite one, thus completing one revolution. There are therefore two changes in the direction of the current in a wire in one revolution. To put it in another way, the poles which are induced in the iron ring constantly shift around in the direction oppposite to the direction of the rotation, and since the shifting of the coils is by units and symmetrical the effort is constant and the current is perfectly continuous. To make a machine as effective as possible the wire of the armature is wound as closely as possible, and the field magnets have the poles extended over a full third or more of the ring, thus bringing a large number of turns, and a great length of wire into a strong magnetic field. On account of the difference of surfaces of the outside and inside of the ring, the inner turns of the wire are much crowded, and the free radiation of the heat developed in ring and coils is prevented. This interference is made even more objectionable by a wooden disc inside the ring.

In practice it is found that, if the brushes resting on the commutator are on the line which divides the field symmetrically, there is very considerable sparking, and to prevent this it is necessary to set the brushes ahead a distance depending upon the strength of field and current, the number of turns of wire, the mass of iron and the velocity of rotation to get the point of least sparking, the *neutral* point. This was formerly attributed to the fact that the iron in the ring did not gain or lose—that is, change its magnetic state instantly; but this explanation not proving satisfactory to account for certain peculiarities developed, M. Breguet conducted experiments, of which I will speak shortly, with a view of explaining not only the shifting of the commutator line, but the action of the iron ring. The Gramme machines seem to be made for certain currents, resistances, and velocities, and the brush holders are therefore fixed at a certain lead. In consequence of this practice, if run under any other conditions than the normal ones, there is much sparking, the commutator blocks and brushes are rapidly burned out, and this can only be partially reduced by changing

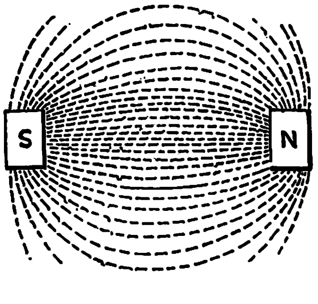

FIG. 5.

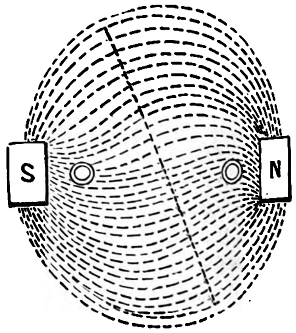

FIG. 6.

the length of a bushy brush—a, to my mind, very unscientific and impracticable way of working. The brushes ought to be compact and mounted on an arm which can be rotated around the spindle. This is a common practice on other machines, and works perfectly. The machine is a very effective one, converting a high percentage of the mechanical into electrical energy. It has, however, the faults already pointed out of an easily heated armature and of fixed brushes. There has been much dispute as to the true function played by the iron ring, it being formerly asserted that the action was the same as if the coils were fixed, and a circular magnet with permanent poles were made to rotate inside and through them.

Breguet's Theory.

With the view of ascertaining not only the truth about the Gramme machine, but about all dynamos, M. Antoine Breguet, a distinguished French physicist, recently deceased, conducted an elaborate series of experiments with various forms of electric machines, from those having but a single bend of wire, with ends dipping in mercury and rotating in front of permanent magnets, to the elaborate mechanical productions of commerce. With regard to the action of the Gramme ring, I will only briefly indicate some of his experimental results, and give the pith of his deductions. In Fig. 5, if N and S are the poles of a magnet, a field will be found between them of fairly regular character, but not very intense unless the poles are quite close. If a mass of iron of any kind be introduced into the field, the character of the field is changed, lines of force converge on the iron, because a line of force travelling through a mass of iron may be considered as shorter than if passing

Digitized by Google

the same distance in air, and lines of force tend to shorten themselves. If, again, a conductor, with a current flowing through, be introduced into the field it will because of its own field, produce a distortion, the magnetic field being attracted or condensed on one side and repulsed on the other. Because of this attraction the conductor, if free to do so, will move, or if, instead of sending a current through it, it be moved through the field, the circuit being complete, a current will be formed in it. The principle of reversibility applies to all generators, which, if a current be passed through them, become motors. The strength of the current, if used as a generator, depends of course on the number of lines cut in a unit of time by a given conductor. If two conductors are used, as in Fig. 6, the current passing up one and down the other, there is a general letter S, or double curve, distortion, and if there are a number of con-

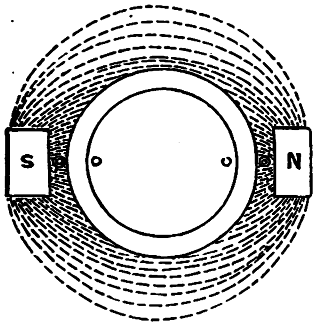

Fig. 7.

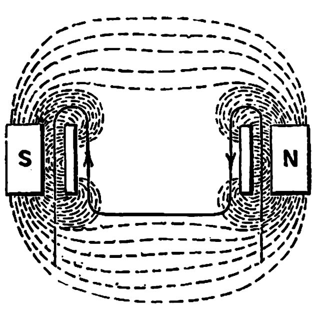

Fig. 8.

ductors this distortion is very marked. If we consider this field thus distorted, it is evident that a rotating conductor will be moving parallel to the lines of force when at a position not at right angles to field-magnet poles, but as shown by the oblique line, and, dealing with this conductor alone, if we are to obtain a continuous current, the connections must be changed when on this line. If, on the other hand, a four-part conductor is used a double distortion is effected, and the rotary effect is that due to the difference of the two, the balance being in favour of the outer coil, because of the longer radius and stronger field. If (Figs. 7 and 9) a ring is introduced in the field, there is a concentration of the lines of force all around, and if the field poles be extended, as in the

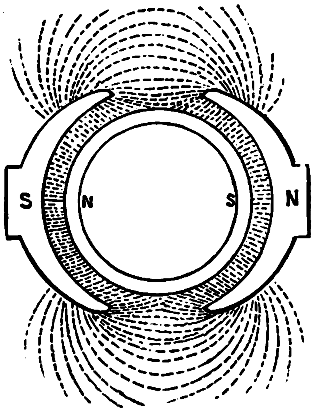

Fig. 9.

latter figure, a powerful field of wide extent is produced. Further, it is to be noticed that there are no lines of force extending across the interior of the ring, and that many lines are concentrated on the edge, and even turned inwards so as to cut the inner turns of wire in a favourable direction; in other words, the ring acts as a *screen* and a *concentrating mass* of iron (Figs. 8 and 9). If this ring be wound with wire, the inner turns (Fig. 8) not only do not act in a retrograde fashion, as in Fig. 3, p. 260, *ante*, but are even partially useful.

To sum up, M. Breguet held that the ring played the part of *concentrator* and of a *screen;* that the displacement of the commutator brushes is due to distortion of the field by the currents in the wires; that such distortion is lessened by the presence of the iron, because of the greater strength of field; that the displacement on account of the retardation of the iron is small—that is, retardation increases the lead if a generator, and lessens it if used as a motor; the machine being run in the same direction, the displacement when used as a generator and as a motor is in opposite directions because of the change of direction in the current, the field remaining of the same character; that the current is generated solely by the passage of the wire through a magnetic field across the lines of force.

Sprague's Theory.

While admitting the careful conduct of his experiment and the force of much of what he says, I cannot fully admit the truth of his deductions concerning the part played by the ring; in short, *it does not act simply as a soft iron ring at rest in a magnetic field.* Let me point out why.

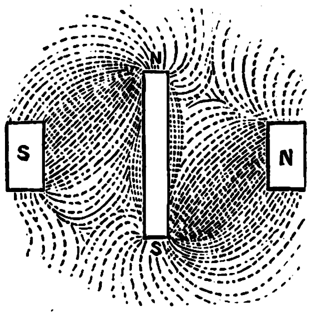

Fig. 10.

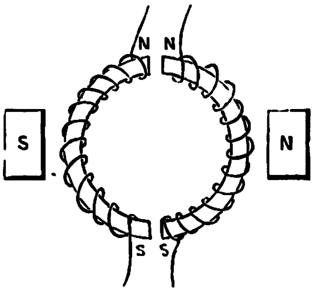

Fig. 11.

In Fig. 10, let a steel magnet, N′ S′, be placed in a magnetic field, just as the soft iron was above. Instead of concentrating the field all along its surface, the field will be much distorted, and in the manner shown, the greatest concentration being between unlike poles. If a semi-circular magnet is made use of, a similar distortion will be apparent, and if two magnets are used, their like poles being connected together, the distortion is still of the same character, and lines of force will be present inside the ring and extending from one of the poles in the ring to the others. There will be a tendency to induce poles at the neutral points of the ring, and if the main poles, N′ S′, are considered as induced by some means in a soft iron ring, which takes the place of the steel ring, then there will be two resultant poles formed at some points between the two single poles.

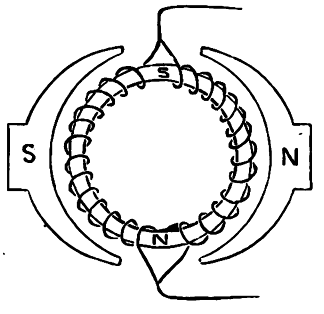

Fig. 12.

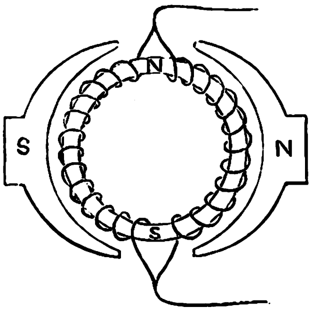

Fig. 13.

Instead of the steel ring we have been considering, let us put a soft iron ring in front of the poles, and induce compound poles at right angles to the induced poles by passing a current around the two halves of the ring in opposite directions, as in Figs. 11 and 12. We then have precisely the conditions we have just supposed, and a distortion which is *also* aided by the convolutions of the wire. If the current is reversed, the field poles remaining constant, the poles in the ring are reversed, as in Fig. 13, and in the two cases there will be a tendency to rotation, and in opposite directions, which tendency is *not alone* that of the mutual action of the current and the field, but *also* of the mutual action of the opposed poles. Now what occurs in practice? Since a current is generated in the coils by their motion in a magnetic field, these currents instantly *convert the ring from a simple soft iron screen into an active electro-magnet, whose poles are at right angles to the induced poles of the field,* and the strength of these poles depends upon the strength of the current flowing. The result is the formation of a compound

Digitized by Google

magnet pole on each side of the ring, and a partial reinforcement and partial neutralisation of the magnetic action. If the generator is used as a *motor* to run in the *same direction* the current in the armature must be reversed, supposing the fields constant, and the distortion is also reversed.

The formation of a "transversal" magnet was pointed out by Pacinotti in the theory of his motor, and it, to my mind, plays an important part in the action of a generator. The "transversal" action and the Breguet theory are intimately associated, and are similar in their results.

(TO BE CONTINUED.)

ELECTRIC LIGHTING FOR WAR PURPOSES.

As we briefly mentioned in last week's "Notes," Aldershot was on Thursday week the scene of an experimental trial of Sautter, Lemonnier, and Co.'s portable electric light apparatus as an aid to the bearer parties whose duty it is to search for the wounded after a battle. The experiments were undertaken at the instigation of Dr. Baron Mundy, the chief of the Viennese Volunteer Society for Saving Life, and the funds were provided by the National Society for Aid to Sick and Wounded in War. The experiments were watched by a number of War Office officials and representatives of the Army Medical Department, Surgeon H. R. O. Cross being specially detailed to report on their success or otherwise. The apparatus was stationed on the brow of Cambridge Hill, and the light was projected on to the slopes of Redan Hill where a supposititious battle had been fought during the day, the result being that many wounded were left on the field. These were represented by soldiers specially told off for the purpose. Here we think that we cannot do better than quote the words of *The Times* reporter. "The demonstration commenced at 9:30 p.m., the night being very dark but starry, with occasional vivid lightning to the south. The bearer column marched out from the field hospital, which was supposed to be established about six miles from Redan Hill, where the imaginary action had just taken place. At a point assumed to be about two miles from Redan Hill, a dressing station was detached from the column. The column then proceeded to within about half a mile (assumed) of the battle-field, where the collecting station was formed with the ambulance waggons of the first line. From this station the bearers advanced to the field with litters to search for the wounded. Here a fine volume of light from the electric lamp very materially assisted them, not only in the search for the wounded, but in applying temporary dressings to the presumed wounds, the nature of which could have been easily ascertained had they existed. Beyond this the concentrated beam would have enabled higher surgical skill to have been brought to bear on the more serious and pressing cases if necessary. The work was very easily performed as an inspection of the numerous little groups dotted over the hill-side showed." Further on, he says:—"Considered as the first one of its kind at Aldershot, and subject only to a brief rehearsal on the previous evening, the demonstration may be considered a success. The light was well thrown on the battle-field, and at times on the collecting station. There were, however, three drawbacks, two of which were probably inevitable from want of time to test carefully the electric light after its transport across the Channel, and to arrange a brief but efficient code of signals. The consequences were that, in the first place, there were occasional short periods of darkness, owing apparently to the regulator of the lamp not acting properly, and, in the second, that the light was more than once directed on the collecting station when it should have been on the battle-field. The third drawback arose from the crowd of sightseers who had assembled from the town, and who at times greatly impeded the work of temporary dressing on the field and hindered the transport of the wounded. The first two of these drawbacks are remedial, while the third could not, of course, arise in practice. With these exceptions the work was very creditably performed. A further question, however, may arise with respect to the transportability of the electric light waggon. It is stated to weigh about three tons, and this is a heavy mass to move about over rough roads, roadless mountains, and sandy or soft soils. Then, again, comes the question of the detrimental action of transport under such conditions upon the comparatively delicate electrical machinery. It is true that the apparatus appears to be strongly constructed and well put together, and, moreover, it may be that the gross weight can be divided up for transport." The *Daily News* correspondent, who has had previous acquaintance with battle-fields, observes that the light was irregular, and points out that the hollows and reverse slopes of the hill, just the places where wounded men crawl when they can move, were left in profounder obscurity because of the intensity of the light falling on this side of them. He speaks, however, in very favourable terms of the experiment, and bestows praise on those who organised and carried it out. These, we may add, are Baron Mundy, Mr. John Furley, who assisted in bringing the apparatus from Paris; Messrs. Sautter, Lemonnier, and Co., its makers; the National Society, who provided the funds; and, lastly, Messrs. Woodhouse and Rawson, the well-known electrical engineers, who looked after and satisfactorily carried out the electrical arrangements. It will be interesting to read what Surgeon Cross has to say on the subject. We trust that there will be no great delay in the publication of his report.

A MINERS' SAFETY LAMP.

The adjudicators for the prize of £500 offered by Mr. Ellis Lever for a new safety lamp have now reported. They are Mr. Thomas Burt, M.P., nominated by the Central Board of the Miners' National Union; Professor Grylls Adams, by the Council of the Royal Society; Sir Frederick Abel, by the Council of the Society of Arts; and Professor Silvanus Thompson by Mr. Lever.

The following is the report:—"The adjudicators had to examine 108 lamps; of these four were electric lamps and 104 oil lamps, of which a few were designed to burn mineral oils. With respect to the electric lamps, there was not one which fulfiled, or approached fulfilment of, the conditions of the award. All the lamps which fulfilled the preliminary requirements were submitted to a series of experiments of progressively increasing severity. These experiments, based upon the experience gained by the Royal Commission, and by experiments instituted by other bodies in this country, were calculated to fulfil even exceptional conditions to which lamps may be exposed in actual practice. While there was a considerable number of lamps which behaved satisfactorily under the normal conditions existing in mine workings, the number was reduced to very few as the extreme tests were reached. Of these there is no one lamp that perfectly fulfils the whole of the conditions enumerated in No. 2, and the adjudicators are consequently unable to make the award to any one of the lamps submitted. Among the best there are two which the adjudicators regard as deserving of special mention—viz., the Marsaut lamp, with three gauzes, which most nearly fulfilled the conditions, and the lamp of Mr. William Morgan, of Pontypridd, South Wales, which presents several good features of marked originality."

Subjoined are the conditions of the prize, which were announced in March, 1883:—

1. The £500 to be invested in the names of three trustees, one of whom shall be Mr. Thomas Burt, M.P., the other two to be chosen by the Central Board of the Miners' National Union.
2. The lamp to be a perfectly self-contained electric lamp, or other lamp, which the working miners can conveniently carry from place to place in the mine, which will continue to give a useful amount of light for not less than 12 hours, and which will not cause an explosion of gas under any circumstances at all likely to represent conditions which may occur in actual practice.
3. The efficiency of the lamps put in for competition to be submitted to five gentlemen, composed as follows:—Three scientists to be named hereafter—one to be selected by Mr. Lever, one by the Council of the Royal Society, and one by the Council of the Society of Arts; one person representing the mining engineers, chosen by themselves, and one person representing the workmen, chosen by the Central Board of the Miners' National Union.
4. The adjudicators to meet in London after the allowed time for sending lamps for competition has elapsed.
5. The prize will not be awarded to any lamp now in use.
6. Not drawings or specifications, but lamps in a condition fit to be tested, must be sent for examination by the adjudicators.
7. The lamps must be sent to 2, Victoria-street, Westminster, London. No lamp to be sent in before 1st December, or none later than 31st December, 1883.
8. If a lamp meeting the requirements herein stated has not been invented, the £500 to revert back to Mr. Ellis Lever.

LEGAL.

The Brush Company v. United States Electric Lighting Company.

An American contemporary says:—"A decision by Judge Shipman was filed a few days ago in the suit of the Brush Company against the United States Electric Lighting Company, which manufactures and uses the Weston apparatus. The suit was upon the two principal patents granted to Charles F. Brush, one for metal-plated carbon points, and the other for an electric arc lamp, which, it was claimed, controlled the entire business of electric arc lighting. Before the argument the plaintiffs withdrew the carbon patent, and Judge Shipman now decides that the lamp patent is invalid and void, and dismisses the bill, with costs, as to both patents."

COMPANIES' MEETINGS & REPORTS.

The Direct United States Cable Company (Limited).

The fourteenth ordinary general meeting of this Company was held at the Cannon-street Hotel, Cannon-street, on Friday, July 25th, 1884, under the presidency of John Pender, Esq., M.P.

Mr. J. W. Fuller (the secretary and traffic manager) read the notice convening the meeting, and the report was taken as read.

The Chairman said: The revenue for the half year to 30th June, after deducting out payments, amounted to £68,573 8s. 11d., and the working and other expenses, including debenture interest and income tax, but exclusive of cost of repairs, absorbed £19,750 2s. 10d., leaving a balance of £48,823 6s. 1d. as the net profit of the half year, making with £3,524 8s. 6d. brought from the previous half year, a total of £52,347 14s. 7d., which has been appropriated as follows: Interim dividend of 5s. per share to 31st March, £15,177 10s.; proposed final dividend of 5s. per share to 30th June, £15,177 10s.; transferred to reserve fund, £19,030 15s. 11d.; final balance of liquidation expenses, £175 10s. 1d.; balance carried forward, £2,786 8s. 7d. This makes the total £52,347 14s. 7d. The revenue shows a decrease of about £2,000 as compared with the corresponding period of 1883. This, as you are aware, is more or less due to the extreme depression which prevails in commercial circles in America at the present time, and in fact in our own country as well. The working expenditure in London and at stations compares as follows with that in the same half of last year, viz.:—The salaries at stations show a reduction of £544, while those in London are £303 higher, the balance of saving on the salary items being thus £241. The items of office expenses and stationery in London, and of petty expenses, repairs, printing and stationery at the stations all show a reduction; but this is slightly counterbalanced by a temporary increase in the cost of maintenance and renewal of instruments, and in travelling expenses, incurred principally by transferring or sending out clerks to Company's stations. These two items are always more or less of a fluctuating nature. The reserve fund, after being charged with £5,127 18s. 9d. (the cost of repairing the short section of cable between Torbay and Rye Beach) and being credited with the interest on the investments and amount transferred from revenue account, shows a balance of £360,000—a net increase of £45,000 for the financial year. The reserve fund investments remain the same as in December last, the slight difference in amount being composed of additional calls on the West of India Portuguese Railway Stock. The uninvested reserve and other moneys remain on deposit at the Company's bankers, in view of the repayment shortly of the Six per Cent. Debenture Loan. The present market value of the Company's investments is about £11,000 more than the figure they stand at in the balance sheet. These are some of the details, which are more fully given than appear in the report, and I believe you will agree with me that upon the whole the report for the last six months may be considered satisfactory. As you are aware, both in America and at home there has been a very extraordinary commercial crisis, particularly in America. A great many men who two years ago, when I was in America, were millionaires are to-day almost penniless. With such changes as these of course telegraphy suffers. It is very different indeed when trade is in the other direction. Profits are made out of almost every transaction—those transactions beginning and very often ending with the telegraph, which, as you can well understand, creates considerable activity. I hope as one extreme begets another we may see a reaction in America, for no doubt when that takes place telegraphy will feel the effects. An important incident in the last six months has been the repairing of our short cable. The cost has been taken from the reserve fund, but we have notwithstanding placed a substantial amount to that fund, and it now stands at a figure with which we have every reason to be satisfied. I may mention that during the last few months I paid, with the traffic manager, a visit to our stations on this side of the water—at Chester, Liverpool, and Ballinskelligs in Ireland—and I am very pleased to say—it was my first visit to the stations—that I found everything in a most satisfactory state. The young men are all very well housed, and are living on the premises, and the business is conducted in a thoroughly satisfactory way. I spent one day there testing our cables. It is not a particularly lively place, because you are very much out of the world there. Well, I thought I might spend a couple of hours pleasantly by carrying on a conversation by cable with Dr. Green, the president of the Western Union Company of America. There was nothing doing on the line, but of course our young men were ready for any business that presented itself. I kept up a very pleasant talk for two hours with Dr. Green in New York, very much in the same way as if I had been carrying on a conversation with that gentleman in this room. It proved to me how thoroughly satisfactory our cable was, not only as to speed, but also as to accuracy; and when I came to look to the amount of matter that passed over the wires in those two hours, I was astounded. We talked about the crisis in America and its effect on telegraphy, and also about the future, and what would probably occur by and by when the new cables were opened, and the marvellous accuracy and quickness with which all this was conducted would have struck any stranger with surprise, as it indeed did me, though I am Chairman of the Company. But quick and rapid as the system seems to be now, such is the progress of electrical science that I have no doubt at all before very long we may find that the present speed is materially increased. I believe, at the present moment there are experiments going on which may lead to a most material increase in speed. When I last addressed you I spoke rather at length. I went into the history pretty much of this Company and the history of submarine telegraphy in the Atlantic generally, and I referred to the coming competition—that is, the competition which is about to take place with the Mackay and Bennett cables. Well, gentlemen, on this subject I have very little to say to-day. One of those cables has been laid. They expect to lay another, I believe, within two months; and I am told that until after the second cable is laid the competition is not likely to arise. All I can say is that when it does arise we shall be prepared to meet it in such a spirit as will protect your interests. I have no idea of throwing away money if we can save it, but our policy will be guided very much by the policy which the competing company may act upon. In regard to the competition, when it does arise there is one thing which I think I may safely say, and that is that we have got experience; we have also got in our combination eight cables, and whoever can do the work quickest and best is likely to get the greater share of the traffic. In commerce there is very little sentiment. Every man knows best what suits his own interest, and sentiment is a thing that he never pays for. He will employ those who do his work best, and I feel satisfied, knowing what we have to compete with, and knowing the experience of those who have to deal with the existing system, that if we do not get our full share, and probably more than our full share of the traffic, we should not be doing our duty. There is another point I may mention, and that is that the present cables are equal to a very much greater amount of traffic than we have got. Mr. Bennett has frequently stated that he is indifferent about outside traffic, as he can pretty well employ those cables for his own press purposes. That may be an advantage, and a very considerable advantage for us. There is very great competition among the press in America, and and they will not let Mr. Bennett have his columns filled with English news without doing the same. And I therefore look upon it in this light—that the newspapers are not likely to send their press messages by such a formidable opponent in the press as Mr. Bennett, of the *New York Herald* is. Therefore, I think Mr. Bennett's action in that respect will contribute very largely to the number of the press messages we are likely to receive. However, as I said before, a few months will tell more than any prophecy of mine will do. I may mention, however, that from what I learn Mr. Mackay is a man of very considerable business ability, and that he understands exactly what he is about. I am told that he has given one of his officials the grand title of Director-General, and has taken upon himself the more humble designation of manager of the company. I believe that in Mr. Mackay, while we shall have an active and energetic opponent, we shall have a man of business, who will meet us on fair ground, and that is the class of men I like to fight in a contest of this kind. There is another important point I wish to refer to, which I think met with the great approval of the shareholders at the last meeting, namely, that we are going to pay off our £100,000 of debentures, and take it from the reserve fund, still leaving a very handsome reserve. Instead of taking £100,000 out of the reserve fund, that being the amount that we have to pay off, I believe we shall only require to sell out something like £70,000 of the reserve fund, and that we shall be able to make up the balance of £30,000 out of our floating reserves. That is a point which I think upon the whole is very satisfactory. I think I have pretty well exhausted all the points to which it is desirable to draw your attention. I am reminded that by paying this £100,000 off it is a saving of £6,000 a year to us. Besides that it places us in a more sound financial position. As to our policy with respect to the future, as I stated, I shall be able to tell you more six months hence; but that policy will always be based upon strengthening as far as we can and maintaining as much as we possibly can the financial position of the Company. With these remarks I beg to move the following resolution:—"That the report of the directors, dated the 16th July, 1884, together with the statement of acounts to the 30th June, 1884, annexed thereto, be and the same are hereby adopted, and that a final dividend be now declared of 5s. per share, free of income-tax, making with the interim dividends already paid a total dividend of 5 per cent. for the year ending 30th June, 1884."

Mr. Wm. Ford: I beg to second the resolution.

The Chairman: Before I put that resolution, if any gentleman at our meeting desires to put any question to me on the report or on the remarks which I have made, I shall only be too happy to answer him to the best of my ability.

Mr. Jackson: If I might occupy your time I should like to ask a question. But before doing so I should like to express as an original shareholder my great satisfaction at the present report. For seven years we have received a steady 5 per cent. dividend, and have accumulated a very handsome reserve fund. I was very glad to hear from you that in your opinion it was not impolitic to reduce the renewal fund, and the saving of £6,000 a year, which is the amount which will accrue to the Company, is more than would cover the expenses of the half-year's payment to the Anglo Company. I think the shareholders of this Company ought to be eminently satisfied at the financial results of the working of this Company, for the parent Company—if so it may be called—is paying its

Digitized by Google

shareholders, or rather it shows a bare 3 per cent. returned, and a very large proportion of its capital is deferred stock. That stock represents 30 per cent. of the total capital of the Company, and they have only paid ½ per cent. on that for the last two years. It must be eminently satisfactory to us, I think, to find that we, who are only an auxiliary as it were, should have received in the face of these facts such a handsome dividend for so long a time, and I think that the shareholders have you and the Board to thank very much for conducting their affairs with such highly satisfactory results. You have assured us that this reduction of the renewal fund is a perfectly safe course. I think that is a very important feature, because outside there is a very general opinion, and I believe a well justified opinion, that a renewal fund is the backbone of a deep sea telegraph company. There is one other question I wish to ask—Why should not the United Companies offer to carry deferred telegrams at a reduced price? I do not presume to do any more than offer a suggestion. I hope you will give us some reply, as your great experience would enable you to say if it were possible.

Mr. JOHN NEWTON: At the last meeting I raised the question of dividing our shares into £10 shares. I mentioned then that it was astonishing to me that our shares should stand no better than they do in comparison with those of every other telegraph company who are not doing better for their proprietors. I think if you made our £20 shares into £10, so that we could compare the price with others in the price list, we should see better how they stand in the comparison, just as we do in in the case of the Eastern and the Eastern Extension Companies. I also hold that one-tenth is better that one-fifth in the matter of these calculations. It strikes me the position of the Company is not fairly represented by the Stock Exchange prices. When you contemplate what it costs to lay a cable from England to America, to establish stations and get together a business, it seems marvellous that our property should stand at the price it does. I think the question of making our shares the same as all the others is well worthy of your consideration.

The CHAIRMAN: I have great pleasure in replying to any suggestion or remarks from Mr. Jackson or Mr. Newton. In the first place Mr. Jackson put the question, and I think put it very properly, do we in any way endanger the position of the Company by reducing our reserve fund by this £100,000? I do not think we do, and for this reason. As you are aware, although we are a single cable—and I do not think this is always considered—we have the guarantee of seven other cables for twelve months—that is, we could not lose much in our income for twelve months, and during that period we have time to make our arrangements for repairs. We are taking up cables now from the bottom of the Mediterranean and the Atlantic, and every year convinces me more that the life of a cable is likely to be a much more prolonged one than we thought a few years ago. As I said now, by paying off this £100,000, we only take £70,000 from the reserve fund, and we save £6,000 a year. Well, that in a few years makes up very soon a considerable amount with the extra value of our investments After taking away this amount from the reserve fund, it would still stand at over £300,000. That is a very handsome reserve. By this reduction of £100,000 we place ourselves altogether in a better position. If our cable broke, and we had £100,000 debentures out, we should have to pay, if we wanted more debentures, very much more interest than if we had no debentures at all. That is a very important point, and I am quite satisfied we shall strengthen our financial position by wiping off that £100,000. I think I have shown you that although we are a single cable we are uncommonly well backed, and that that backing is worth a considerable amount to the Anglo-American. When the bargain was made I think it was pretty well understood that we got a very fair share of the traffic at that particular time. Mr. Jackson has made a point which, I must say, has very often struck me—that is, that telegraphy has not made the leaps and bounds that it did in its early stages; but I must tell you that submarine telegraphy is at the cheapest an expensive luxury in business. It is rarely taken up in social life, and consequently upon the growth of trade in a great measure depends the growth of telegraphy. We are passing through very dull times, and times which I hope will not continue for ever. But there is this advantage that we have. If some people say trade is going to leave this country, it is going to other countries; and such is the ramification of the submarine telegraph system now, that if we lose at one point we shall gain at another, because, whatever is produced in a distant country is not kept for the consumption of its particular inhabitants, but is scattered all over the world, and it is through the submarine telegraph system that this scattering takes place. If we could enlist something in the way of social telegraphy, as Mr. Jackson has hinted, no doubt it would materially increase our traffic. But you must bear in mind this important point, that submarine telegraphy is not like land telegraphy. We can only carry a certain number of messages upon a submarine cable. When we get at that point, if the money we can make out of those messages does not pay us, then it becomes a loss. We cannot extend as we would upon a railway, where you can put down an extra rail. We can only run so many words in a minute, and if that number does not give us a return it is no use working at a loss. I may also say that we had tested the shilling rate and the sixpenny rate upon submarine cables, and it is a remarkable fact at the shilling rate we only got something after a year's trial like 30 per cent. increase in traffic. That 30 per cent. left a very serious loss indeed upon the working of the cable. If we were paying handsome dividends we might experiment a little, but as we are paying what I consider a very moderate dividend indeed, we must protect the shareholders first before we deal with the general public. With regard to Mr. Jackson's suggestion, however, I have some ideas in my head which I hope will be carried out by and by. But probably it would not be very safe to say very much about that at the present time. I do think, however, that we may make some attempt by and by to try and tap the social system. This is a point that will be fully considered, and if we can do it it will be done. I may add that probably, as competition goes on very actively, we may reduce our rates, but that is a prophecy which I do not say much about now. As to reducing the denomination of the shares, the Board have given that question their full consideration. It cuts both ways. It is true that our shares are now £20, and if we reduced them to £10 of course they would stand in the market a little above £5. That is a very great discrepancy, and it is not a position which our shares are at present entitled to occupy, because I consider the shares of this Company a really valuable and great property. But which would have the greatest effect on the investor? It is a question to me whether the shares are not better at the present moment to stand at £10 or £11 than at £5 or £6. I think the investor is a little more inclined to go in a little over par rather than a little under par. We have, however, considered this point, and I do not think at the present moment it would do the good that Mr. Newton believes it would do in the way of increasing the value of the shares. If we saw it in a light that it would benefit us in any way, by increasing the value of the property, we would do it. Although this is our present view of this question it is a matter which still admits of consideration, and we may possibly by and by change our opinion.

He then put the resolution in the usual manner, and declared it carried unanimously.

Continuing, the CHAIRMAN moved the re-election of Mr. Wm. Ford as a director.

Mr. E. M. UNDERDOWN seconded the motion, which was carried unanimously.

The CHAIRMAN next moved the re-election of Mr. C. J. Gunther to his seat at the Board.

Lord HAWKE seconded the motion, which was carried unanimously.

Mr. JACKSON proposed the re-election as auditors for the ensuing year of Messrs. John George Griffiths and John Sawyer. Those gentlemen, he observed, represent our interests, and I have much pleasure in proposing their re-election. I think the results of the working of the Company afford satisfactory evidence that their audit is a good one.

Mr. VARLEY seconded the motion, which was carried unanimously.

The CHAIRMAN having intimated that that closed the business of the meeting,

Mr. VARLEY said: I have great pleasure in proposing a vote of thanks to the Chairman and the Board for the very admirable manner in which they have conducted this Company's business. I also, like the Chairman, look on these shares as a very splendid investment at the price, and I only wish that some of the shareholders would do what a relative of mine has done—purchase some shares, borrowing the money at 3 per cent. to do it, and he has very nearly paid the loan out of the investment.

A SHAREHOLDER seconded the motion, which was carried unanimously.

The CHAIRMAN: I have very great pleasure in returning thanks for the compliment which you have paid us in thanking us for our good management of the Company. I have also to thank you, especially as Mr. Ford requests me to do so on his behalf and on behalf of Mr. Gunther, who is absent. As I have said, your Board's first consideration is the interest of the Company. We have known it in adversity, we have plucked it in some measure from the fire, and I think none of us, either on this side or that side of the table, have any reason to regret the action that was taken. The Company now holds a very good position. I believe it to be a very sound investment and, believing as I do that telegraphy must grow, I do not see why we should not grow with it.

The proceedings then terminated.

Globe Telegraph and Trust Company, Limited.

The eleventh ordinary general meeting of this Company was held on Tuesday July 29th, at the City Terminus Hotel, Cannon-street, under the presidency of John Pender, Esq., M.P.

The SECRETARY (Mr. Wm. Payton) read the notice convening the meeting, and the minutes of the last meeting. The report of the directors was taken as read.

The CHAIRMAN: Before I ask you to approve of the report, I shall give you a few particulars of the incidents of the last twelve months' working which do not appear in the report. As you observe, we pay this year the same dividend as last—namely, £4 15s. per cent. on the ordinary shares, which with £6 on the preference shares, is equal to a dividend on the combined stocks of £5 7s. 6d. per annum. As regards the revenue, you find that there is a falling off in the dividend of the Anglo-American Company—on their preferred stock—during our financial year of ½ per cent., which is equal to £1,546. This, however, they have made up by their last dividend. The Brazilian Submarine Company has also paid 1 per cent. less—6 per cent. as against 7 per cent. in the previous year. This has arisen from an unfortunate break they had, which represents a difference of £2,548 to this Company. The Indo-European Company also paid 1 per cent. less—8 per cent. as against 9 per cent.—representing £1,172, the higher dividend of the previous year being attributable to the interruption of other lines. Some other companies in which we have but a small interest also paid lesser dividends, making a difference of £5,500 in all. Against these items, however, may be placed what the Eastern Company have paid—½ per cent. more, or 7 per cent., as against 6½ per cent., equal to £7,895—and this has enabled our Company not only to maintain our position as compared with the previous year, but to carry forward a larger balance, as the accounts show—£2,088 this year against £1,375 last year. The items of expenditure on revenue account are a trifle less than last year. Our proprietary is increasing. We have now 7,000 shareholders, being 500 more than last time, and as you are aware, this entails, as we pay quarterly dividends, a considerable amount of outgoings for stamps, &c. The report explains that we have been able during the past financial year to free the Company from a liability on capital account in respect of the Eastern Extension Company's shares for which we stood as creditors to the extent of £130,130 in our last balance-sheet. We accepted an offer for the issue of an equal number of our own shares, preference and ordi-

Digitized by Google

nary, in combination, and we have transferred 3,182 of the Extension Company's shares. This gives us now a clean position. In issuing our Globe shares we have to deal with them according to the market value, and while the preference shares are at a premium the ordinaries are at a discount, although at the present market price the ordinary shares pay 6⅝ per cent. The discount on the total issue has to be added to the cost of the shares. This transaction was a fortunate one for that company. The Company has now been in operation for eleven years, and at this first meeting of our second decade we take with advantage a retrospect of your position, and it will show, I think, that no class of shareholder who bought his interest in the Globe Company has, if he calculates interest and dividend, any cause to regret it. I have just referred to the time of the formation of the Company. When this Company was formed the Anglo-American Company was paying 8 per cent., and we took over their stock at 152. The difference in value is a very material and a very serious one to-day. The Atlantic seems to have been a very favourable channel for investing money, and even now we are likely to meet—that is, the telegraph companies—still further competition. How that may end it is very difficult to say. The public, no doubt, will derive a certain advantage for the moment, but whether they will derive it in the long run it is difficult to say. There is a steady progress in telegraphy, and that steady progress has perhaps more rapidly developed in the Atlantic, more particularly when trade is active on the other side of the Atlantic, and on this side it is marvellous the progress it makes. Meantime it is all depression, and those who are now coming into the contest will find that it is no light venture that they have entered upon. Those in possession are likely, from their great experience and the number of cables at their command, to do the work so much better than any new competitors, and I am quite certain that their proportion will always be the largest proportion as compared with their competitors. I may mention also that the French stock was taken at £36 10s. The change there is also very striking, but, at the same time, we have maintained our dividend very fairly to you, from the fact that the Eastern and the Eastern Extension shares, which were taken at share for share, also the German Union, are now paying advanced dividends—not only paying dividends, but the value of the stock is very largely improved. The Brazilian Submarine Company are now, we may say, in a very sound and safe position. Any company with duplicate cables is likely to keep up continuous earnings. I believe that the loss alone during the time the Brazilian Submarine Company's cable was broken down, and before they got duplicate cables established, amounted to over £30,000. That is a very large item out of the dividend for a year. That is now, I hope, at an end, because the Brazilian Submarine Company has duplicated its system, and in that Company we are large shareholders. I need say very little with regard to these American cables at the present time, but I may say, as to our Eastern system, that it seems to me that we may expect a fair progress there. We have always been ready not only to meet the requirements of the Government—I speak of the Eastern and the Eastern Extension Companies—but it has been done in a way to command the approval of the Government, and I think also the approval of the telegraphing public, and with rather an advantage than otherwise to the shareholders of those respective companies. As you know, we are entirely dependent on the good management of those submarine telegraph companies, but speaking from a thorough knowledge of them, I have no hesitation in saying that the Boards of those companies are quite alive to the changes that are taking place from time to time, and from their great experience and general knowledge know how to meet every difficulty. I think their prospects are such that, apart altogether from American competition, we shall be able to maintain a fair dividend arising out of those other companies. Now, gentlemen, with these remarks I beg to propose "That the report and accounts for the year ended 18th July, 1884, submitted to this meeting, be and they are hereby received and adopted, and that a dividend be now declared payable after this day of 3s. per share on the preference shares, making, with previous quarterly payments, a total dividend for the year of 6 per cent. on the preference shares, and 3s. 6d. per share on the ordinary shares, making, with previous distributions, a total payment for the same period of 4⅞ per cent."

Sir Daniel Gooch, Bart., M.P., seconded the motion, which was at once carried unanimously.

On the motion of the Chairman, seconded by Mr. H. D. Gooch, Mr. Wm. Ford was re-elected a director.

The Chairman next moved, and Sir James Anderson seconded, the re-election of Sir Daniel Gooch, Bart., M.P., to his seat at the Board, and the motion was carried unanimously.

On the motion of Mr. Burnham, seconded by Mr. John Newton, the auditors, Mr. John Griffiths, F.C.A. (Messrs. Deloitte, Dever, Griffiths and Co.), and Mr. W. Griffith, B.A., were re-appointed.

Mr. Heiron next proposed a vote of thanks to the chairman and directors.

Mr. W. Griffith, B.A., seconded the motion, observing that their position was all that they could desire. They had reason to believe that everything was going on as it ought to do, and he found that the public at large were approving of the Company, and that it was rising in favour.

The motion was carried unanimously.

The Chairman: I beg to thank you on behalf of my colleagues sitting at this Board. I have limited my remarks to-day, because within the last few days important meetings have been held of some of our submarine companies at which there has been a greater amount of detail. There is nothing which has not been more or less highly satisfactory, and as you know we are dependent on those companies, and the management of those companies is very much in the hands of those who are sitting at this Board, and I am satisfied without having gone into greater detail our affairs throughout the year have been on the whole satisfactorily, and I see no reason why that ought not to continue.

The Consolidated Telephone Construction and Maintenance Company (Limited).

An adjourned meeting of the shareholders of this Company was held at the Cannon-street Hotel, on Friday last, to receive the report of the committee of investigation appointed by the shareholders at the ordinary general meeting of the Company held on the 23rd May, 1881. Mr. Charles L. W. FitzGerald, chairman of the committee, presided.

The Secretary (Mr. C. Curtoys) read the notice convening the meeting. The report of the committee, and the circulars issued by Colonel Gouraud, the Hon. Howard Spensley, and Mr. P. Carnegy, in answer thereto, were taken as read.

The Chairman then addressed the meeting at great length on the various documents which had been circulated amongst the shareholders. He began by saying that the committee of investigation had decided to accept the resignation of Colonel Gouraud from the Board of the Consolidated Company. He had written to that gentleman on the subject, and requested him to send in his resignation in writing. Colonel Gouraud had, however, failed to do so, for reasons best known to himself. He wished to make a few remarks on Colonel Gouraud's reply to the report. First, as to the allotment of shares. He found, from a minute of the 22nd April, 1881, that 15,000 shares were allotted to Sir Julius Vogel, 15,000 to Colonel Gouraud, 2,500 to Mr. Patrick Carnegy, and 2,500 to Sir Alexander Armstrong. He now understood that a great proportion of those shares were allotted to the various directors' nominees. The next remark he wished to make on the document in question was concerning the 95,000 shares held by Colonel Gouraud in the Edison-Gower-Bell Company, which he also copied from the official register. He discovered from the minutes that 175,000 shares were allotted as follows:—T. A. Edison 72,000, Colonel Gouraud 95,000, Mr. Bigelow 4,000, and Mr. Bell 4,000. The next thing that he need allude to was that Colonel Gouraud said he was not a director at the date of the formation of the Edison-Gower-Bell Company. Colonel Gouraud resigned on the 11th of August, and he (the Chairman) found from a minute that on the 10th of August there was a letter read from Colonel Gouraud dated the 5th of August, which showed that negotiations were commenced with the Edison-Gower-Bell Company, which he thought was cutting it rather fine. He would allude to Messrs. Spensley and Carnegy's remarks as he went on with his speech. The moment he saw that allotment he said to himself, "That is the downfall of this Company." He would not trouble the meeting with references to the fresh issue of capital. They all knew about that, and where the money went. As to the 4,000 telephone contract, he could only say that it was to his mind a most mysterious business. In plain English they, as shareholders of the Consolidated Company, paid Mr. Gower a very large sum of money for that contract. Mr. Gower of course handed on that contract to them, it might be in perfect good faith, and when their directors on the 7th October got uneasy about the gentlemen who contracted to take those telephones they began to press them, and when they did so they discovered that they could not get the telephones taken up. This went on, as they would see by the report, until the 14th of July, when the Board decided to issue a writ against Messrs. Biglow, Cargill, and Colonel Gouraud, and they did issue that writ; but they repented, and there was no record whatever to show what induced the directors to change their mind. He would like to hear from Mr. Carnegy what induced him to change his mind, and he would also like Colonel Gouraud to state why he could not fulfil the contract, because it appeared to him that they were perfectly ready to make the telephones and get a profit on them. These were points which ought to be cleared up. Speaking roughly, he was told that they had paid Mr. Gower between £25,000 and £30,000 for that contract, and they received back to compromise matters only £6,800 cash, which he could not regard as a very good bargain. The Chairman here read the resolutions come to in regard to the settlement on the 18th and 25th of August, and said that he would like to go a little deeper into the subject of the contract from a legal point of view. He need not say much about the Oriental patents. He did not know whether the shareholders understood the "very delicate and complicated character" of the contract which the Board could not see their way to carry out or enforce. He now came to the Edison-Gower-Bell Company. They knew that Sir Julius Vogel made that extraordinary agreement. Colonel Gouraud was on the opposition then, and he must give that gentleman the credit for having got very much the best of the bargain. The agreement was made in Paris. Colonel Gouraud was there, and so also was Sir Julius Vogel as well as others, but he did not know who they were. Perhaps Colonel Gourand could tell.

Colonel Gouraud said he was listening attentively, and would reply to everything touched on.

The Chairman characterised that agreement as something "too dreadful" to contemplate, and read the resolution from the minute book bearing on the subject, remarking that he had asked the Board of the Edison-Gower-Bell Company to give him a statament of what they considered their rights in those properties, and he was sorry to say that he had not received a reply.

Colonel Gouraud wished to call attention to a reply made on the day before the receipt of the Chairman's letter.

The Chairman said he had never seen the letter referred to.

Colonel Gouraud: That must be the fault of the secretary.

The Chairman said he would now pass on to a much pleasanter subject—the United Telephone Company. Provided people came for telephones more than they were doing, that business could be made to pay. That people would by and by apply for telephones was a certainty, but at present the business was not sufficient to make the factory a paying concern from that one particular source. He should here remind them that they did not buy the patent absolutely from Mr. Gower. They had paid

Digitized by Google

that gentleman a sum of money, and they held the Gower patent for the United Kingdom in trust for the United Telephone Company. They were not the absolute possessors of the patent.

A SHAREHOLDER: Have you no interest in it?

The CHAIRMAN replied that they had an interest as long as their agreement lasted with the United Telephone Company. They would also see that the United Telephone Company paid them £25,000 if they terminated the agreement. He now came to the manufacturing account, which was a very difficult subject. He had been in his present position only for two months, and the business of the Company when he first looked into it seemed to be in a very bad way. He did not mind telling them that it was looking better now, and that they were doing a good deal of work. He went to the works every morning at 8 o'clock, and they had got a man there who told him that he would make the business pay. His own impression was that it could be made to pay a little, though not very much at present. The debts, according to the report, were £3,180. He did not know how he had done it, but he had managed to reduce that amount to £2,400. The accountants told him that he had made a mistake in saying that the sales showed a loss of £6,253 for 1884. He was very glad to hear it. He hoped he had made the mistake. It would be far more satisfactory to him to know that they were making a profit and not a loss. He ought also to say that Mr. Griffiths at the outset of the Company made Sir Julius Vogel put on one side £6,000 to meet some questionable profit. That was a very important point in favour of the auditor.

A SHAREHOLDER: What to meet?

The CHAIRMAN: Some doubtful profit. Sir Julius Vogel wanted to divide the profits all at once. As to the issue of fresh capital, he thought it would have been far better if the directors had taken the shareholders into their confidence, and told them the exact position of their affairs, because he really thought the business was a fairly good one, as far as he could judge; and if they had gone to the shareholders, and said, "We can make a profit on the Austrian concession and the River Plate, and we can see our way not to lose money on the manufactory," they would have said, "All right, gentlemen, we will give you money; go on." If he had been a shareholder he would certainly have said so. It seemed to him that the joint account was a very unfair one to their Company. And as to the Oriental Company, the explanation of Messrs. Spensley and Carnegy, "that that Company stipulated at the outset that no payment should be made by the Oriental Company to the Consolidated Company for goods supplied until payment was received by them," seemed a peculiar arrangement; because, suppose the goods were kept hanging about unsold for years, and they did not get payment for those goods, the Oriental Company were not to pay the Consolidated Company any money at all. His idea was that they should try and arrange with the Oriental to work on a system of royalties. It seemed to be a much fairer way of doing business. Sir Julius Vogel was quite right to ask for money to go out to Australia, but he thought that that gentleman might have waited for profits before taking the second £250, a sum which he thought the Company was justified in demanding back. Mr. Power's commission had been already explained. As to the Articles of Association, he thought they ought to be revised [Col. GOURAUD: "Hear, hear."]. He said that with regard to all the companies, because their articles were very nearly all the same. As to the capital account, he thought it must be reduced. He saw no way out of that at all. They had not sufficient assets to represent their capital, and, as they were aware, even if they made a dividend it could not be declared while that was the case. He also suggested that an able accountant of the name of Mackay should be asked to go through all the books, and see whether the Company could claim any money from anybody. Seeing the magnitude of the solicitors' bills (which he personally had not yet examined), he recommended that they also should be closely scrutinised. On page 13 the committee placed before them a table of the possible dividends to be divided during the period ensuing from that date to July, 1885. He saw no reason to doubt that the table would prove a correct one if the figures that had been given to him were accurate, and if his suggestions were carried out as to pushing the Austrian business. He had gone into the River Plate business, and it seemed to him to be a good one. The fact was, as he stated on page 15 of the report, that, combining £33,650 amount of shares issued, and the £28,000 debt due to the Consolidated, the amount earned last year was about 11 per cent. net on the £61,650. He thought there were a good many of them who would like to earn that on their business. The only other remark he wished to make in this connection was as to the expenses. The directors' fees were £1,117, office charges £759, law expenditure £147, and interest £473. Now that seemed to be a very high figure for directors' fees, and after all said and done the business was not managed in London, but in the River Plate. Concerning the Edison-Gower-Bell Company, about which he had not said much, he did not know whether the following suggestion would meet the approval of the shareholders. As that company had apparently put into the business only a few hundreds for the Portuguese concession, and the Consolidated had provided £15,000 as working capital, giving the Edison-Gower-Bell Company credit for three years for a further sum of £10,000, it occurred to him that they should demand from the Edison-Gower-Bell Company debentures for that £15,000, or failing that, let the Edison interest put in £25,000, and let them go on and work that business and push it in Portugal. The Consolidated should have bills for that indebtedness. We have got them. The exchanges were working at a profit, small as they were. They had only 600 subscribers, and if they absolutely owned the business, and there were no London expenses, it would return them 9 per cent. They now came to the Austrian concession, which, after all said and done, was what brought about the crisis. When they first joined the Board there was a terrible personage of the name of Wessely, with a formidable account to settle amounting to £10,000, and they had about £100 to settle it with, and the original Board seemed very much alarmed at Mr. Wessely coming forward with his claim. Well, he liked to face things, and he said, "Let Mr. Wessely send in his account." After some little pressing that gentleman came over to London, and he found him a very nice person indeed, and solely actuated in trying to get the Austrian business to a paying basis. Their manager, Mr. Krause, came with him. Mr. Krause's accounts were kept in the most perfect manner, and he (the Chairman) believed if they put money into the Austrian business it was possible it would some day pay better than the River Plate. Colonel Gouraud went to Austria. He had made a long statement about that which he (the Chairman) could not understand at the time, namely, about "limiting liabilities," and so on. But it was a most extraordinary thing, when he came to go into the matter, he found that Colonel Gouraud, instead of limiting liabilities, incurred a further burden by taking over four more small towns, which had caused him (the speaker) no small anxiety, because he could not see his way how those towns could be made to pay, having in them under a population of 60,000 each. Colonel Gouraud, in fact, made the Company pay £2,500, besides a sum in caution money for the arrangement. Altogether, they had spent about £5,000 on those small towns. He believed, however, from what Mr. Krause told him that they might ultimately be made to pay. He had gone closely into Mr. Krause's statement, and it seemed that there were a certain number of people waiting for telephones to be put up. Well, he could only say that as soon as he could send out those telephones those people would pay a subscription of £7 per telephone. Therefore it was clearly to the interest of the shareholders that the instruments should be despatched to that part of the Continent as quickly as possible. That was one of the reasons why he wished them to buy the River Plate shares to provide the working capital. To show them how good telephone business was, he might mention that of the nine towns where they had the concession three of them were absolutely at the present moment supporting the working expenses of the other six. Well, now he would tell them what was done in the case of Mr. Wessely's claim. On going through that gentleman's account it was found that there was about £7,300 owing to him by the Company.

A SHAREHOLDER: For what?

The CHAIRMAN replied that it was on account of wires and installations erected in the various towns. In other words, Mr. Wessely had spent money on account of the Consolidated Company, which the shareholders had to find, while the Company had a debt owing to them by the Austrian Company of about £24,800. Well, they agreed together that they would take debentures of the Austrian Company for the amounts, Mr. Wessely to receive £7,500, and the Consolidated Company £25,500. To his mind that was the most satisfactory arrangement they could possibly make, because by some peculiar arrangement there was a clause in the agreement by which the Consolidated could not wind up the Austrian Company, or at any rate the clause would have rendered it exceedingly difficult to do so. After having heard what Mr. Wessely had to say on the subject, it was thought far better in the Company's interests not to attempt to wind it up; and for this reason, that they had been so delayed in going on with the business in Austria that it was a question whether the Austrian Government would not have forfeited the concession, and taken it from the Company. They therefore accepted those debentures, and determined to send out more telephones to put the various stations on a paying basis. The reforms he proposed were the greatest economy in working, and the ordering of fresh stores only as they were required to fulfil contracts. When he arrived at the factory he found to his intense surprise a great pile of stores of all sorts which had accumulated for he did not know how long. That was not his idea of carrying on business. Some of those stores he had been able to utilise. The next thing he would propose was that there should be a reduction of directors' fees on all the Boards of the companies, and that there should be three directors on the River Plate Company, three on the Austrian Company, and three on the Edison-Gower-Bell Company, and that those nine directors should constitute the Board of the Consolidated. He knew perfectly well that three directors could do the business of those companies abroad. If any very difficult question cropped up it could be decided by the nine directors of the Consolidated Company. He then pointed out that under the Articles of Association the River Plate Company was pledged to pay to its directors £1,200; the Austrian Company, £1,200; the Chairman of the Edison-Gower-Bell, £250; and whatever the shareholders chose to give to the directors; and the Consolidated, £2,000, making in all £4,670. Those amounts he proposed to reduce as follows:—The River Plate, £500; Austrian, £500; the Edison-Gower-Bell, £300; and the Consolidated Company, £1,500, making a total of £2,800 for directors' fees. He would detain them but for a minute or two more to call attention to the Edison Gower-Bell balance-sheet. There was a certain £1,000 there which he had not got a satisfactory explanation about. Messsrs. Spensley and Carnegy alluded to it, but their statement was not convincing. He found that there was a further sum of £833 on account of the Italian expenses. He had gone into that and discovered that the items for that were, for goods sent to Italy, £169; for goods sent to Rome, £217; and Italian caution money, £493. What was the explanation? Why did they send goods to Italy, and why did they pay caution money? There might be a satisfactory explanation, but it had not been forthcoming. They would see also that there were very heavy expenses in connection with the European Telephone Company—£3,380. They would hardly believe that that was spent in advertising. He thought he saw his way to put the Austrian business into a paying condition. He had told them also that the River Plate was paying, and that the Edison-Gower-Bell would return, he believed, with reduced expenses, a small sum of money. But they must have funds from some source or other, and it occurred to him that the way to

Digitized by Google

meet the difficulty was that the shareholders should come forward and take up some of the River Plate shares. He was perfectly ready, as well as his friends on the committee, to take up their fair proportion. Personally, he was willing to take 100 of them. A report of the meeting would be sent to the shareholders, with an application form for River Plate shares, and he hoped it would meet with a generous response. He concluded by moving "That this meeting adopt the report of the committee of investigation, and authorise the expenditure incurred in legal expenses, printing and otherwise, in connection with the committee of investigation."

Mr. BUCKINGHAM seconded the motion, and bore testimony to the zeal of Mr. FitzGerald in his efforts to place before the shareholders the real position of the Company. Although they might not all clearly understand the report, it was evident that there had been some roguery somewhere, and the committee having gone thus far with their inquiry, he suggested that they should be further empowered to institute the legal proceedings recommended in the report.

Colonel GOURAUD, while exonerating the Chairman from any desire to prejudice him in the eyes of the shareholders, thought it necessary, because of the frequency with which his name had been dragged into the Chairman's speech and the report, to make certain personal explanations, lest the shareholders might put a wrong interpretation on any of the remarks that Mr. FitzGerald had made. He then proceeded to say that he felt it due to himself, while still adhering to his wish, as stated on the 23rd of May, to retire from the Board, to be present at this meeting as a director of the Company. As to those things which the Chairman had referred to him (Col. Gouraud) for explanation, he would merely say that he was perfectly able and willing to explain everything which originated with the Board while he was a member of it. Further than that, it would be out of place for him to go. While acknowledging the difficult nature of the task which the committee of investigation had had to perform, he reminded the meeting that he himself seconded the election of three of the gentlemen forming it, although they were strangers to him, and he could not help saying that had they been a little more frank and not above receiving information the directors might have greatly aided them in their labours. He then pointed out that the Chairman did not read the correct minute as to the allotment of shares which took place on the 26th of April, the minute as to which he accordingly read. There had not been a farthing drawn for fees from the Austrian Company, and as to the River Plate Company, although the directors had had money constantly passing through their hands, they had received no fees since April last. In the matter of the settlement with the Austrian Company, he reminded the meeting that it was the result of negotiations extending over a year and a half, although the report made it appear that it was effected exclusively by the committee. The inclusion of the four Austrian towns which had been referred to was a *sine quâ non* of the whole scheme.

The Hon. HOWARD SPENSLEY and Mr. P. CARNEGY very briefly addressed the meeting, and an animated and protracted discussion ensued, during which several amendments and counter-amendments were proposed.

Finally, on the motion of Mr. PITT COBBETT, seconded by Mr. GERMAINE, the following amendment was carried unanimously:—"That the shareholders, whilst approving the action of the committee, refer the matters dealt with in the report to the committee for a further and more specific report—1. As to the advisability of taking proceedings against those concerned in the various transactions referred to in the report, and including the reduction and taxation of the solicitor's expenses. 2. As to an alteration in the Articles of Association. 3. As to the consolidation of the Boards of the various companies, and changes recommended in the directorate and officials of these companies."

On the motion of Mr. BUCKINGHAM, seconded by a SHAREHOLDER, it was agreed to add Mr. Germaine to the committee.

Mr. SPENSLEY and Mr. CARNEGY announced their intention to retire from the Board if it was the wish of the shareholders that they should do so.

Mr. GRIFFITHS, of the firm of Messrs. Deloitte, Dever, Griffiths, and Co., was appointed one of the auditors of the Company for the ensuing year, and the meeting was then adjourned until a further report shall be received from the committee.

An adjourned extraordinary general meeting was subsequently held, Mr. FitzGerald presiding.

The SECRETARY having read the notice calling the meeting,

The CHAIRMAN moved the following resolution:—"That the action of the Board with reference to the settlement of the accounts of the River Plate Telephone and Electric Light Company (Limited) is hereby approved and confirmed, and that the arrangement made by the River Plate Telephone and Electric Light Company (Limited) is hereby adopted, and the directors are authorised to carry the same into effect, and take all necessary steps for that purpose."

Colonel GOURAUD seconded the motion, which was unanimously agreed to, and a vote of thanks having been accorded to Mr. FitzGerald for presiding the proceedings terminated.

Cuba Submarine Telegraph Company, Limited.

At a meeting of the directors of this Company on Wednesday the audited accounts for the half year to June 30 were submitted, and it was resolved, after providing for the dividend on the preference shares, and placing £1,266 to the reserve fund, to recommend the payment of a dividend on the ordinary shares at the rate of 9 per cent. per annum, free of income tax, leaving £367 to be carried forward.

The Anglo-American Telegraph Company.

Report of the directors to the ordinary general half-yearly meeting of the proprietors, to be held at the City Terminus Hotel, Cannon-street, E.C., on the 6th August, at 12 noon. The total receipts from the 1st January to the 30th June, 1884, including a balance of £657 4s. 1d. brought forward from the last account, amount to £231,892 18s. 2d. The traffic receipts show a decrease as compared with the corresponding period of last year of £13,775 consequent upon continued depression of trade between Europe and America. The total expenses of the half year, including repair of cables, &c., as shown by the revenue account, amount to £49,389 6s. 9d. The directors, under the powers conferred upon them by the Articles of Association have, before declaring the net profits, set apart the sum of £75,000 to the renewal fund, leaving a balance of £107,503 11s. 5d. One quarterly interim dividend of 12s. 6d. per cent. on the ordinary stock, and of 25s. per cent. on the preferred stock, was paid on the 1st of May, 1884, absorbing £43,750, and a second quarterly dividend of 17s. 6d. per cent. on the ordinary stock, and £1 15s. per cent. on the preferred stock, will be paid on the 1st August, 1884, absorbing £61,250, leaving a balance of £2,503 11s. 5d. to be carried forward to the next account. The Company's repairing steamship "Minia" has been engaged during the half year in repairing the 1880 cable, broken off the coast of Ireland; the 1869 cable, broken off Brest, and St. Pierre Miquelon; the Duxbury cable, broken at the same place; and the South Placentia cable, broken at a distance of ninety miles from Placentia N.F. She has also been engaged in the repair of the Direct U.S. Cable Company's cable, between Torbay and Rye Beach, having been chartered to that company for the purpose. The Company's entire system of cables is now in good working order. At the general meeting held in February last a resolution was passed by a majority of the proprietors present, recommending the directors to reduce the yearly contribution hitherto placed to the credit of the renewal fund. The resolution did not state the amount of reduction proposed, but from the discussion which followed the meeting appeared to be desirous of reducing the yearly contribution to that fund from £150,000 to £100,000, or less. After very careful consideration of the proposed reduction in connection with the condition of the cables, their present age, and probable life, and taking the most reliable opinions which could be procured on the subject, the directors have arrived at the conclusion that for some time to come no diminution can be made without great injury to the prospects and property of the Company, and seriously jeopardising the proportion of gross receipts accruing to the Company under the existing joint purse agreements. The directors look with confidence to the great body of the proprietors for their co-operation and support in the maintenance of the renewal fund, upon the sufficiency of which the whole existence of the Company depends. The Commercial Cable Company, promoted by Messrs. James Gordon Bennett and J. W. Mackay, appear to be actively progressing with their cable-laying operations, so that at least one cable may be expected to be opened almost immediately. It is difficult to realise the fact that two persons could be found able and willing to embark so large an amount of capital as is required in such an enterprise as the laying of two Atlantic cables, and to accept the risk, anxiety, and responsibility incident to their working and maintenance without any reasonable prospect of profit. No information has yet been obtained as to the tariff at which the new cables are to be worked. By the death of the Hon. Robert Grimston, which occurred in the month of April last, the directors have lost an esteemed friend and valued colleague. His long connection with this Company, and his great experience in the management of analogous undertakings, acquired as Chairman of the Electric Telegraph Company, and first Chairman of the Indo-European Telegraph Company, rendered his services of much value to the Board. Monsieur C. Crapelet, of Paris, has resigned his seat at the Board, as he was unable to attend its meetings in the manner prescribed by the Articles of Association. It is not proposed to fill up either of these vacancies, and as the number of directors is decreased, the Board resolve to reduce the fees by £500 per annum.

Submarine Telegraph Company.

Report of the directors to be submitted at the meeting of the proprietors held at the Company's offices, 2, Throgmorton-avenue, E.C., on Aug. 1, at 1 p.m.:—The accounts for the six months ending 30th June, 1884, show that the gross receipts amounted to £62,757 11s. 11d., which is less than the sum received in the corresponding six months of 1883 by £1,574 11s. This reduction is attributable to the reduced length of the messages transmitted; in the six months there were transmitted 40,410 more messages, but the number of words transmitted was 342,016 less than in the six months ending 30th June, 1883. In the first six months of 1884 the average length of a message was 12·04 words, whereas in the some period of 1883 it was 12·65 words. The total expenses show, on the other hand, an increase of £614 12s. This arises partly from an increased sum that the French Administration has charged for French clerks working the circuits between the French coast stations and London, and partly from additions to salaries of clerks and others in the employment of the Company. The net result of the business for the six months enables the directors to add to the reserve fund £7,830 9s. 1d., and to recommend a dividend at the rate of 13 per cent. per annum, carrying over a balance of £170 6s. 11½d. The directors have frequently had occasion to refer to the unsatisfactory condition of the cables between England and Holland belonging to the English Government and worked by this Company, and they took advantage of a favourable opportunity to make urgent representations to the Post Office on the subject. They have now much pleasure in reporting that the Government has laid down an excellent new cable, containing four conductors, between England and

Digitized by Google

Holland, which is to replace the North Zandvoort cable, and that the South Zandvoort cable will hereafter be thoroughly overhauled by the Government. The directors trust that this improved communication will produce a satisfactory increase in the Dutch traffic. All the cables worked by the Company are now in good working order.

Anglo-American Brush Electric Light Corporation.

The following *ad interim* report has been issued to the shareholders of this Company:—

In accordance with the desire expressed by several shareholders, the directors have pleasure in submitting a short report on the business of the Corporation during the six months ended 30th June. The shareholders are already aware that the proposition of the Board to reduce the capital of the Corporation was unanimously adopted by two general meetings, and that the special resolution on this subject was in ordinary course sanctioned by the Court. An application has been made to the committee of the Stock Exchange to quote in the official list the new in place of the old denomination of shares, and it is expected that the application will shortly be granted. In accordance with the suggestion contained in the annual report, which was approved by the general meeting, the directors gave the holders of partly paid shares the option of making their shares fully paid before the 1st June, and this option has been exercised by about 100 shareholders, who have paid in the aggregate nearly £8,000. The directors are glad to be able to inform the shareholders that during the past six months further considerable progress has been made in perfecting the manufactures and in developing the business of the Corporation. The excellence of the apparatus supplied by the Corporation, both for arc and incandescence lighting, is now generally recognised, and the Corporation stand high in the estimation of the public, not only as manufacturers of the highest class electric lighting plant, but also as contractors for electric lighting installations. The Corporation have been successful in establishing the reputation for high efficiency of their Victoria dynamos and lamps for incandescence lighting, and their especial suitability for the purpose of lighting ships, contracts having been obtained among others from the Admiralty, after severe competitive tests, for fitting up the following of Her Majesty's ships of war with the incandescence light: — "Colossus," "Triumph," "Raleigh," "Bacchante," and "Conqueror." Among the other important work undertaken by the corporation may be mentioned a provisional installation of three 500-light dynamos at Buckingham Palace, the supply of the machines for lighting the Parliament Houses at Melbourne, and the exclusive lighting of the Forestry Exhibition at Edinburgh. Although, owing to the continued depression in electric lighting generally, the volume of business effected during the past half year has not been so large as was hoped for, yet it is a satisfactory feature of the business that shipments have been made to nearly all quarters of the globe, and that there is a continuance of orders from distant countries. In consequence of the liquidation of the Metropolitan (Brush) Electric Light and Power Company, the Brush and Lane-Fox licences for the important district occupied by that company have reverted to the Corporation, and the directors anticipate a considerable accession of business from this cause. The directors are giving their earnest attention to the question of establishing agencies in countries and places where the interests of the Corporation are not already protected by local subsidiary companies, and it affords them much satisfaction that their efforts in this direction have met with success. They have granted the sole agency for the German Empire to a firm who are able to bring adequate capital and powerful influence to bear upon the development of electric lighting in Germany, while agencies have been granted to influential persons in other European and transatlantic countries. The directors regret to have to inform the shareholders that the appeal against the judgment which was given in favour of the Corporation, about the time of the general meeting, in the action brought by Messrs. Muir and Co. for £736, the price of a machine ordered by the Corporation as long back as 1882, but refused on the ground that it had not been completed within the specified time, has been decided against the Corporation. The South Eastern Railway Bill, 1884 (various powers), has passed both Houses of the Legislature, and the question of whether the railway company shall take the whole or only a portion of the Corporation's Victoria Works, and the compensation to be paid, will be decided under the terms of the Act, when the South Eastern Railway Company acquire additional land for widening their line at this point, as is now in contemplation. The half-year's working shows a net profit on trading, after including exceptional law charges, and after making provision for all book losses and depreciation of property. This result compares very favourably with the trading account of the previous year, and warrants the hope that, with even a partial revival of electric lighting enterprise, the Corporation will be able to make fair returns on the capital subscribed. In conclusion, the directors feel that there is ground for congratulation in the fact that at present not only are all charges, ordinary and exceptional, met by revenue, but that the financial position of the Corporation is such as to enable the Board to undertake important contracts which they have in view, involving further expenditure of capital, without asking the shareholders to provide additional supplies.

PRICE FOURPENCE.

STATE MONOPOLY or PRIVATE ENTERPRISE?

CIVIL SERVICE COMMISSION.—EXAMINATION for ASSISTANT EXAMINERSHIPS in the Patent Office (21-25), 29th August. Salary £250 to £400.
The date specified is the latest at which applications can be received. They must be made on forms to be obtained with particulars from the Secretary, Civil Service Commission, London, S.W.

UNIVERSITY COLLEGE, BRISTOL.
The Council are prepared to receive APPLICATIONS, on or before the 16th August, for the post of DEMONSTRATOR in EXPERIMENTAL PHYSICS.
For further information apply to
ALFRED E. STOCK, Registrar.

SALE BY AUCTION, at the office, and through the medium of, Mr. SEGOND, Notary, of Paris, Rue Laffite, No. 7, on the 20th AUGUST, 1884, at 2 o'clock, of FOUR LOTS of LETTERS PATENT for an Invention patented in France, Germany, England, and Italy for the ELECTRIC LIGHTING of RAILWAY CARS, BOATS, and other vehicles (Tommasi's system). Starting prices: French, German, and English patents, each 25,000 francs; Italian patent, 20,000 francs. 5,000 francs to be deposited beforehand for each lot.

CONSULTATION and TUITION.—An experienced Electrician gives TECHNICAL ADVICE and ASSISTS INVENTORS at moderate fees. Evening Class now forming for Electrical Engineering at Highbury Institute, N. For appointment and terms write M.S.A., care of *The Electrician* Office, 1, Salisbury-court, Fleet-street, E.C.

WANTED, SITUATION as ELECTRICIAN in an electric light company, or with firm of electrical engineers. Advertiser has had several years' practical experience in both arc and incandescent lighting. Good testimonial from last place.—S. G., 6, Samos-road, Anerley, near London.

PRICE, SONS, and COMPANY,
THE OLD STONEWARE POTTERIES
BRISTOL.
MANUFACTURERS of the IMPROVED HIGHLY GLAZED VITRIFIED BRISTOL STONEWARE, specially suitable for the manufacture of
Insulators, Primary and Secondary Battery Jars,
Combining the superior strength of stoneware, with a glaze free from metallic impurities, impervious to the action of chemicals, and smooth as porcelain.
POROUS POTS AND PLATES, ACID TAPS, WICKERED JARS.
Samples may be seen at International Health Exhibition, Stand 766.

NOTES.

EARTHQUAKE IN BOSNIA.—Severe shocks of earthquake were felt at 2 o'clock and 3.45 p.m. on the 3rd instant at Foca, in Bosnia.

THE PHILADELPHIA EXHIBITION.—The buildings of the International Electrical Exhibition at Philadelphia are now finished, and exhibitors have begun to make arrangements for placing their exhibits.

TELEGRAMS TO FOOCHOW.—The Eastern Telegraph Company notifies that telegrams are accepted as usual for Foochow, the courier service between the landing place of the cable at Sharp Peak and Foochow having been resumed.

WORKS STRUCK BY LIGHTNING.—A telegram from Philadelphia, dated 5th August, says:—The Baldwin locomotive works, at Philadelphia, were struck by lightning, and partly burnt down, last night, the loss sustained being upwards of 200,000 dollars.

NATIONAL TELEPHONE COMPANY. — From an available balance of £6,672 the directors of this company propose to pay a further dividend of ¾ per cent. on the ordinary shares, making 1¼ per cent. for the past year. A balance of £3,297 remains to be carried forward.

ELECTRIC LIGHTING IN PORTUGAL.—The Companhia Portuguesa Electricidade has been formed at Lisbonne with a capital of 2,500,000 francs (£100,000) to supply electric light. A central station will be erected, and it is said that the company already have orders on hand.

THE PORTRUSH ELECTRIC RAILWAY.—On Saturday last the members of the British Medical Association concluded their meeting at Belfast by a series of excursions, many hundred members paying a visit to the Portrush Electric Railway, and travelling to the Giant's Causeway by it.

SOUTH EASTERN BRUSH COMPANY.—The petition presented to the Chancery Division of the High Court of Justice on the 24th April last, for confirming a resolution reducing the capital of this company from £100,000 to £51,000, is to be heard to-day (Saturday) before Mr. Justice Chitty.

ATHLETICS AND ELECTRIC LIGHTING.—So successful were the recent athletic games given at the Boston Union Grounds with the aid of the electric light that, says an American paper, it is determined to repeat the experiment. This method of avoiding the summer heat and glare promises to become very popular.

CUBA SUBMARINE TELEGRAPH COMPANY.—The number of messages passing over the lines of this Company during the month of July was 3,596, estimated to produce £3,200, against 2,929 messages, producing £2,755 in the corresponding month of last year. The traffic receipts for the month of April, estimated at £3,300, realised £3,401.

A MINER'S SAFETY LAMP.—Messrs. Shippey Brothers write to us, explaining that in the Lever competition for the best miner's safety lamp, the lamp sent in for competition by them as the London agents of Mr. Morgan was made according to Mr. Morgan's first patent, but that since it was taken out great improvements have been made by the patentee.

OVERHEAD WIRES IN NEW YORK.—Dr. N. S. Keith stated at a recent meeting of the New York Electrical Society that the number and extent of aërial wires in New York had been largely overstated. On reliable authority he found that the telephone companies had about 6,000 or 7,000 miles, the Western Union about 3,000, and the other companies in proportion.

THE FRENCH ELECTRICAL POWER STORAGE COMPANY.—Vice-Chancellor Bacon made an order on Saturday last for the winding up of this company on the petition of the Faure Electric Accumulator Company. It was stated in court that the proceeding was rendered necessary by the frauds of M. Phillippart, whose name has been so intimately associated with disaster to electric lighting and accumulators.

ANOTHER EXHIBITION.—An exhibition which includes many electrical appliances, and which is lighted by electric lamps, was opened at Steyr, in Upper Austria, on Saturday last by the Archduke Charles Louis. The motive power for the electric light machinery is derived from water wheels, and we hope that the opportunity will be taken of obtaining reliable figures as to the cost and effectiveness of this much-talked-of source of energy.

ELECTRIC LIGHTING IN KENSINGTON.—At the last meeting of the Kensington Vestry, on the recommendation of the Works Committee, it was decided to revoke the order granted to certain persons for the purpose of lighting by electricity a certain district in South Kensington, the undertakers not having complied with the Orders Confirmation Act in depositing the necessary sum (£12,000) to the satisfaction of the Board of Trade.

THE TELEGRAPH IN IRONWORKS.—The monster works of Krupp at Essen, the birthplace of many a score of cannon, employ no less than 20,000 workpeople. There are also in use there 439 steam boilers, and 450 steam engines representing 185,000 horse-power. In addition to 40 miles of rails, 28 locomotives, and 69 horses, Herr Krupp has pressed into his service 40 miles of telegraph wire, which run between 35 stations, and 55 Morse instruments.

ELECTRIC LIGHTING IN LAUSANNE.—The Swiss Electrical Company have lighted the Cantonal Hospital at Lausanne on the Edison system. The installation comprises 236 lamps and three dynamos, the latter being driven by three turbines. The company also have a central station in the same town, where there are two dynamos driven by two turbines of 35 horse-power each. These supply current to 280 lamps. There are 72 subscribers to the company's system.

OVERHEAD WIRES IN LONDON.—The Kensington Vestry have decided not to entertain the request of the Wandsworth Board of Works to contribute towards the expenses of an appeal in the recently heard case of the Wandsworth Board *v.* the United Telephone Company. They have, however, resolved to concur in a proposition of the Marylebone Vestry, to request the Government to bring in a Bill giving local authorities control over wires in their several districts.

ATMOSPHERIC PHENOMENA.—The daily papers of Tuesday last stated that some gorgeous sunlight effects had again been observed over the Yorkshire Wolds. For several nights past the sky had been one mass of richly-blended colours, commencing at the horizon with a broad belt of deep yellow light, and then band above band of orange and purple, the latter colour predominating in horizontal streaks, whilst up to the zenith the heavens were flooded with a magnificent glow from the setting sun.

A METEOR.—The Philadelphia correspondent of *The Times*, telegraphing under date August 1, says:—"A magnificent

Digitized by Google

meteor was observed at 2 o'clock this morning at the Redhouse Observatory, in Phelps, New York, moving from near the zenith towards the west. It was unusually brilliant, illuminating the country like the electric light, and leaving a train of sparks 40 deg. long, which was visible for several minutes. It was seen through the telescope to roll and curve like a wreath of smoke, with a slow motion northward."

TELEGRAMS FOR CHINA.—The Great Northern Telegraph Company announce that, the courier service from the landing point of the Shanghai-Foochow cable up to the latter town having been stopped by the Chinese authorities, telegrams for Foochow as sent hitherto will only be accepted at sender's risk. Telegrams for Foochow may, however, be forwarded *viâ* Shanghai by means of the Chinese land lines. The rate for telegrams forwarded in this manner, which should be marked "*viâ* Chinese land lines" (these words are not charged for), is 10s. per word.

TELEPHONIC EXPERIMENTS.—A Reuter's telegram, dated Rome, Aug. 4, says:—"Some interesting experiments were made with the telephone yesterday evening between this city and Florence, Signor Genala, the Minister of Public Works, who was present at this end, several times communicating with Signor Gadda, the Prefect of Florence, at the other end. The two telephones, which were connected by ordinary telegraph wires, worked successfully enough, although the buzzing of the thermo-telluric (*sic*) currents precluded a perfectly distinct transmission of the voice. On the other hand, a cornet played at the Florence end was very well heard here."

ELECTRIC LIGHTING AT BRIGHTON.—At the third concert of the season given at the Pavilion, Brighton, last week, incandescent lamps were very largely employed for illuminating the exterior of the building as well as the grounds. The pinnacles and ornamentations of the Pavilion, which lend themselves readily to illuminating purposes, were picked out with lamps, and the trees and lawns were adorned in the same way. The result was very pretty. About 600 twenty-candle Swan lamps were used altogether, and the whole installation was carried out by Mr. Magnus Volk, electrical engineer to the Brighton Corporation, with the success which always marks and attends his work.

BUSINESS NOTICES.—Messrs. W. F. Dennis and Co., of 101, Leadenhall-street, E.C., sole agents for Messrs. Felten and Guilleaume, of Mülheim-on-Rhine, inform us that they have now combined their Liverpool and Birmingham districts, and placed the conduct of the business under the management of Mr. Henry N. Cross, who will in future reside at Liverpool, but gives the whole district his personal attention.—Mr. H. C. Harold informs us that he has established himself at 30 and 31, St. Swithin's-lane, E.C., as a manufacturer's agent for the sale of every description of telegraph, telephone, and electric light material. Mr. Harold was until lately with Messrs. Johnson and Phillips.

IMPROVEMENTS IN ACCUMULATORS.—M. Paul Gadot has, says the *Révue Industrielle*, made several improvements in the Faure-Sellon-Volckmar accumulators, which have considerably increased their capacity. He obtains a duty of 13 ampere-hours per kilogram of lead, with a mean pressure of 2 volts. The current is very constant and the storage capacity is about 9,400 kilogrammetres per kilogram of lead. His lead electrodes are as usual covered with oxide, but their make is improved, and they do not dip in acidulated water but in a liquid, the composition of which is still kept a secret. This liquid, which has a depolarising action, facilitates the attack of the metal plates; it also permits of a greater or less duty being got out of the accumulator, according to the requirements of the moment.

ELECTRIC LIGHTS FOR LIGHTHOUSES.—The *Daily Telegraph* says:—"During the past week the lighthouse experiments at South Foreland reached an important stage, at which a committee of the Elder Brethren of the Trinity House were enabled to form a pretty correct notion of what will be the nature of their ultimate report upon lights. It has been found that by means of concentric lenses a light nearly as powerful as the electric can be obtained without the same amount of risk of failure, and at a comparatively small cost." This sounds unfavourable to the electric light, but whether it is gas or oil which has given the superior result mentioned our contemporary does not say. It would be rash to draw conclusions from a paragraph like the above, and we therefore give it as a piece of news merely, until more definite information is in our hands.

NEW CABLE IN SUNDA STRAIT.—The following notice has been issued by the Admiralty:—The Netherlands Government has given notice, dated 28th June, 1884, that a telegraph cable has been laid in Sunda Strait, from Nieuw Anjer (Merak), in Java, to Kalianda, on the eastern shore of Lampong Bay, Sumatra:—From the beacon with triangle on the shore at Nieuw Anjer the cable takes a direction N. 42° W., passing about one mile northward of Merak Island, where it is marked by two buoys. From the western buoy the cable is laid to pass one mile southward of Thwartway Island, and one mile south west of Hog Point to a position S. 71° E., distant 1¼ miles from the south eastern of the Tiga Islands. Thence it takes a northerly direction, and is marked by two buoys, situated respectively N. 51° E., distant 1¼ miles, and N. 14° E., distant four miles from the south eastern Tiga Island. From the northernmost of the two last-mentioned buoys the cable takes a N.E. by E., and E.N.E. direction to the beacon with triangle and the cable house at Kalianda. The buoys and beacons marking the telegraph cable are painted white; the buoys have the word "Kabel" on them, and are surmounted by an iron flag (Dutch colours), on which is the word "Telegraaf."

THE CANDLE-POWER OF LONDON GAS.—Dr. A. W. Williamson, F.R.S., the chief gas examiner of the Board of Trade, has reported for the information of the Corporation of London the results of the daily testings of the gas supplied in the City by the Gaslight and Coke Company during the past quarter. With respect to illuminating power, the average at Aldgate was 16·9 in standard sperm candles, at Cloth Fair 16·6, and at Salisbury-square, 16·6. In each case the average was higher than the parliamentary standard. At the King-street, Cloth Fair, testing station, the minimum was slightly below the requirements on the 15th May. At Aldgate the minimum was equal to the requirements, while at Salisbury-square it was slightly above them. As regarded purity, the gas had been wholly free from sulphuretted hydrogen. The average proportions of sulphur in other forms were, per cubic feet of gas, 10·4 at Aldgate, 9·7 at Cloth Fair, and 9·7 at Salisbury-square. These averages were less than the limit allowed, and the maximum amount recorded was also less than the quantity permitted. Ammonia had not been present during the quarter in the gas tested at the Aldgate and Cloth Fair stations. At Salisbury-square it appeared frequently, but only in slight quantities.

NEW CARBON BATTERY.—Messrs. Tommasi and Radiguet have brought out a new carbon battery. It is composed of a

Digitized by Google

rectangular basin of porcelain, at the bottom of which is placed a carbon plate surrounded by a paste of peroxide of lead, forming one of the electrodes. The other electrode is formed by a second plate of carbon similar to the first, but containing in its upper part fragments of platinised retort carbon. These two plates are placed one on the other, and separated by a piece of parchment paper so arranged as to divide the basin into two perfectly separated compartments. To make the battery work, a small quantity of saturated chloride of sodium solution is poured into the compartments in such a way as on the one hand not to hinder the peroxide of lead too much, and the other so that the fragments of carbon covering the upper electrode shall be only partly in the solution. This battery, which works only when the circuit is closed, gives an E.M.F. of ·6 volt. The negative pole (the zinc of ordinary batteries) is formed by the carbon plate, which does not touch the peroxide of lead. If for the solution of chloride of sodium other salt solutions such as sulphate of ammonia, sulphate of soda, chlorhydrate of ammonia, or even weak sulphuric acid be substituted, the E.M.F. does not sensibly vary.

Provisional Orders.—The Board of Trade having had under their consideration applications from various electric lighting companies for a further extension of time within which to comply with the provisions under which the provisional orders were granted last Session for the electric lighting of the provinces, and of places outside the London area, they have decided to grant an extension of time to the 31st December next for the lighting of Croydon, Margate, Ipswich, and Sudbury, and until the 1st June, 1885, for the lighting of Birmingham, Redditch, and Walsall. They have, however, refused to further extend the time, already once extended, for the lighting of Gravesend, and this order will therefore be revoked, as will also the orders for the lighting of Cambridge, Folkestone, High Wycombe, Sunderland, and Wolverhampton. It may be stated that of the 25 orders granted to public companies last Session for lighting the provinces only 12 remain in force, and of these the companies holding the first seven orders above-mentioned have already had the time originally granted them to comply with the provisions of the orders twice extended, while in the case of the remaining five—namely, Canterbury, Maidstone, Lowestoft, Luton, and Rochester, the time had already expired, and the question of granting any further extension is still under the consideration of the Board of Trade. During the present Session not a single provisional order has been applied for by any company for lighting the provinces, nor have any applications for licenses been received, and of those which had previously been applied for, that affecting Colchester is the only one which has been proceeded with by the promoters.

Electric Lighting in Belfast.—As briefly mentioned in our notes of last week, the electric light was very extensively used in the Queen's College, Belfast, during the recent sittings of the British Medical Association. The magnificent library, which stands apart from the main building, was beautifully lighted (for the first time since its erection on account of the risk of injury to the books by the use of gas) by incandescent lamps arranged in a continuous line around the balcony, which brought out in a very fine manner the architectural design of the building. Two of the reading rooms attached to the library were also lighted by the same means, one serving as a small refreshment room, the other being the office of the editor of the daily journal. The main refreshment room, situated at the further extremity of the college, was illuminated by a large electrolier suspended in the centre of the room, while incandescent lamps also served to illuminate the corridors, cloisters and staircases, &c., while, on the night of the *conversazione* a row of 10 candle-power lamps was used with good effect as foot lights to the temporary stage erected in the library. The lighting of the main portion of the building was effected by arc lamps which were placed in the main hall of the college, the large examination hall, and the museum, while the grounds were also lit by the same means. Among various concerts, exhibits, experiments, &c., provided for amusement, the projection on the screen of the electric arc, as also the spectrum of blood by Professor Letts in the chemistry room, attracted a very large number of visitors. The current for the incandescent lamps (Victorias) was supplied direct from a Victoria dynamo, driven by a Clerk's gas engine, while the arc illumination was effected by "Belfast" lamps, and a series-wound, direct-current Newton dynamo, driven by a Marshall portable steam engine. Both lamps and machine, as also the carbons used, were of the latest and most approved make, manufactured by the Belfast Electric Appliances Company (Limited), by whom the entire work was carried out, under the superintendence of the manager, Mr. G. Annesley Grindle.

Thunderstorms in America.—An American paper gives the following summary of accidents from lightning which occurred during the first three weeks of July:—"The loss by fire in Brooklyn, at the furniture factory struck by lightning, was not less than 100,000 dols. In New England and in various parts of New York many houses were struck, while telegraph and telephone wires were frequently rendered useless. At Greeneville, near Norwich, Conn., on July 13, an electric bolt fell into the kitchen of the farmhouse of a Mrs. M'Donald. She felt no shock, but was astounded to see the iron sink detach itself from the wall, spin twice around the room, and fall in small pieces on the floor. At the same moment the stove and every piece of furniture in the kitchen were riddled, and the minute fragments were flung about the woman in a shower. A ground swell set the floor undulating, and the plaster fell from the walls over the ruined furniture. No other room was visited. Another bolt exploded in the street opposite Mr. Durfey's residence, half a mile away, moved his heavy granite door steps several rods up street, and smashed every pane of glass in the lower story front without touching the house. At Roaring Creek, Pa., the barn of a farmer was struck on the night of the 12th, and destroyed with all its contents, including valuable cattle, the loss amounting to 5,000dols. Two of the farmer's sons and another man were fatally injured while attempting to rescue the stock. Paterson, N.J., had a serious visitation on the 12th also, at midnight. The play of lightning on the wires was terrific, and balls of fire rolled along the car tracks in the streets. Forty wires were burned out at the central telephone exchange, and poles and fire alarm apparatus suffered damage. But the most astounding statement in connection with the display at Paterson is that, according to the newspapers, an electrician gravely calculated that the flash which played such havoc contained as much electricity as could be generated by 357,600 dynamos. The papers are all very precise as to the figures from this new style of lightning calculator, but they all omit any information as to the capacity of the dynamos. It seems to us that these occurrences and the scores of others recorded by the press within the month should direct attention to the desirability of using lightning rods, and rods that may be depended upon, of the right height, properly put up and well grounded." English reporters often lose their heads when reporting thunderstorms and their effects, but for

Digitized by Google

tall talk their American brethren can, to be slangy, "lick their heads off."

TRAIN LIGHTING.—Among the many methods of lighting trains by incandescent lamps but few have stood the test of practice. Among the latter may, however, be placed what is known as the Stroudley-Houghton system, which comprises the utilisation of power from the axle of the brake van by an arrangement of belting and shafting on to the spindle of the dynamo; a dynamo of an E.M.F. as required; an accumulator of sufficient power to absorb the output of the dynamo when no light is required, and to add to such output the requisite supply of current when the whole of the lamps are on; and an apparatus which automatically excites the field magnets of the dynamo prior to the closing of the circuit, shuts it out of the circuit until the speed of the train is such as to create an E.M.F. in the dynamo sufficient to charge the cells, or when the speed is so reduced that the E.M.F. of the dynamo is less than that of the cells, then to cut the dynamo out of the circuit, as otherwise the cells would play back on to the dynamo. The apparatus also prevents any excess of current being generated in the dynamo when the train is running at an abnormally great speed. Another important feature of the apparatus is that it is automatically reversible, and consequently works no matter in which direction the train is going. The local train on the London, Brighton, and South Coast Railway fitted up with the Stroudley-Houghton system commenced public work on November 29th, 1883, and has, we are told, worked without cessation ever since. During the foggy weather the light was often burning from two or three o'clock in the afternoon until midnight, and yet never once was there any failure. The express train to Brighton, which has been newly fitted up, is so arranged that there are two lights to each compartment to prevent the possibility of a compartment being left in the dark owing to the breakage of a lamp. The present lamp glasses and holes in the roof of the carriage are also utilised, and the electric lamps may be removed and replaced by a man on the roof quite readily. The whole of the labour, discomfort, and dirt of oil disappear, equally so the waste of time and extra weight of material necessary for gas lighting. The installation consists of a specially modified form of Brush dynamo, a storage battery, twenty of the Electrical Power Storage Company's cells, and the Stroudley-Houghton automatic apparatus, the whole being fitted in a portion of the guard's brake van. Any direct current dynamo is utilisable. The connections between the carriages are so constructed that they may easily be uncoupled, and in slip carriages will do so automatically. At the present time the apparatus has been fitted only on to the usual undergear of English railway brakes where the axles are fixed, but the apparatus may be used with equal facility on the bogey frame, the arrangement of the belting being altered in a suitable manner. The patents for this system are the property of the Railway Electrical Contractors (Limited), of 4, Great Winchester-street, E.C.

ELECTRIC LIGHTING.—A correspondent, signing himself "A. S.," writes to *The Times* as follows:—"The question is being asked, with increasing frequency, why electric lighting does not progress more rapidly. All the experiments made in public thoroughfares and in private establishments prove the excellence of the light, and in the latter, especially in offices and warehouses, its immense advantage over gas, owing to the non-impaired purity of the air it maintains. On a dark, dreary winter's day, when lights have to be kept continually going, the difference in the air one breathes, as time passes, under one and the other system of lighting is such as only those who have experience of both can realise. Nevertheless electric lighting does not go ahead. Wherefore? I will tell you, and I trust the public through you. It is entirely the result of the Electric Lighting Act of 1882, which provides that only a 19 years' contract may be entered into. How is it possible that electric companies should be able to recoup themselves in 19 years for their outlay in plant, machinery, stations, laying of wires, &c., and make a fair and reasonable trade profit out of the price they could sell their light at? So long as there is no street lighting there can be no house-to-house lighting, because it is from the street wires that the accumulators, in which the electricity has to be stored for distribution in the houses, have to be charged. What gas lighting, street or house, would be possible were gas companies similarly handicapped? It is from the street mains that the supply of gas for house use is carried into the houses. Electricity, since it came into public notice a very few years ago, has passed through a serious ordeal. It was fastened upon by a horde of schemers as a means of gambling; bogus companies were promoted, and shares driven up to most extravagant prices. Then the other side, the wreckers, took their turn, and prices were driven as far below the mark as they had been above it, with this advantage, however, that the bogus companies and their promoters, or dupes, as the case may have been, have gradually vanished, and the provisional orders they took from the Government were not acted upon. The remaining comparatively few companies, there is no reason to doubt, are inherently sound, but the Electric Lighting Act of 1882, as already shown, debars them from giving to the public the undoubted advantages of electric lighting, which I believe could, if established on a large scale, be enjoyed at no greater cost than gas. If you will only start this subject, no doubt the public will soon be fully informed on the matter of cost and many other matters of detail by those better acquainted with the *minutiæ* of the question than I am. No doubt the Government are fully aware of the circumstances I have endeavoured to place before you. Why, therefore, is nothing done to facilitate the progress of electric lighting? Can it possibly be that every step in advance in electric lighting means an equivalent retrograde step in gas?—that the gas interest is enormous, every town and even every village in the land of any importance has its gas company, and almost every possessor of gas stock has a vote?"

TAPPING TELEGRAPH WIRES.—A contemporary said a few days ago that "Americans are always either ingenious or enterprising." We think both ingenuity and enterprise might properly be assigned as attributes of the heroes of the following story, though their ingenuity and enterprise might have been more legitimately employed if not more advantageously. The story is taken from the *Electrical World*, of New York, and runs as follows:—"David Stewart, a lineman employed by the Western Union Telegraph Company, made the discovery, on the 14th July, that the line of that company at Coney Island had been tampered with, and at once made a searching investigation, which proved successful. He ascertained that two young men had engaged board at the Arlington House, at Coney Island, and had been assigned to rooms No. 35 and 36, which are situated on the top floor of the hotel. Stewart at once went to Chief of Police John Y. M'Kane's office and obtained his permission to have three trusted policemen accompany him to the aforesaid Arlington House. At the door of the hotel they met Captain Wise, the proprietor, who stated that two young men had engaged rooms at the hotel about two weeks ago. They asked to be given

Digitized by Google

rooms on the top floor, as they preferred all the breeze that could be obtained at the island. The rooms were given to them, and they appeared to be well suited with them. Stewart then proceeded to Justice Stryker's office and obtained a search warrant. When he returned to the hotel he was accompanied to the rooms by the policeman and Captain Wise. Room No. 35 was the first to be searched. In this room nothing was found to confirm the suspicions which had been aroused in Stewart's mind. When the next room was searched the carpets were torn up, and when the search was about to be concluded Mr. Stewart happened to look under the bed. With a cry of joy he sprang to his feet and said: 'Now we've got it, just look under the bed and see the telegraph instrument.' The men looked under the bedstead and discovered that there was a full set of lineman's tools, and also four telegraph repeaters, which were of the finest quality and finish. They had wires attached to them that could be used under water. Over the bedstead in the ceiling was found a hole large enough to allow several telegraph wires to be put through. Inside of the washstand were found a complete battery, and everything that was necessary for a well-regulated telegraph office. The instrument and other paraphernalia were then taken to Chief of Police M'Kane's office, and the lineman notified him of the discovery which he had made. The instruments were used to tap the wires of the Western Union Company on race days at Monmouth Park and Chicago, and the two men would first receive the messages which gave the name of the winning horses in the various races, and would hold the message until one of the accomplices could go to the pool room at Paul Bauer's Club House and buy tickets on the horses which had won the race. In the course of half an hour or so thereafter the men would send in the original message, and as soon as the names of the winning horses had been placed on the bulletin the accomplices would go to the club house and have their tickets cashed. In this manner they made a heap of money. The men were notified by some of their friends that their secret had been found out, and they did not put in an appearance, but left for parts unknown. They are supposed to be the same parties who tapped the wires of the Western Union Telegraph Company at the Iroquois Hotel last year. The law as passed by the last Legislature makes the tapping of telegraph wires a crime, and the parties, if caught, are liable to imprisonment in the Penitentiary for five years and a fine of 500dols."

THE ELECTRIC LIGHTING ACT.—Mr. George Offor, the manager of the South Eastern (Brush) Electric Light and Power Company (Limited and Reduced), writes to the *Pall Mall Gazette* of Tuesday as follows:—"I am far from believing that the Act is perfect; it would be wonderful if the first attempt to legislate on the subject were so. I also think that in one respect, to which I shall refer presently, the Act itself has not been wisely worked by the Board of Trade; but, on the other hand, the public ought not to allow the Act to be made the scapegoat for all the shortcomings of electric lighting systems and want of efficient management. The terms of the Act and the rules made under it by the Board of Trade were well known when Mr. Arnold White, among others, applied for provisional orders. Why, then, did he fight so hard and successfully to obtain powers for his company in one of the best districts of London if he really believed that by accepting the conditions he was assisting in 'blindly throttling' the new industry? How should we fare if we had no Electric Lighting Act at all? It is true that at Hastings and Eastbourne central stations have been established and mains laid through the streets with the assent of the local authorities, and business is being carried on without reference to the Act of Parliament or Board of Trade, but it it doubtful, to say the least, if the local authorities possess supreme power to allow the streets to be disturbed for electric lighting purposes, and it is clear that in towns where the governing bodies are opposed to the electric light being introduced at all, it would be impossible to carry on the industry without an Act of Parliament. What, then, is really required is such a modification of the rules from time to time as the experience of practical working may render necessary; and, speaking from personal experience in connection with this company's work at Colchester, the Board of Trade appear to be fully alive to all this, and have met the requirements of our electrical engineers in a practical spirit. The provision of the Act which excites Mr. Arnold White's especial disfavour is that under which consumers are at liberty to use any lamp they please; but if the Edison claim—which they are now prosecuting in the law courts—be successful, this difficulty will be remedied by the inability of any one but Edison to supply an incandescent lamp, from which disaster the public may profoundly desire to be preserved! But, as a matter of fact, the consumer must use a lamp suitable to the current with which he is supplied, and this will practically limit him to those recommended by the undertaker. It cannot be in the interest either of consumer or undertaker to use an uneconomical lamp, especially if the storage system is employed, as it is clear that according to the amount of energy used in giving a certain quantity of light, so must be the charge for it. As to picking your customers, that, I take it, is impossible and undesirable in any general system of lighting. It is not likely that powers would be given to an electric lighting company to pick out all the plums and leave the rest of the consumers to get their light from the gas companies; nor would it be fair to the gas companies to compel them to supply the small consumers only. If both parties are relieved from the unprofitable trade, then what will this section of the public say to it? I am astonished to learn that, under the Edison system, it is necessary to pick your customers in order to make a large installation pay at the equivalent of 7s. 6d. per 1,000 feet of gas. At Colchester, where we are charging at the rate of 5s. for gas, the business will pay well with a supply of only 2,000 lamps with an average burning of 300 hours each per annum. The action of the Board of Trade to which I take exception is with respect to the 11th clause of the Act, under which licenses and provisional orders may be assigned with the consent of the Board of Trade. This power the Board of Trade decline to exercise, and, in consequence, provisional orders, which might be assigned to local companies, must be worked with the capital of the original undertakers, or a fresh Act of Parliament obtained to sanction the assignment. This decision of the Board of Trade has, I venture to think, done more to 'throttle' the industry than anything else; they probably feared the encouragement of speculation in provisional orders, but by withholding consent from all assignments not based on fair terms, all abuses of the kind could have been prevented. A great deal of work has, no doubt, been undertaken by electric lighting companies at considerable loss as a means of advertising their business. Mr. Arnold White recommends a reduction of the capital account of the electric lighting companies and a general fusion of interests. As to the first, I contend that the great need of the industry is more capital; and as to the second, it will be necessary to find which interests are identical before any fusion is possible. Systems diametrically opposed in principle could not be improved in working by amalgamation."

THE ELEMENTS OF ELECTRIC LIGHT ENGINEERING.

BY E. C. RIMINGTON.

(CONTINUED FROM PAGE 272.)

If the reader does not happen to have a bridge at hand, and has no means of procuring one, he can easily construct the form known as the metre bridge thus

A German silver wire of, say, one yard in length and No. 22 B.W.G., is strained on a board between two terminals F and H (Fig. 8), and divided into 100 divisions by means of a scale marked on the board; D is a contact piece sliding along the wire, R is a fixed resistance taken as near the unknown

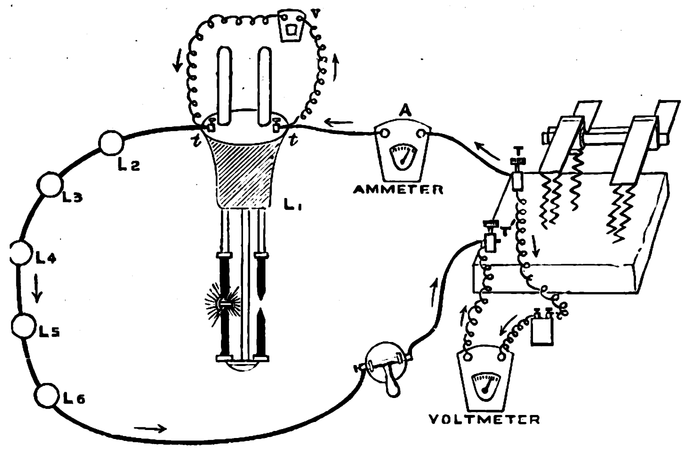

FIG. 8.

one, x, as possible, say three ohms, the connections being made as in Fig. 9. The wire F H forms the two arms A and B of the bridge, the resistances of which are in this case varied, while R is kept constant. The contact piece D is slid along the wire until the galvanometer gives no deflection when k_1 is depressed. Suppose when this happens D points to 20 divisions, then $B = 20$ and $A = 100 - 20 = 80$; therefore $x = \frac{80}{20} \times 3 = 12$ ohms, or to formulate, if d be the number of divisions indicated by the pointer,

$$x = R\left(\frac{100}{d} - 1\right)$$

Siemens's universal galvanometer contains a bridge of this form. Blackkurn's portable testing bridge described in *The Electrician*, Vol. X., p. 488, is also made partly up on this plan, and is an exceedingly portable little instrument for electric light testing work.

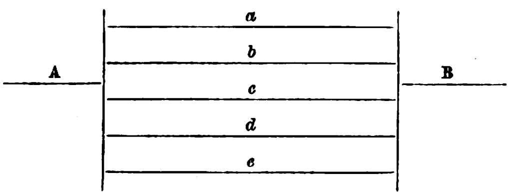

FIG. 9.

The resistance of any dynamo is best measured *immediately* after it has been running (care being taken to completely stop it, and to disconnect the external circuit), on account of the current heating the coils, and thus rendering their resistance slightly higher than it would be if they were measured when cold.

If we wish to measure the resistance of the field-magnets and armature separately in a series dynamo like Fig. 1, to obtain the former we must connect one of the lead wires from the bridge to T and the other to B; to obtain the latter connect one lead to T_1 and the other to B.

In a dynamo whose connections are similar to Fig. 5, the resistance of the armature can be found by connecting the leads to B and B_1; and to obtain that of the field-magnets connect one lead to B_1 and the other to T_1, the resistance found will be that of one of the field-magnets. Now disconnect the leads and connect them to B and T, which will give the resistance of the other field-magnet.

The resistance of the field-magnets can, however, be found more accurately when the dynamo is working by taking the E.M.F. at their ends and the current flowing through them, then dividing the former by the latter, as described further on.

The resistance of the external circuit, provided it contains no secondary batteries or voltameters, can be measured by the bridge in the same manner as the resistance of the dynamo.

If the circuit consists of a number of similar arc lamps in series, its resistance will be equal to the resistance of one of the lamps, as measured through its terminals by means of the bridge, multiplied by the number of lamps, to which product is to be added the resistance of the leads. If, however, the lamps are not all of the same resistance, we must add their resistances, and then add the resistance of the leads.

In the case of conductors or lamps (generally incandescent) in multiple or parallel arc, as Figs. 9 and 10, if r_1, r_2, r_3, r_4, &c., be the separate resistance of the conductors or lamps a, b, c, d, &c., then their joint resistance, or the total resistance of the arrangement, is equal to the reciprocal of the sum of the reciprocals of the resistance of each, or

$$= \frac{1}{\frac{1}{r_1} + \frac{1}{r_2} + \frac{1}{r_3} + \frac{1}{r_4} + \&c.},$$

which, in the case of four conductors or lamps in parallel arc

$$= \frac{r_1 r_2 r_3 r_4}{r_1 r_2 r_3 + r_1 r_2 r_4 + r_1 r_3 r_4 + r_2 r_3 r_4}.$$

If there are only two conductors or lamps having resistances r_1 and r_2, their joint resistance

$$\frac{1}{\frac{1}{r_1} + \frac{1}{r_2}} = \frac{r_1 r_2}{r_1 + r_2}.$$

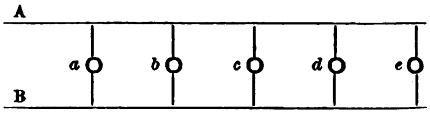

FIG. 10.

If the conductors in parallel arc are all of equal resistance, *e.g.*, a number of incandescent lamps, then the joint resistance of n of them

$$= \frac{1}{\frac{1}{r_1} + \frac{1}{r_2} + \frac{1}{r_3} + \ldots + \frac{1}{r_n}},$$

where $r_1 = r_2 = r_3 = r_n = r$.

Therefore, the joint resistance $= \frac{1}{n\left(\frac{1}{r}\right)} = \frac{r}{n}$, where r is the resistance of one conductor. So that, to find the resistance of a circuit composed of any number of similar incandescent lamps arranged in parallel arc, when no current is flowing through it, we measure the resistance of one of the lamps by means of the bridge, and divide the result by the number of lamps. Thus, suppose the resistance of one lamp as measured by the bridge was 100 ohms, and we had 50 of them arranged in parallel arc, the total resistance would be 2 ohms exclusive of the resistance of the leads.

Having measured the external circuit by means of a bridge, we obtain a result which, although valuable, is very different from the resistance that has to be overcome when the current is running. The resistance of the leads should remain constant, as their temperature should not be allowed to become

Digitized by Google

raised by the current sufficiently to alter it. When, however, we come to the lamps, motors, or whatever we may be running, we find a great difference. Arc lamps have a really higher resistance when running, that obtained by the bridge measurement consisting simply of the resistances of the carbon rods and the coils of wire governing the working of the lamp, while the principal resistance in running is the resistance of the arc, which is chiefly composed of highly-heated carbon vapour and volatilised carbon.

Motors and secondary batteries have an apparently higher resistance, due to back E.M.F., while, on the other hand, the hot resistance of an incandescent lamp (or resistance when the current necessary to produce the proper candle-power in the lamp is flowing through it) is only about one-half the cold resistance as measured on the bridge.

Let us now take some measurements on a circuit of arc lamps, say six, working off a Brush dynamo, using Ayrton and Perry's ammeter and voltmeter.

In any part of the circuit we insert the ammeter, so that the whole of the current to be measured passes through it, as in Fig. 11. Remove the keeper, and turn the current on. The pointer immediately moves from zero to the right or left, as the case may be, and almost instantly, if the current is steady, comes to rest. In this instrument and also in the voltmeter the needle is deflected towards the terminal, at which the current enters. This of course means in the case of the voltmeter that the terminal, to which the needle points, is at a higher potential than the other. Thus in Fig. 11 the

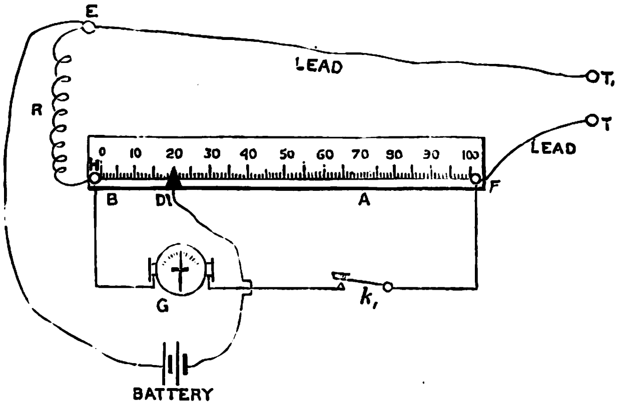

Fig. 11.

current is entering at the right-hand screw of both the ammeter and voltmeter, showing the current to be running in the direction of the arrows. The needle of the ammeter comes to rest in the present case at 7° on the scale. On referring to the table supplied with the instrument we find that 7° to the right means 10·1 amperes. If we now want to know the E.M.F. at the binding screws *t t* of any particular lamp we take the voltmeter and join its terminals to the said binding screws. This may be done with quite fine wire (20 to 22 B.W.G.), as only a very small current passes, and the resistance of the instrument is so high that two 10 feet lengths of No. 20 ($\frac{1}{5}$ ohm) make no appreciable difference. These wires from the voltmeter must be strongly and thoroughly insulated and great care taken not to short circuit the terminals of the instrument. On connecting the voltmeter to the lamp, as shown in Fig. 11, we obtain a deflection of 9·5°, which, according to the table, we find to mean 43 volts. The current remaining the same as we just found it, we have for this lamp

$$C = 10{\cdot}1 \text{ amperes,}$$
$$E = 43 \text{ volts.}$$

From these we know by Ohm's law that $R = \frac{E}{C} = 4{\cdot}36$ ohms. Again, these data will give us the electrical horse-power consumed in the lamp, for

$$\text{h.-p.} = \frac{CE}{746} = \frac{10{\cdot}1 \times 43}{746} = {\cdot}58 \text{ h.-p.}$$

In this way we can of course measure each of the other lamps L_2, L_3, &c.

Before measuring the E.M.F. at the terminals of the dynamo it is necessary to calculate roughly what it will be, for fear it may be too high for the voltmeter. There are six lamps in circuit, and we found the E.M.F. at the terminals of one of them to be 43 volts, so we may reckon on having about $43 \times 6 = 258$ volts or more at the dynamo terminals. The voltmeter we are using only reads up to 190 volts. We will make it less sensitive. Suppose the resistance of the instrument is 2,000 ohms; if in series with this we join a coil of 4,000 ohms we shall make the total resistance three times as great, consequently with the same E.M.F. we shall only get one third the current, and therefore one third the indication which we should with the voltmeter alone, so that the instrument is now one third as sensitive, and will consequently read up to $190 \times 3 = 570$ volts. If a coil cannot be obtained an exact multiple of the voltmeter resistance, any one of known resistance may be used, and the values found in the tables multiplied by $\frac{R + r}{R}$, where R is the resistance of the voltmeter and *r* that of the extra coil.

In the present case we want to reduce the sensitiveness to at least one half, $R = 2{,}000$, so *r* must be at least as much; adding a coil of 2,500 ohms we obtain a multiplying power of $\frac{2000 + 2500}{2000} = 2{\cdot}25$. On connecting the voltmeter with the coil of 2,500 ohms in series with it to the dynamo terminals we obtain a deflection of 25·5°, which the table gives as corresponding to 116·5 volts. Multiplying this by 2·25, we find the terminal E.M.F. of the dynamo to be 262 volts. If the true or total E.M.F. is required, for instance for tracing the characteristic curve of the dynamo, it is easily found from this. Suppose the internal resistance of the dynamo when warm has been previously taken and found to be 4·65 ohms. We have also $C = 10{\cdot}1$ amperes, terminal E.M.F. $= 262$ volts. To send a current of 10·1 amperes through 4·65 ohms requires (since $E = CR$) $10{\cdot}1 \times 4{\cdot}65 = 47$ volts, so that the total E.M.F. (at that point inside the dynamo where it is developed) is $262 + 47 = 309$ volts.*

The electrical horse-power expended in the dynamo (exclusive of mechanical friction†) is, as we saw above $\frac{CE}{746}$ horse-power,

$$\text{or since } (E = CR) = \frac{C^2 R}{746} = \frac{(10{\cdot}1)^2 \times 4{\cdot}65}{746} = {\cdot}634 \text{ horse-power,}$$

all of which is of course a dead loss, the total horse-power we have in the current, or "turned into electricity," as it is sometimes incorrectly expressed, being

$$\frac{309 \times 10{\cdot}1}{746} = 4{\cdot}18 \text{ horse-power,}$$

to obtain which, however, the engine may perhaps indicate some 6 or 7 horse-power in the cylinder.

(TO BE CONTINUED.)

AN ELECTRICAL TESTING ESTABLISHMENT.

As a rule a want has only to be put into words and made public in these days to be satisfied. There are many electricians and mechanics who have from time to time felt the want of a place where they could work out their ideas without fear of having the fruits of their labours indirectly pirated or directly filched from them—a place where the necessary tools, steam-power, testing apparatus, *et hoc genus omne*, would be at their disposal on moderate terms. Many, again, are able to perfect their work at home, but have no means of test-

* There is also a small (apparent) increase of resistance, when running, due to self-induction, which varies, for any particular machine, with the speed; so that the total E.M.F. would be slightly greater than that found above.

† Also of electrical friction in the form of Foucault currents, which are however reduced to a minimum in all well constructed dynamos.

Digitized by Google

ing its performances or capabilities. A man may, for instance, make an incandescent or arc lamp, or build a dynamo, construct a battery or turn out a switch, but have no photometer, current meter, or other means of testing his productions. He may know of many places where the necessary apparatus is to be procured, but the price is too much for him, inventors as a rule having but little cash, and having already spent as much as they can afford in producing their apparatus in the rough. Or, again, there may be many works with which he is acquainted where the requisite testing instruments or machines are to be had, but he is shy of going to them from fear of his secret leaking out, a fear which, rightly or wrongly, strongly possesses inventors. What is wanted, then, is an establishment provided with every requisite for working and testing all kinds of electrical machinery and appliances, where an inventor may work out an idea *ab initio*, or where he may complete his rough model, test it thoroughly, and, if he desires, obtain an expert's report as to its capabilities. The idea of a place such as this has probably occurred to many before now, but the credit of making the idea public must be given to our contemporary, *The Engineer*. The want expressed has at once been met by an endeavour to supply it.

Mr. F. Geere Howard, of 36, Cleveland-street, W., has for some time past been using incandescent lamps to light a portion of his works, and has also devoted considerable time and attention to electrical engineering. Having plenty of steam-power, a workshop with every convenience in the shape of machine tools, and some light airy rooms at his disposal, Mr. Howard proposes to establish just such an electrical testing establishment as we have sketched above as being required. We recently paid a visit to his works, and may briefly state here what we saw. The major portion of the works is given up to furniture making, many machines driven by steam-power being used in the work. The engine used to drive these machines indicates 60 horse-power, which is considerably more than is required for use in the work, so that Mr. Howard can dispose of from 1 to 30 horse-power for driving dynamos, &c. The rooms which it is proposed to devote to electrical purposes are separated from the works, but shafting runs through to the dynamo room and tool shop, which is fitted with fast and loose pulleys, so that power is always available. There is also a Crossley Otto gas engine in the dynamo room always ready for use, but as it does not run very steadily Mr. Howard will replace it by a steam engine. At present there is only one dynamo in place, viz., a Siemens machine, giving 70 volts and 35 amperes, used to feed the incandescent lamps in the toolshop and test room. The former is immediately above the dynamo room, and is fitted with lathes, drilling and planing machines, all run by steam power, and every kind of hand tool. The incandescent lamps in this shop are so fitted above the different machines that they can be lowered or raised to suit the convenience of the worker. From the tool shop we pass into the test room, which is large, well-lighted, and airy. The lighting is effected both from the roof and the side, and it would be hard to find any room better suited for testing purposes. Here there are rows of secondary batteries, both the Elwell-Parker and the Crompton-FitzGerald, ready charged, so that any one wanting forty amperes, say, for half an hour, can have them. Here also are meters, variable resistances, incandescent lamps, switches, and other apparatus. We noticed amongst others Ayrton and Perry's volt and ampere meters, Crompton and Kapp's current and potential indicators, Siemens's dynamometer, &c. In a room below this is a powerful press, which might be used for secondary battery plates or for any purpose requiring great pressure. All of the above instruments and apparatus will be at the disposal of users of Mr. Howard's testing establishment.

For those who wish to carry out tests or experiments in the strictest privacy, Mr. Howard is fitting up two rooms on the other side of the works. One of these will be turned into a dark room for photometer work. Mr. Howard's idea is to run wires into these rooms, supply his customer with all the apparatus he requires, learn what current and E.M.F. he wants and for how long, and then, having fulfilled his wishes in this respect, leave him to lock himself in and carry out his experiments in as strict seclusion as the most suspicious of mortals could wish for.

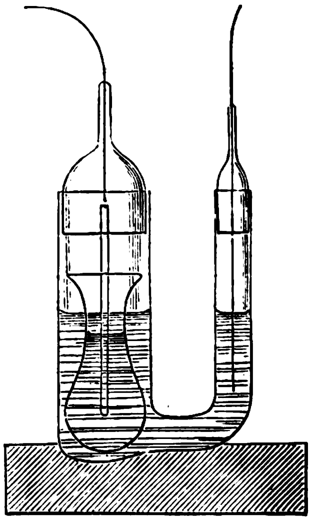
From what we saw during our visit there is no reason why Mr. Howard should not succeed most thoroughly in his endeavour, nor why his establishment should not develop a reputation in the electrical world similar to that enjoyed by Mr. Kirkaldy's famous testing works amongst engineers and ironfounders.

ON AN ELECTROSTATIC STANDARD OF POTENTIAL.*

BY MM. CROVA AND GARBE.

Having had occasion to make continuous use of Thomson's quadrant electrometer (Mascart's model), we have been struck by the variations, often considerable, of the potential of the charging battery, formed, as is known, of small zinc-platinum elements and pure water, variations which are partially corrected by frequent testing (*étalonnage*) of the electrometer, by means of a Daniell cell taken as a standard. We have assured ourselves, by preliminary experiments, that these variations are due to two principal causes.

The first is defective insulation of the elements. It is a fact that, though often satisfactory at first starting, the insulation gradually deteriorates, by reason of the damp which condenses on the external surface of the elements and their support, and by the deposit of dust, which causes a varying short circuit, the effect of which is to diminish the difference of potential at the two poles.



MM. Crova and Garbe's Cell.

The second is the polarisation of the platinum in the water element, a consequence of the short circuiting we have just mentioned, and of that which may be produced accidentally in the handling of the electrometer, when one of the poles of the battery is connected, if only for an instant, with earth. The weakness which results is such that a sensibly long rest is requisite for the battery to regain approximately its initial potential.

The electrometric determinations attained on the other hand a great degree of regularity when we used our own charging elements. We proposed to obtain elements with a constant potential under rigorously defined and easily realisable conditions, by rendering their insulation perfect, and by preventing diffusion of the liquids and polarisation; it is true that, under these conditions, the internal resistance of the elements is enormous, but this fact also renders them very constant, even when they are short circuited for a very long time. We have kept elements insulated for three months; at the end of this time their potential had not varied, and there was not a trace of alteration of any kind. Each element is composed of a glass tube, as shown in the illustration. It has a lateral tube soldered to its lower part, and the two openings are closed by

* Translated from the *Journal de Physique* for July.

Digitized by Google

hollow glass stoppers, as shown; the conductors are fused into the thin end of the stoppers. Finally the tube is fixed on a small ebonite support, and is varnished with gum lac over the whole of its outer surface. To form one Daniell element we put into the two connecting tubes a solution of pure sulphate of copper previously saturated at the temperature of zero, then decanted and preserved for use. A small glass tube whitened with a basis of potash (in order to render it more hygrometric), with its lower end closed, is filled with a solution of pure sulphate of zinc, also saturated at the temperature of zero, and placed in the axis of the large tube in which it is fixed, by means of conveniently formed swellings, which hold it in place.

A copper wire fused into the stopper of the small tube dipping into the sulphate of copper, and an amalgamated zinc wire soldered to a platinum wire fused into the stopper of the large tube, dipping into the sulphate of zinc, comprise the poles of the cell. The level of the liquids is below the opening of the sulphate of zinc tube; thus mixing of the liquids is impossible, and electric communication is established by the layer of water condensed on the surface of the sulphate of zinc tube. (A cell which resembles ours in this last point has been proposed by M. O. Lodge, *Phil. Mag.*, Vol. V., p. 1, 1878, but the conditions of comparison, and above all insulation, seem to us far superior in the cell we have constructed.) It is a good plan to heat this tube to a red heat to destroy all traces of greasy matter on its surface before filling it, and not to handle it afterwards, except with metal pincers previously heated. The use of these cells as a standard leaves nothing to be desired. If the charging battery is constant, the same number will always be found on the divided scale as the value of the Daniell cell, even when the cell has been left for several hours on short circuit. We have not been able to measure its internal resistance; for, on introducing between the poles a resistance of 7,000 ohms, we could not detect any appreciable difference of potential between them in the electrometer; we could not succeed in obtaining the smallest deflection on a galvanometer, nor the slightest noise in a telephone. This great internal resistance necessitates good insulation of the poles, for the least derivation by surface conductivity would produce a notable decrease of potential; for this reason we have so made the cell as to place the greatest possible distance between the poles. The varnish of gum lac renders the insulation perfect, as we have assured ourselves.

We have modified the construction of this element in order to render it less liable to accident when being carried about. Our plan is to replace the two liquids by powdered pumice stone, calcined at a red heat with sulphuric acid, then saturated with the two solutions. The potential is the same whether use is made of the liquid or pumice stone battery, or even of one Daniell element with a porous jar charged with the same two solutions, before diffusion has modified their composition. These elements can therefore be employed either as a standard or as a charging battery; in the latter case they are arranged in a closed box, and rigid conductors pass without touching them in the axis of the two ebonite tubes fixed in one of the sides. Instead of Daniell elements bichromate elements constructed in the same manner (zinc, sulphate of zinc, bichromate acidulated with 1-10th of sulphuric acid, platinum) may be used as charging batteries, the liquids being consolidated by pumice, as we have already described. These elements give about two volts, and do not change after having been on short circuit for several hours. By measuring the difference of potential at the two poles, between which we interposed a considerable resistance, we have been able to measure in certain cases their internal resistance, which was about 100,000 ohms, and we have been able to hear slight noises in a telephone; but these results are very variable. The potential alone does not vary.

The standard of electromotive force can thus be readily obtained, either in a lasting manner, for electrostatic measurements, with the batteries we have just described, or in passing, for electro-dynamic measurements, with the same liquids separated by a porous jar, taking care, in the latter case, to renew the liquids, which are perfectly defined at each determination. For greater exactitude the element should be kept at zero, or, if working at the ordinary temperature, its electromotive force should be corrected by the coefficient, not very great, by the way, of variation with temperature. The various numerical determinations will form the subject of a later communication.

MEASURING THE CAPACITY OF A CONDENSER AND DETERMINING THE PERIOD OF A TUNING FORK.*

BY R. T. GLAZEBROOK, F.R.S.

The experiments described in the following paper were undertaken at the request of Messrs. Latimer Clark, Muirhead, and Co., for the purpose of testing one of their condensers "which," quoting from a letter from the firm, "has lately been made and which we use in the factory. In its construction it is the same as all our condensers, and is made of sheets of mica and tinfoil, and laid with paraffin wax."

The method employed was a modification of one given by Maxwell (Vol. II., sec. 776), and used by J. J. Thomson (*Phil. Trans.* III., 1883) in his recent determination. The following is his description of the arrangement:—

"In a Wheatstone bridge, A B C D (Fig. 1), with the galvanometer at G and the battery between A and B, the circuit B D is not closed, but the points B and D are connected with two poles, R and S, of a commutator, between which a travelling piece, P, moves backwards and forwards. P is connected with one plate of a condenser, the other plate of which is connected with D. Thus, when P is in contact with S the condenser will be charged, and until it is fully charged electricity will flow into it from the battery; this will produce a

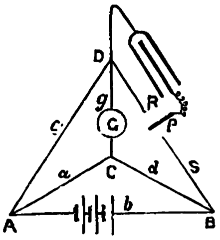


FIG. 1.

momentary current through the various arms of the bridge. When the moving piece P is in contact with R the two plates of the condenser are connected, and the condenser will discharge itself through D R; and as the resistance of D R is infinitesimal in comparison with the resistance in any other circuit, the discharge of the condenser will not send an appreciable amount of electricity through the galvanometer. Thus, if we make the moving piece P oscillate quickly from R to S, there will, owing to the flow of electricity to the condenser, be a succession of momentary currents through the galvanometer. The resistances are so adjusted that the deflection of the galvanometer produced by these momentary currents is balanced by the deflection due to the steady current, and the resultant deflection is zero. When this is the case, there is a relation between the capacity of the condenser, the number of times the condenser is charged and discharged in a second, and the resistances in the various arms of the bridge."

The investigation given by Maxwell is only approximate; we shall quote, therefore, the result given in Thomson's paper.

Let a be the resistance of A C,
b „ „ A B,
c „ „ A D,
d „ „ B C,
g „ „ D C.

Let C be the capacity of the condenser, n the number of times it is charged and discharged per second; then

$$nC = \frac{a\left\{1 - \frac{a^2}{(a+c+g)(a+b+d)}\right\}}{cd\left\{1+\frac{ab}{c(a+b+d)}\right\}\left\{1+\frac{ag}{d(a+c+g)}\right\}}.$$

* *Phil. Mag.* for August.

Digitized by Google

The commutator was the one used by J. J. Thomson, and we quote his description :—" The current from some Grove cells passes first through a tuning-fork interrupter and then through the coils L M (Fig. 2) of an electro-magnet. P N is a strip of brass with a piece of iron wire attached to it. When there is no current passing through the electro-magnet, the elasticity of the rod P N makes it press against the screw T, which is electrically connected with the binding-screw R. When the current passes through the electro-magnet the magnet attracts the iron attached to the rod P N, and brings it into connection with the stop G, which is electrically connected with the binding-screw S. The letters P R S indicate the same points in this figure as in Fig. 1. All the places where contact is made are covered with platinum, and the whole arrangement is fastened down to an ebonite board. As the current passes intermittently through the coils L M of the electro-magnet, the vibrating-piece P N strikes alternately against the parts G and T. When it strikes against G, the opposite plates of the condenser are connected with the two poles of the battery; when it strikes against T the condenser is discharged."

The main advantages of this method over the one ordinarily employed for the determination of the capacity of a condenser whose capacity is comparable with a microfarad are easily seen. In the first place it is a null method; no assumptions are required as to the constancy of the battery. In the second, the galvanometer can readily be made much more sensitive. For accurate work in the ordinary method, the field of force in which the galvanometer-needle hangs should be nearly uniform. The earth's force is much too strong, unless an enormous battery-power be employed, and it is difficult to secure a uniform field by a control magnet. Something may, of course,

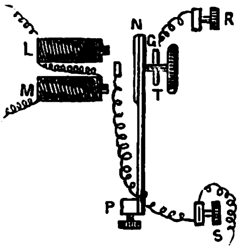

Fig. 2.

be done by the use of an astatic galvanometer-needle; but it is impossible to increase the sensitiveness in this way very much, because the torsion of the suspending fibre then becomes important. Again, in the ordinary method, the time of swing cannot be determined accurately if it be made too small; the moment of inertia of the suspended parts therefore must be considerable, and the deflection produced by a given quantity of electricity suddenly discharged through the galvanometer is proportionately decreased; for, if T be the time of swing, θ the throw produced by a quantity of electricity Q, then T sin $\frac{1}{2}\theta$ is proportional to Q. In addition to this, there is the correction for damping which has to be considered.

On the other hand, objections may be raised to the method which has just been described. The most important of these is founded on the fact that the time during which the plates of the condenser are in contact either with each other or with the poles of the battery is very short. It may happen, then, that the condenser is neither charged nor discharged completely at each vibration of the commutator; while if there be any electrical absorption in the condenser, its effects will depend on the time during which the contact lasts. The experiments to be described were undertaken with the view of testing the method for these defects. The time during which the plates of the condensers are connected with the battery is the time during which the spring P N is in contact with G. This is only a fraction of the period of the tuning-fork which governs the commutator, a fraction which depends on the distance between the end of the screw T and the point G, and on the strength of the current in the electro-magnet.

A series of experiments were made to test the effect of varying the position of the screw T, keeping the battery the same. In these, four Leclanché cells were used in the battery-circuit A B, and two pint Groves to drive the commutator. The position of the spot of light on the scale was noted, and then the value of the resistance d adjusted until no deflection was produced when the galvanometer-circuit was closed by means of a key.

The commutator, when working correctly, emitted a definite sound which was readily recognised, and it was found that the screw T could be adjusted within certain limits without altering this sound.

Table I. gives the results of these observations.

Table I.

Commutator Adjustments.	Value d in B.A. units.
Screw T set	905
Screw T readjusted, note good	906
" " " "	906
" " " bad	906
" " " good	906
Screw T loosened one turn. Spot off scale.	
Screw T readjusted, note good	906

Thus the value of d required to give a balance is practically the same throughout, and the commutator with a definite battery power can readily be set to give a definite result; moreover, a balance could never be obtained except with the resistance 905 or 906. In the fourth observation the note of the commutator was marked as bad; but the spot remained stationary, showing that though there seemed to be a slight irregularity in the sound, it was too small to affect the balance. The sensitiveness was such that an alteration in d of 1 B.A. unit produced a deflection of from two to three scale divisions. The number of vibrations of the fork was about 32 per second.

Another set of observations was then taken to test the effect of varying the battery power driving the commutator, thus altering the force with which the spring P N is attracted to G, three Grove cells being used in place of two. The values of d found in two separate observations were 905·5 and 905.

Observations were made to test the effect of varying the period of the driving fork. Forks of frequencies of approximately 16, 32, 64, and 128 to the second were taken, and the pitch of the lowest of these determined absolutely by comparison with the clock in the method described by Lord Rayleigh (*Nature*, XVII., p. 12; *Phil. Trans.*, 1883, Part I.). This fork and the 32 fork were then set going on independent circuits, and a pointer attached to the 32 fork was watched over the top of a plate of thin metal which had been all along fixed on to the 16 fork, the eye being placed so that this pointer was visible for only one position of the 16 fork in each vibration. In this way the beats between the octave of the 16 fork and the 32 fork were visible, and could easily be counted.

Thus the period of the 32 fork was found, and then in a similar manner those of the 64 and 128 forks. By loading with wax one of the two forks under comparison it was easy to find which of the two was gaining.

Each of these forks was used in turn to drive the commutator, and the value of the capacity calculated from the observations. The values of the resistances were as follow:—

a was a standard coil of 10 B.A. units, d a resistance of 1,000 B.A. units, taken from a box by Messrs. Elliott Bros., and c a variable resistance from another box by the same firm.

g, the galvanometer resistance, was about 11,000 B.A. units; and b, the battery resistance, from 5 to 6 B.A. units. The galvanometer resistance was higher than necessary, but it was for other reasons the most convenient instrument for the purpose. The value of c varied from about 1,800 to about 240 B.A. units.

It will be found that, with these values, the equation giving the capacity may be written

$$nC = \frac{a}{cd\left\{1 + \frac{a}{d\left(1+\frac{c}{g}\right)}\right\}}$$

Digitized by Google

[The approximate equation given in Maxwell is

$$nC = \frac{a}{cd}.]$$

We shall use N_{16}, &c., to denote the frequency of the fork of approximate frequency 16.

The following are the results of the observations :—

(1) Fork 16 used.

Fork compared with pendulum. Fork loses 1 vibration in 7·46 seconds.

$$N_{16} = 15{\cdot}866 \text{ sec.}$$

Resistance observation :—

$$a=10;\ d=1000;\ c=\left\{\begin{matrix}1895\\1892\\1893\end{matrix}\right\}1893 \text{ mean.}$$

Sensitiveness 1 scale-division for alteration of 1 B.A. unit in c.

From these we find

$$C_{16} = {\cdot}3300 \frac{\text{ohm}}{\text{B.A. unit}} \text{ microfarad.}$$

(2) Fork 32 used.

16 beats occur in 42 seconds between octave of 16 and 32. Fork 32 gaining.

$$N_{32} = 32{\cdot}11.$$

Resistance observations :—

$$a=10;\ d=1000;\ c=\left\{\begin{matrix}934\\934\\934\end{matrix}\right\}934 \text{ mean.}$$

Hence

$$C_{32} = {\cdot}3304 \frac{\text{ohm}}{\text{B.A. unit}} \text{ microfarad.}$$

(3) Fork 64 used.

10 beats occur between 64 and octave of 32 in 50 seconds. Fork 64 gaining.

$$N_{64} = 64{\cdot}42.$$

Resistance observations :—

(α) $a=10;\ d=1000;\ c=466;$

$$C_{64} = {\cdot}3299 \frac{\text{ohm}}{\text{B.A. unit}} \text{ microfarad.}$$

(β) $a=10;\ c=1000;\ d=\left\{\begin{matrix}461\\461{\cdot}5\end{matrix}\right\}461{\cdot}3 \text{ mean.}$

$$N_{64} = {\cdot}3299 \frac{\text{ohm}}{\text{B.A. unit}} \text{ microfarad.}$$

(4) Fork 128 used.

16 beats occur between the 128 fork and octave of 64 fork in 26·25 seconds. Fork 128 gaining.

$$N_{128} = 129{\cdot}05.$$

Resistance observations :—

$$a=10;\ d=1000;\ c=232{\cdot}5.$$

Hence

$$C_{128} = {\cdot}3301 \frac{\text{ohm}}{\text{B.A. unit}} \text{ microfarad.}$$

The sensitiveness throughout these observations was such that an alteration of 1 in 2,000 in the resistance produced a deflection of about one scale-division in the spot of light.

Hence the greatest difference in the observations amounts to about 5 in 3,300, or about 1 in 660 ; and there is no trace visible of variation in the capacity with the time of charging.

We will collect the numbers together :—

C_{16}	·3300
C_{32}	·3304
C_{64}	·3299
C_{64} (second arrangement)	·3299
C_{128}	·3301

$$\text{Mean value of capacity} = {\cdot}33006 \frac{\text{ohm}}{\text{B.A.U.}} \text{ microfarad.}$$

Taking the Cavendish-Laboratory experiments we have

$$1 \text{ B.A.U.} = {\cdot}9867 \text{ ohm.}$$

$$\therefore\ C = \frac{{\cdot}33006}{{\cdot}9867} \text{ microfarad.}$$

$$= {\cdot}3344 \text{ microfarad.}$$

If we take the legal ohm and the value of the specific resistance of mercury in B.A. units, adopted by the B.A. Committee,

$$1 \text{ B.A. unit} = {\cdot}9889 \text{ ohm,}$$

and $C = {\cdot}3336$ microfarad.

This value supposes that the various coils used have their nominal resistance in B.A. units. And this assumption is correct, at any rate to 1 in 1,000. Thus it seems that the method gives satisfactory results, and may safely be used to determine the capacity of a condenser.

But the converse of the method may be even more useful. The fundamental equation gives us C if we know n and the resistances ; it will equally give us n if we know C and the resistances ; and in many cases this may be the readiest method of finding n, especially if the period is too long to give an audible note. Thus in the above experiments I require to adjust a fork to vibrate about 16 times a second, the lowest I could obtain being one of a frequency of almost 20.

I made observations with the 32 fork, the pitch of which was marked on it by the maker, of the value of c required to produce a balance, then doubled this value of c, and set the fork which it was required to adjust to drive the commutator. Leaden weights were then fixed with screws on to the prongs of the fork, and their position was adjusted until the galvanometer balance was not disturbed on making contact. It was clear, then, from the approximate formula that the frequency of the fork was very nearly 16. And on making the comparison with the clock, it was found to be 15·866, as already stated.

My thanks are due to Messrs. Wilberforce, Whitehead, and Fitzpatrick for assistance in making the experiments.

CORRESPONDENCE.

DYNAMOS.

TO THE EDITOR OF THE ELECTRICIAN.

SIR : I have noticed the papers and discussions that have appeared from time to time in *The Electrician*, and have experienced some disappointment from the paucity of the various writers. It appears to me that a valuable paper like "ours" ought to contain something more than a repetition week after week of the "construction of dynamos" under various headings when the main part of the subject is left entirely out. If some of the contributors to this journal would go deeper into the subject and give some formula by which the resistances of the armature and field-magnets might be worked out from—*i.e.*, the proportions which should exist between them, so that the most work could be got out of the machine, and also a formula by which the amount of wire necessary for a shunt machine might be calculated, they would be doing a great many of your readers much valuable service. Hoping some one of the writers will take this matter up, yours, &c., G. S.

EDUCATIONAL.

TO THE EDITOR OF THE ELECTRICIAN.

SIR : Could any of the readers of *The Electrician* inform me whether there is any institute in or near London, S.E., where I can obtain the necessary coaching for the assistant examiners', patent office, civil service examination ?—Yours, &c.,

LUX.

THE GREAT NORTHERN TELEGRAPH COMPANY.—The traffic receipts of this company for July were £26,360; for the period from 1st January to 31st July they were £155,880, against £145,659 for the corresponding months of 1883, and £137,965 for the same period of 1882.

EASTERN EXTENSION TELEGRAPH COMPANY.—The traffic receipts of this Company for the month of July amounted to £36,770, and to £37,177 in the corresponding period of 1883.

THE TELEGRAPH AND COLONIAL FEDERATION.

When last we had occasion to refer to the part played by the telegraph in the international game of politics, Prince Bismarck had just been anathematising those swift winged messengers which have made the labours of his declining years almost too much for him to bear. What would have been his frame of mind had Germany possessed a colonial empire it is needless to conjecture. The methods of an irresponsible and irremovable Minister are not our methods, and probably we never shall enjoy the experience of a ruler whose eye must be watchful everywhere, and whose hand must exert control over everything. Nevertheless, even to English statesmen the telegraph is attended with inconveniences, which we have dwelt upon more than once in these pages, not the least of which is the loss of responsibility in our agents abroad. The race of men of whom the late Sir Bartle Frere was an illustrious example is becoming extinct, and in the presence of the telegraph can never again be revived. Our Pro-Consuls abroad have almost ceased to act on their own authority, and are steadily accustoming themselves to the habit of working, if not with a rope, with a wire round their necks. That the British Empire is no longer a school in which uncrowned kings can be educated may be a matter for sentimental regret, but it is a fact, and a fact which has to be faced whether we like it or not. The burden of empire which was formerly distributed over the shoulders of its representatives abroad has now to be borne by responsible Ministers at home. The titular dignities remain, and will probably long survive, but their functions are now curtailed to dimensions which grow rapidly smaller and smaller.

This we say is the irrevocable fact; and it has been created mainly, indeed almost solely, by the telegraph. How great has been the revolution effected through this instrumentality was well illustrated the other day at the Westminster Palace Hotel, where a number of statesmen, representing various shades of political thought, met together to inaugurate a movement for the confederation of our Colonial Empire. Into the merits of this project it is not our province to enter, but we are justified in pointing to the causes which have rendered the idea a feasible one. So recently as ten years ago, or even later, not only would it have been pronounced a dream, but a very foolish and mischievous dream. There were public men then who openly advocated disintegration. It is disputed that a certain professor ever uttered the phrase "Perish India," but the fact of its now being denied is highly significant. At all events there were men, and plenty of them, who virtually said as much concerning the bonds that united the British colonies to their mother country. These political philosophers were of home growth, it is true; the colonies never produced any such that we know of. But where are they now? They have probably not changed their minds, but they are silent; and we venture to assert that it is the telegraph that has proved stronger than their convictions. While they were brooding over their theories of colonial independence, which nobody desired to put into practice, but which might have developed, as theories are apt to do, into decisive action, the telegraph has been welding us closer and closer with our distant brethren, and making separation almost a physical impossibility even if we wished it ever so. Commenting on this Federation scheme one of the daily papers had the unheard of temerity to say that a great deal of good would have accrued to the human race had the English Colonists who founded the United States remained true to the English crown. The utterance is chiefly remarkable as showing what a radical change has come over public opinion in recent years; but it may be added that had the telegraph existed then the War of Independence would never have occurred. Irresponsible vice-royalty has its drawbacks, and the arbitrament of war is one of them. The telegraph is a great peacemaker, and it may be confidently asserted that if ever the colonies give themselves over to the teaching of the philosophical disintegrationists, their final message will be peacefully transmitted per cablegram, not at sword's point. But that message is never likely to arrive, for every increase of facility for interchange of views renders misunderstanding less easy and conflict more improbable. It has been truly said that most wars have arisen through misunderstanding; we should prefer to say through practical difficulties in the way of coming to an understanding. The telegraph removes one chief difficulty by bridging time and space, and averting the consequences of impatience and angry impulse which distance and blank separation are liable to intensify.

We have nothing to do with the rival methods of confederation which will form a subject of debate for some time to

Digitized by Google

come; but we are safe in assuming that confederation of some kind is demanded, and will ultimately be in operation. Without the telegraph this could not have been; if government by proxy is no longer permissible, government by telegraph is the only alternative, and it is a thoroughly practicable one. Steam-power has rendered our remotest colony almost as near in point of time as were the north of Scotland and Ireland in the days of mail coaches and fast-sailing cutters. The telegraph has done more than this, for it has brought even the most distant points virtually within earshot of each other. With the exception, perhaps, of the Mauritius, there is hardly an English colony or naval station of any importance that is not now in practically direct communication with Downing-street by means of at least one, and often by two or three cable routes under the seas. Commercial enterprise has led to this great innovation, and probably commercial considerations will ultimately determine the form which Colonial Federation shall take, for it is as true that trade follows the flag as that cable laying carries it. But be that as it may, the movement now set on foot for forming a United States of the British Empire is one that only the telegraph could have brought within the range of practical politics. The inconvenience complained of during the period of transition through which we are now passing, when the telegraph is voted a nuisance and an encumbrance, is only temporary, and will entirely disappear when the final stage of permanency has been reached.

HEALTH EXHIBITION.—V.

We have seen that in electric lighting, as in gas lighting, there are three important parts of the system to consider, the prime motor—be it a steam engine, gas engine, water wheel, turbine, or any other source—the generator of the electricity, and the burner. In gas lighting we find retorts, gasometers, and burners, the gasometer being connected to the burners by pipes, while in electric lighting the generator is connected to the lamps by means of wire.

Suppose this is our first visit to the Healtheries, and we enter during the day to stroll round, see the various exhibits, not forgetting that great centre of admiration, Old London. Passing through the representation of Old London, one of its passages leads us into the electrical machine room, or we may reach this department by a more direct way from the main entrance. There is nothing very prepossessing in this room in the day time, few people are to be seen, and those seen are busily engaged among the machinery. A glance shows a wilderness of wheels and belting, huge boilers in front of us, large engines to the right and left, with dynamos sprinkled about like accents in a page of Greek. The maze at Hampton Court you will think a simple puzzle to that of finding a clue to this maze of machinery, and yet, under the superintendence of Mr. Gooch, the engineer, it is arranged in due order, and so that every foot of space is utilised to advantage.

The whole of the motive power to drive the electric light machinery has been supplied by the well-known firm of Messrs. DAVEY, PAXMAN and Co., of Colchester. The power required to drive this machinery amounts in the aggregate to no less than from 1,300 to 1,500 horse-power. This power is given off by six large engines, which obtain the necessary steam from eleven boilers, the whole offering to the visitor a fine display of first class machinery. Entering from the hall we notice six boilers standing together facing the passage which is parallel with the south gallery. Each of these, we are informed, is 40 horse-power nominal, *i.e.*, they will, when fired with good Welsh coal, easily generate steam of 80-100lb. pressure per square inch. This steam is used for supplying the two pairs of coupled engines, which are together giving off when running each evening about 700 indicated horse-power, or power enough to lift about 10,000 tons one foot high in one minute. These engines each consist of two horizontal fixed engines coupled together and give off the power from fly-wheels fixed on the crankshaft between them. The cylinders of the right-hand engine are 19in. in diameter, with 32in. stroke. The two fly-wheels are each 12ft. in diameter, weighing collectively about 8½ tons. These fly-wheels take 15in. belts. The left-hand engine has cylinders of 18½in. diameter, 32in. stroke, with one fly-wheel of 12ft. diameter, weighing about 5¼ tons. This wheel takes a 24in. belt. Both engines are mounted upon strong, massive, cast-iron girder frames, and are in all respects meeting the requirements of the electric light. The utmost regularity of speed is obtained, and great economy in fuel, for which indeed these and all other engines exhibited by Davey, Paxman and Co. are noted. This is to a great extent due to the excellent way in which the adjustable governor in combination with the patent automatic expansion gear controls the engine, admitting at each stroke of the piston only the exact quantity of steam necessary to do the work. In order to illustrate the working of the governor and the expansion gear we will assume that the driving band of the left-hand coupled engine suddenly broke when the engine was transmitting about 300 horse-power and running at its normal speed of about 72 revolutions per minute. The natural inclination of the engine, having now no work beyond its own friction to do, would be to run considerably quicker, but as soon as the engine speed increases, the speed of the governor also increases, and the centrifugal force causes the balls to rise higher. This movement is transmitted to a link, which in being lifted shortens the travel of the expansion valve so as to admit only steam enough to the cylinder to keep the engine running at its normal speed. It may not be uninteresting to know that the driving belt of the left-hand engine a few weeks ago actually did break under exactly such circumstances as above assumed, and that the engine in less than one revolution resumed its normal speed of 72 revolutions per minute. We should imagine that this is almost unique in the history of steam engines. About 320 out of the 1,300 indicated horse-power necessary to drive the electric light machinery at the Health Exhibition is supplied by two compound engines of different types. One is a horizontal fixed engine with cylinders of respectively 15 and 22½in. diameter provided with steam from two steel boilers of the locomotive type, and the other is a so-called semi-fixed engine with cylinders of respectively 12¼ and 20in. diameter. This engine is mounted underneath the boiler. The stroke of both engines is 24in., and the piston speed about 400ft. per minute. Without entering into any elaborate explanation of all the benefits derived by using a compound engine in preference to an ordinary non-condensing engine we may just mention that whilst in the ordinary non-condensing engine the steam, after having done its work, is exhausted into the air at a pressure considerably above the atmospheric pressure, the steam, after having done work in the small cylinder of a compound engine, is exhausted into a larger cylinder, in which it is allowed to expand until it is exhausted into the air at a pressure of about the atmosphere itself. Consequently the loss of steam which takes place in the ordinary non-condensing engine is avoided in the compound engine. Hence the great saving of fuel and always increasing demand for this class of engines, especially for electric light purposes. The next two engines exhibited by Messrs. Davey, Paxman and Co. are both double-cylinder engines, one a semi-portable engine, *i.e.*, with engine on top of the boiler, and the other of the semi-fixed type, with the engine underneath the boiler, and mounted upon a strong wrought-iron frame. The semi-portable engine has cylinders of 10½in. diameter and 14in. stroke, and will indicate about 80 horse-power, with 80lb. pressure of steam per square inch. The semi-fixed engine has cylinders of 12in. diameter, 14in. stroke, and will indicate about 100 horse-power, with 80lb. pressure. As before mentioned, all the engines are fitted with the improved adjustable governor and the patent automatic expansion gear. Passing from mere description to simple criticism, it seems to us that Messrs. Davey, Paxman, and Co. are devoting a considerable amount of attention to specially adapt engines to the require-

Digitized by Google

ments of electric lighting, and in the long run they will meet with all the success they desire as well as merit. The electric light may be under a shade just now—not at the Healtheries—but its time will come, and then those who have studied its requirements should reap their reward. It might be mentioned here that the shafting is carried in high pedestal bearings, supplied by Mr. Mumford, of Colchester. The engines are supplied with Schonheyder's sight-feed impermeators, in fact in no one respect has anything connected with the motive power been left to chance, but every detail has been carefully considered, with the result that night after night the running of the machinery is carried on without a hitch.

Turning from the engines we will look round at some other exhibits:—

The Edison and Swan Company's installation of incandescent lamps at the Health Exhibition is one of the largest and finest displays of electric lighting yet witnessed in England. It comprises about 1,000 incandescent lamps, of which rather more than one half are Edison lamps, and the rest Swan lamps, distributed as shown in the plan, Fig. 1, from which it will be seen that all the lamps are placed at a considerable distance from the machine room. They are all situated in one direction as regards the machines, and are all on the same circuit, so that visitors to the Exhibition are able to judge what sort of thing an electric light cable to convey current for 1,000 lamps actually is. In addition to the lamps installed by the company themselves, a large number of Swan lamps are used by other exhibitors, making the total of Swan lamps in the Exhibition between 3,000 and 4,000.

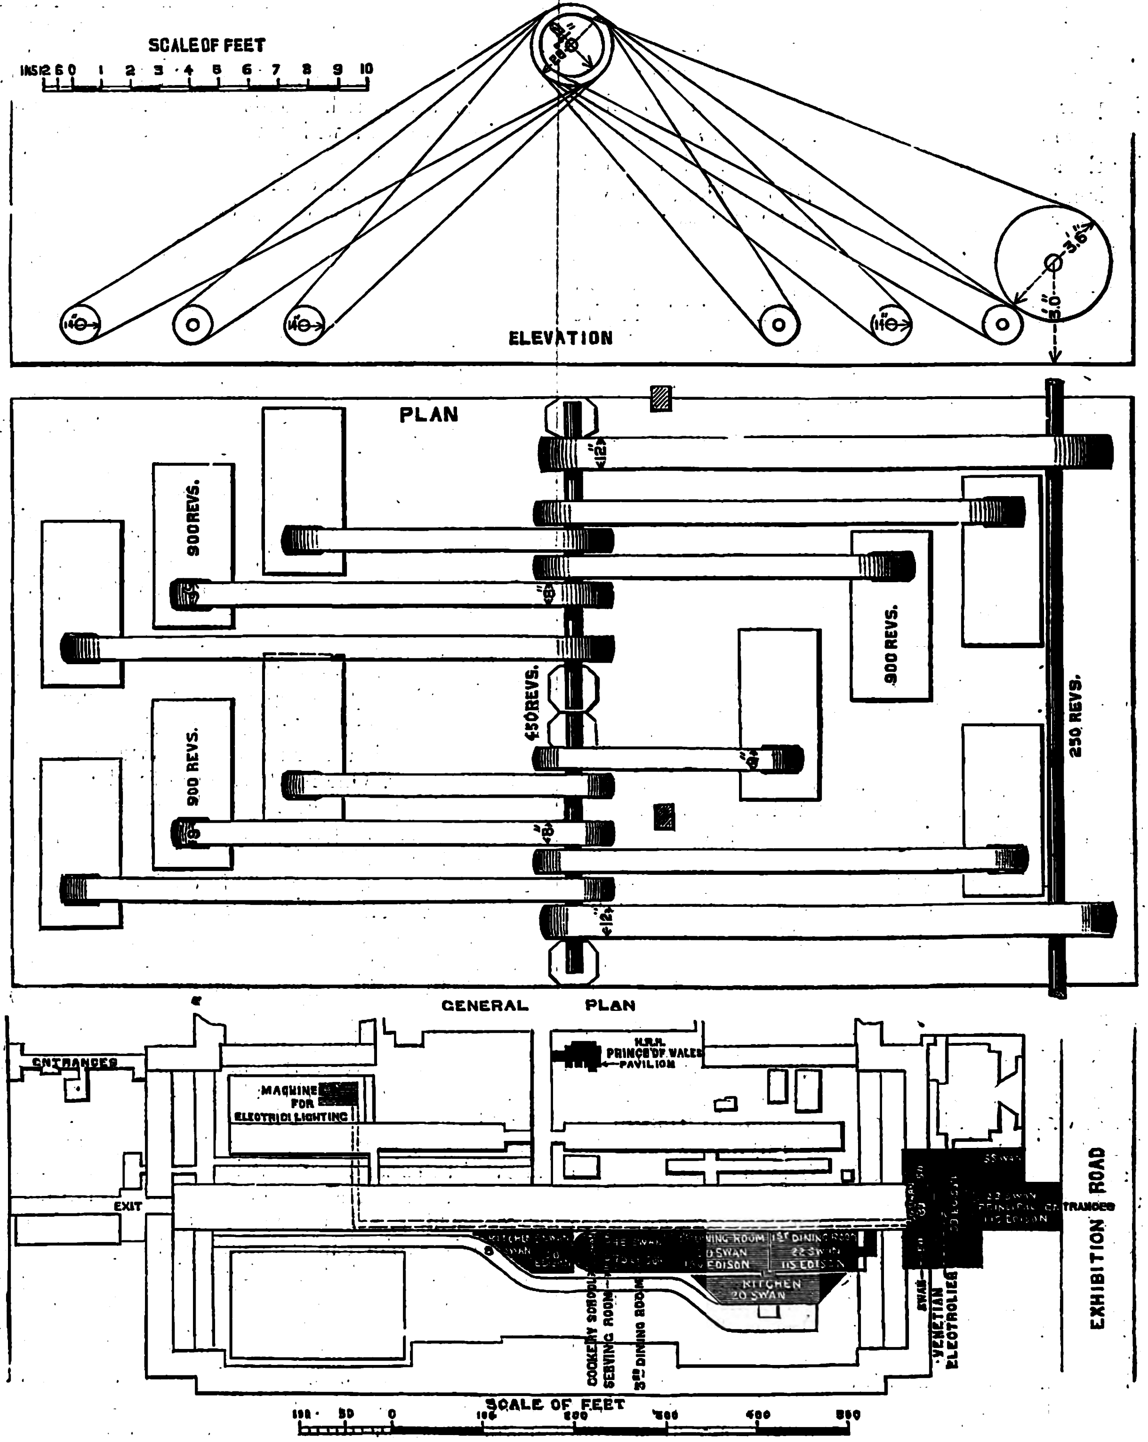

Fig. 1.—Arrangement: Plan and Elevation of Edison Dynamos; Plan of Distribution of Lamps.

For the first 150 feet from the dynamos Edison electric tubing, with an area of 1·054576 square inches of copper, surrounded by insulating compound, and encased in cast-iron pipes, has been employed, each cable being in a separate pipe; for the remainder of the distance—that is, about 650 feet—a

Digitized by Google

similar Edison tubing, but with an area of ·776826 square inches of copper, has been used. The accompanying Figs. 2 and 3 show sections of the two sizes of tubing. The branch cables and wires are all heavily insulated with india rubber, tape, &c., and are all mechanically separated in the manner invariably adopted by the Edison and Swan Company.

The relative resistance of the main and sub-main cables, which measure about ·02 of an ohm, to that of the lamps has been calculated to allow of a fall of potential between the machines and lamps of about 12 per cent., assuming the working load to be not less than 1,000 lamps, all situated at the end of cable.

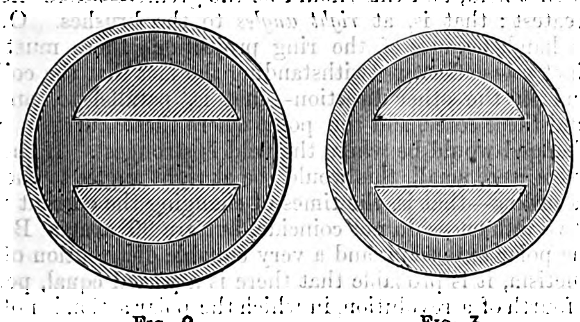

FIG. 2. FIG. 3.

At a distance of 530ft. from the dynamos, a branch cable is taken off for supplying the dining rooms and kitchen, and the cables for supplying the vestibule and the entrance hall are taken off at a distance of 800ft., which may be considered the end of the main cables. It will thus be seen that the main cable forms a loop, of which the total length is nearly a third of a mile, its section being such that at no point with a full load will the current passing through it ever exceed 1,000 amperes per square inch of copper. The lamps, with hardly any exception, are all high-resistance lamps, requiring an

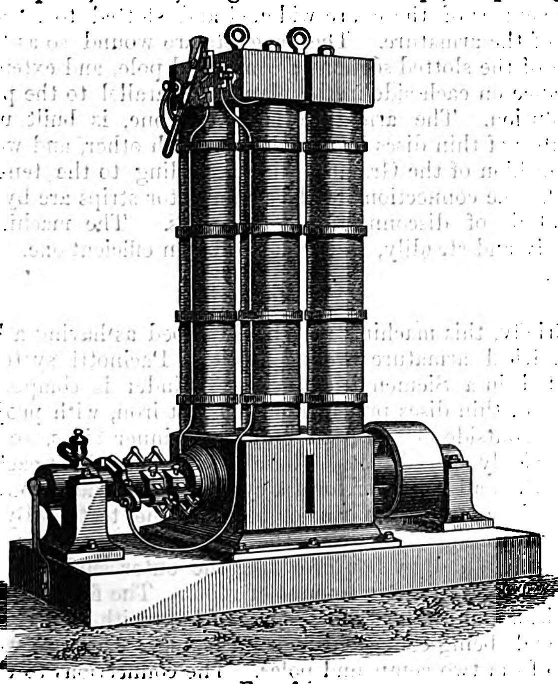

FIG. 4.

electromotive force of 90 volts, those of the Edison type consuming about ·75, and those of the Swan about ·7 ampere each, giving respectively a light equivalent to 16 and 20 candles.

The dynamos, ten in number, are of the Edison L type (Fig. 4), each capable of sustaining 150 lamps, the speed being calculated at 950 revolutions per minute, which will allow a useful margin in case of reduction in speed owing to accidents or other causes. These machines have been used as being the most readily available; but a newer type of dynamo is now (Wednesday) being erected to substitute in place of some of them. Two separate counter-shafts driven off the main counter-shaft have been fixed, each one driving five machines. Each set of five is arranged to be stopped or started, one by means of an Addyman friction clutch, and the other by striking the belt on to a loose pulley. The entire ten machines are connected in parallel circuit to the main cables, and each of the ten can be controlled entirely at will both as regards the field and the main-circuits. The field circuits of all the dynamos are in multiple arc between the mains, in two groups of five

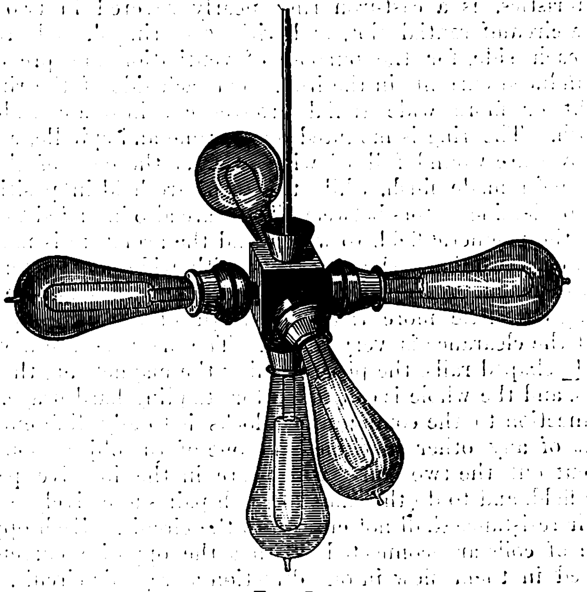

FIG. 5.

each, each sub-division being controlled by a variable resistance thrown in at pleasure. The total field-resistance is two ohms, and the total field-exciting current is about 50 amperes. By this method of throwing in a variable resistance the electromotive force will be so governed as to maintain a constant potential of about 90 volts at the furthest end of the main cables, the electromotive force at the machines being prob-

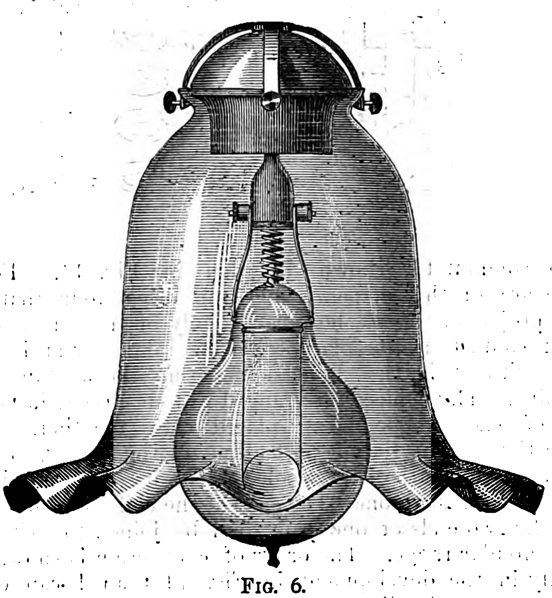

FIG. 6.

ably rather over 100 volts. About 5,000 watts will therefore be expended in the fields.

With the exception of the lamps in Messrs. Verity Bros.' large flower basket chandelier, which will be remembered in connection with the Edison Company's exhibit at the Crystal Palace Exhibition, and those in a handsome cut glass chandelier made by Defries and Son, the lamps have all been placed on simple wooden supports, the majority being arranged in groups of five, as shown in Fig. 5, and fitted with coloured shades, the remainder being fixed as single light pendants, of which an example is given in Fig. 6, which is illustrative of the Swan lamp. There is no doubt but this exhibit is admirable in every respect.

DYNAMO-ELECTRIC GENERATORS.

(CONTINUED FROM PAGE 282.)

*Brush.**

The armature of this machine, one of its most peculiar characteristics, is a cast-iron ring nearly severed in two parts by a circumferential slot, and with three ring-shaped grooves, on each side, for the purpose of ventilation and prevention of induced currents in the iron. On each side of the ring are eight or more wide radial grooves cut into a considerable depth. The ring is mounted on a frame and spindle, and the grooves are wound full of wire, so that the faces of the ring are again made flush, while the turns are held in position by the projecting sectors between. These are also intended to intensify the magnetic field, to which end the armature is mounted between two horse-shoe magnets with wide polar extensions. These magnets are so placed that like poles oppose like, being but little more than the width of the ring apart, so that the clearance is very slight. The magnets are mounted on L shaped rails, the pieces joining the magnets are the bearings, and the whole is calculated for standing hard usage. The connection to the commutator blocks is totally different from that of any other machine, and one of the objects sought is to cut out the two coils, which are in the inactive part of the field, and to do the same for each pair successively, so that their resistance shall not enter into the circuit. Each opposite pair of coils are connected so that the opposite currents induced in them flow in one direction as regards circuit. The ends are then carried through a hollow shaft to eight strips

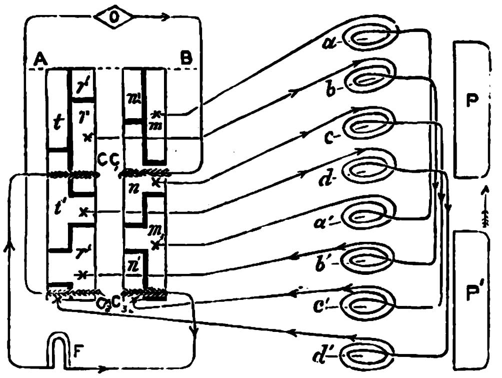

FIG. 14.

of a commutator shown in plan in Fig. 14. Four of these are of the shape *m'*, and the other four that of *m*. The projection on *m'*, however, is only of use for affording a wider contact, as its place could be taken by an insulating piece without in the slightest changing the working of the machine. These pieces are ranged in four circles, in two sets, one of each shape being placed close together, and the projection of the adjacent part filling up the space that is left. The relative length of the whole strip to its projection is about three and a half to one. The ends of the coils are connected, so that the two ends of one pair shall be joined to strips in the same circular range. The order of connection is shown more plainly in the development in Fig. 14 than I can explain. There are four binding posts, and four brushes, C C_1 C_2 C_3, C and C_3 being joined to the field terminals, and C_1 C_2 to the external circuit.

This method of joining makes the current pass in successive stages of a revolution, the order being: first, magnetic field, two pairs in parallel circuit, external circuit, one pair; and then, field, one pair, external circuit and two pairs in parallel circuit; and so on, alternating, six coils being in operation, and one pair cut out for one eighth of a revolution.

The current developed is of high E.M.F., the particular size described driving 16 arc lights, requiring about 35 volts at the terminals of each lamp. The iron heats moderately, but the machine can be run for long times without any trouble.

There seems to me to be an opposed action, which tends to lessen the efficiency of the machine. The opposing poles of the field magnets being of like character, they tend to set up on opposite sides of the ring poles which are in opposition to the primarily induced poles. This is not of so much matter, for the ring being nearly divided, this influence is much lessened. But there are, I think, two directly opposed influences to generate a current besides the internal polar influence. First, there is the passage of conductors through a magnet field, and this should be the greatest where the field is greatest; that is, at *right angles* to the brushes. On the other hand, because of the ring projections there must be a distinct *polar* effect, notwithstanding the fact that the coils are wound in the other direction—that is, parallel to, and not around these cores, and the point where these currents would be changed would be where the field is strongest. If the field magnets were small, this would be at right angles to the commutator line—that is, the times of changing the current under the two influences do not coincide, but are 90° apart. Because of the polar extension, and a very equable distribution of field magnetism, it is probable that there is a period equal, perhaps to a fourth of a revolution, in which the polar action is nothing, and the period of magnetisation and demagnetisation is limited to a zone which embraces but a short distance each side of the commutator line. This machine is part of a system in which the lamp plays an important part. Of this latter I will make some further mention.

* Descriptions and illustrations of the Brush machine have appeared in *The Electrician*, Vol. X., pp. 271, 379.

*Schuckert.**

This is also a high-tension machine. It consists of two vertical frames curved in the middle, and open on one side, so as to allow of the removal of the armature, between the upper and lower ends of which extend two cylindrical field magnets. The centres of these are widened and slotted to receive the rim of the armature. The magnets are wound so as to make each of the slotted sections a compound pole, and extend some distance on each side in the plane, or parallel to the plane, of revolution. The armature is a thin one, is built up of a number of thin discs insulated from each other, and wound in the fashion of the Gramme ring according to the tension desired. The connections to the commutator strips are by screws, to admit of disconnection for repairs. The machine runs quietly and steadily, and seems to be an efficient one.

Maxim.†

Briefly, this machine may be described as having a built-up cylindrical armature wound on the Pacinotti system and rotated in a Siemens field. The cylinder is composed of a series of thin discs punched out of soft iron, with projections on the outside, or on both outer and inner sides, something like widely spaced teeth. These are insulated from each other, and when all together form a cylinder with wide grooves, and with air spaces in the ribs or between the teeth. By having the projections between the coils the magnetic field is intensified, and by not crowding the outer surface, the inner turns are given a fair amount of room. The field-magnets are vertical, and are made of a range of bars with curved middles, the ends being connected by solid plates. They are wound so as to form two compound poles. The connections to the commutator are exactly like those of the Gramme machine.

Sometimes two distinct systems of coils are wound on the same bobbin, and a commutator being placed at each end, and the brushes connected with a junction block, several arrangements of circuits may be made to suit the work required to be done. A very ingenious device is fitted to some of the machines, but one which does not act on a true principle—that is, one to be really commended. The brushes are mounted in a movable arm, which can be rotated around the spindle of the armature so as to shift the line of contact. This is connected by gearing to the middle of three cog-wheels, which are geared together. The upper and lower wheels are on the same spindles as two ratchet wheels, between

* Vide *The Electrician*, Vol. XI., p. 519. † *Ibid*, Vol. VIII., p. 228

Digitized by Google

which is suspended a tongue, which has a to-and-fro motion imparted by a rock-shaft and pulley deriving motion from the armature spindle. If the tongue is lifted up it engages the upper wheel and pushes it forward step by step, imparting motion to the commutator brushes. If the tongue drops it engages the other wheel, and the opposite motion is imparted. Two sets of magnets, whose keepers are regulated by springs, are placed on the top of the machine; one is for use in series and the other on a shunt. To one of these is hung the tongue and the keeper regulated to keep the tongue clear when a certain potential exists at the magnet terminals. This arrangement works very well where small currents are used, and may be of service when a machine is used for exciting another, as is done in the Maxim distribution; but it is evident that the proper place for the brushes is at the point of least sparking, and, were heavy currents used, much trouble would result. The machine is compact, well made, and efficient.

*Bürgin.**

The field-magnets are of cast iron, cast in two pieces, fitted together and bolted at the flanges, and accurately bored out to receive the armature with a certain clearance. The armature is built up of eight hexagonal hanks of soft iron wire wound on a small star frame, which is strung on the spindle. The spaces between the arms of the star frame are wound with insulated wire, the coils being thicker in the middle to bring the general shape nearly that of a circle. The hanks are strung on so that any hank is one forty-eighth part of a circumference in advance of the next. This brings the last hank that amount behind the next succeeding one at the other end. The last ends of the coils at the commutator end of the armature are connected with the advance ends of the coils at the other end, which are but one forty-eighth removed. The first and last ends of the intermediate coils are connected seriatim, and the bights of all connections joined to the strips of the commutator in succession, there being as many strips as there are coils. The brush-holders are ingenious, and the whole machine is mechanically thoroughly well made, is compact and easily handled, and fairly efficient. I think it would be better not to cut out as many coils as is done by the practice of using a flat brush in contact with five or six sections of the commutator. In removing the armature care must be taken not to bruise the coils, as may easily be done.

INTERNATIONAL INVENTIONS EXHIBITION, 1885.

The preliminary arrangements for the Inventions Exhibition, which is to succeed the "Healtheries," as the latter did the "Fisheries" last year, are already settled, and a meeting of the executive was held on Wednesday to consider the division of space and other matters. The exhibits will be classed under two grand divisions, the first consisting of apparatus, appliances, processes, and products, invented or brought into use since 1862, the second consisting of music. These divisions are in turn subdivided into 34 groups, each group containing a separate class of exhibit. Among the groups which will probably form the principal features of interest are Mining and Metallurgy, comprising the machinery used and actual processes of quarrying, foundry work, &c.; Engineering, together with the making of roads, docks, harbours, &c.; Railway Plant, Aeronautics, Hydraulic Machinery, Electricity, Firearms, Explosives, Paper, Printing, and Stationery, and Photography; while under the division Music will be included Instruments of the Ancients and Historic Collections. It will be seen that a very much larger number of machines and machinery in motion will be included in next year's show than has before been attempted. In the grounds the various processes of mining and ore washing will be exhibited and explained.

EXPERIMENTS ON THE EFFICIENCY OF INCANDESCENT ELECTRIC LAMPS.*

BY HORACE B. GALE.

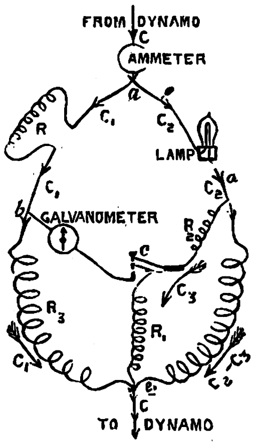
(CONTINUED FROM PAGE 258.)

PART II.

There were thus two simultaneous measurements of current to be made. As there was, however, but one reliable ammeter at the writer's disposal, an arrangement was devised by means of which the strength of two electric currents—for example, the current through the lamp and the current through a resistance coil in derivation with the lamp—could be compared with each other by means of the Wheatstone bridge.

As this method is the most accurate one known to the writer for comparing strong currents of electricity, and as it requires no special apparatus except an ordinary Wheatstone bridge, it will be described in full, in the hope that other experimenters may find it useful. The arrangement will be understood from the accompanying diagram.

The current C, from the dynamo, passes through the ammeter, and divides at the point *a*, between the two branches, *abe* and *ade*, of the circuit, one portion of the current, whose strength is denoted by C_1, passing through the resistance coil, R; and the other, C_2, passing through the lamp, which stands in its place at the end of the photometer bar. *be* and *de* are two coils of heavy copper wire of small resistance, but exactly equal to each other, the resistance of each being denoted by R_3. After traversing these coils, the currents C_1 and C_2 unite at *e* and return to the dynamo. *de* and *ce* are two arms of the Wheatstone bridge, whose resistances are marked R_2 and R_1. The bridge proper, containing the galvanometer, is from *b* to *c*, the circuit through it and the resistance coils, R_2 and R_1, being closed in the ordinary manner by a double key at *c*. When the key is closed, a small portion of the current C_2 is shunted around *de* through the coils R_2 and R_1 of the bridge. This current is denoted by C_3. Then the current passing through the portion *de* of the circuit is $C_2 - C_3$, as indicated in the diagram.



In using the apparatus, the arm R_1 is made a certain fixed resistance, say 1,000 ohms. The resistance R_2 is then adjusted until, on pressing down the key, no current passes through the galvanometer. The points *b* and *c* are then at the same potential. It follows that the difference of potential from *b* to *e* is the same as the difference of potential from *c* to *e*. But the difference of potential, or the electromotive force, between two points of a circuit is the product of the current and the resistance between those points.

Therefore, $C_1 R_2 = C_3 R_1$, or $C_3 = \frac{C_1 R_3}{R_1}$.

Our purpose, it should be remembered, is to ascertain for each lamp the variation in candle-power and current strength as the electromotive force is increased, for which object it is necessary to vary the candle-power by a series of steps, and take simultaneous observations of the current and electro-

* Reprinted from *Van Nostrand's Engineering Magazine*.

Digitized by Google

motive force at every point. Knowing in each case the value of the total current C, if we can find the ratio between the currents C_1 and C_2 traversing the two main branches of the circuit, we shall have not only the current flowing through the lamp C_2, but, by multiplying the resistance of the branch *abe* by C_1, we may obtain the electromotive force.

Our object is now to find the ratio between the currents C_1 and C_2. It is evident that the electromotive force from *d* to *e* is equal to the sum of the electromotive forces on *de* and *ce*; or, using instead the products of the currents and resistances on these branches, we have

$$(C_2 - C_3)\, R_3 = C_3\, (R_2 + R_1)$$

Substituting for C_3 its value $\frac{C_1 R_3}{R_1}$ previously found, we have

$$\left(C_2 - \frac{C_1 R_2}{R_1}\right) R_3 = \frac{C_1 R_3}{R_1}\left(R_2 + R_1\right).$$

Clearing of fractions,

$$C_2 R_1 - C_1 R_3 = C_1 R_2 + C_1 R_1.$$

Transposing and combining,

$$C_2 R_1 = C_1\, (R_1 + R_2 + R_3)$$

or

$$\frac{C_2}{C_1} = \frac{R_1 + R_2 + R_3}{R_1}$$

When the resistance R_2 of each of the equal coils of large copper wire is so small in comparison with the other resistances that it may be neglected, we may write

$$\frac{C_2}{C_1} = \frac{R_1 + R_2}{R_1}.$$

Expressing this equation in words, we say that the current passing through the lamp is to the current passing through the resistance coil R_1 as the sum of the resistances of the fixed and variable arms of the bridge is to the resistance of the fixed arm.

Having thus found the ratio between the currents in the two branches of the circuit, and knowing also by observation of the ammeter the value of the total current C, which is the sum of the two portions C_1 and C_2, it is an easy matter to find the absolute value of the current in each branch of the circuit. The electromotive force on the branch *abe* is thus computed by multiplying the resistance of that branch by the current passing through it, and this gives us the electromotive force between the terminals of the lamp, after deducting the trifling amount necessary to overcome the resistance of the wire in the branch *ade*. The horse-power expended in the lamp is then found by multiplying together the values of the electromotive force and the current, and dividing the product by 746.

The resistance R_2 of each of the equal coils *be* and *de* was in this case only 0·424 ohm, and the fixed arm of the bridge was generally made 1,000 ohms. The value of R_3 was not neglected in the calculations, but as the error that would have been caused by its neglect would be in the fifth decimal place, its use was an unnecessary refinement. The above method of ascertaining the electromotive force and current of an incandescent lamp possesses several practical advantages over any method in which the lamp itself forms one arm of a Wheatstone bridge. First, no special apparatus is required; second, instead of passing the entire current constantly through the coils of the bridge, we may, by adjusting the resistance of the fixed arm, reduce the current to a strength just sufficient to obtain deflections of the galvanometer; third, while the current passes constantly through the lamp, the circuit through the bridge is closed only when the key is depressed. It was found that with ordinary care the ratio of two currents could be thus ascertained accurately to four decimal places.

Precautions Observed.

The accuracy of this method of comparing currents evidently depends upon the exact equality of the resistances of the two coils, *be* and *de*. They consisted of No. 6 copper wire, covered with paraffined cotton braid. Such wire will carry fifty amperes without warming perceptibly, and as the currents used in these experments rarely exceeded two amperes, there was no danger from unequal heating of the two coils. Before beginning the tests, these coils were adjusted to equality by means of the Wheatstone bridge, the final adjustment being made by a sliding contact resting on the wire, with the galvanometer so sensitive that a variation of $\frac{1}{100}$ of 1 per cent. was perceptible. Their equality was again tested at the close of the work. To insure that the two coils should always be at the same temperature they were wound on a frame into a single loose coil.

It was also important that the resistance of the coil R should not be altered by the passage of the current. This coil consisted of about 200 ohms of No. 18 German silver wire. It was wound with silk, and hung loosely over a frame, so that the air could circulate freely through it. The current traversing it never exceeded one ampere, and was generally much less, so that it did not warm perceptibly. This coil was also arranged so that it could be instantly taken out of the circuit and connected with the bridge, and its resistance measured at intervals during the progress of a test. It was found that the error due to the heating of this coil never exceeded $\frac{1}{10}$ of 1 per cent.

This part of the work was carried on at times by two observers, one of whom observed the ammeter and the bridge, while the other took simultaneous observations with the photometer. At other times the writer alone took all the observations, reading first the ammeter and the bridge, then the photometer, and then, to ensure that no change had occurred, again reading the ammeter and bridge.

The Photometric Tests.

In these, and all the observations with the photometer, five or more readings were taken at every point, and their mean used as the true reading. After considerable practice, these photometric readings could be made quite exactly.

In these measurements a Carcel lamp burning colza oil was used as a standard of light, the employment of a candle for this kind of work being impracticable for various reasons. In order to obtain as steady a light as possible from the Carcel the top and bottom of the flame were diaphragmed off, and only the middle, or least variable portion, was used as a standard. The width of the aperture was adjusted so that the lamp gave an average of about ten candle-power. Though the light of the Carcel lamp was not subject to sudden fluctuations, like that of a candle, and would remain practically constant during a single series of observations, there was nevertheless a slow variation, due to the gradual crusting over of the wick, and to differences in the temperature of the room at different times The error from these causes was eliminated, as far as concerned the variation in the candle-power of each individual lamp, by taking always a series of observations in which the candle power was gradually increased, and immediately following it by another series in reverse order in which the candle-power was decreased to the starting point.

The results of these observations, then, while showing accurately the relative changes in the candle-power of each lamp for given variations in electromotive force and current, could not be implicitly relied upon for comparisons between different lamps.

Accordingly, while the electrical quantities were here obtained in absolute measure, it was not attempted in this part of the work to measure candle-power with absolute accuracy, but merely to obtain the data from which a curve could be constructed for each lamp showing on some arbitrary scale the variation in candle-power with different electromotive forces.

The remaining problem was to reduce all these curves to the same absolute scale. One of the lamps was next run for some eight hours at about its rated candle-power, and very carefully compared with a standard candle, measurements being constantly taken of the candle-power, current, and electromotive force.

The candle was hung on the arm of a balance made for the purpose, and the time required for the consumption of each twenty grains was noted, and the proper corrections made. Several standard candles were used, all of which were obtained from Tufts Brothers, Boston, and burned very nearly 120 grains per hour.

Digitized by Google

The average of the above observations gives us the absolute candle-power and electromotive force for a single point on the curve of this individual lamp. To get the entire curve into absolute measure it is simply necessary to change the scale of the diagram to conform to this measurement. Having done this, we have two correct curves for a single lamp, in which abscissas represent volts, and ordinates represent, in the one curve, amperes of current, and in the other candle-powers.

Direct Comparison of Efficiencies.

The remaining curves were next reduced to the same absolute scale by a system of direct comparisons of the lamps at opposite ends of the photometer.

The method consisted in placing at one end of the photometer bar a lamp whose curves of candle-power and current had been already obtained in absolute measure, and at the other end the lamp whose curve was to be deduced to that standard. The lamps were then run at their rated candle-power, and their relative brilliancy ascertained by the photometer. If the two lamps were the same kind, or required about the same current strength to bring them to their normal brightness, they were connected in series, and the strength of the current through both ascertained by the ammeter. In other cases they were placed in multiple arc, adjusted to the proper relative candle-power by a variable resistance in one branch of the circuit, and the current through each branch measured by the bridge method.

By thus obtaining accurately the ratio of the currents flowing through two different forms of incandescent lamps while they are running at a given relative brilliancy, and knowing from our previous experiments the ratio of the resistances of the two lamps with these given currents, the *relative efficiencies* of the lamps are ascertained independently of the absolute measurements.

Having obtained in this way the relative candle-power of two lamps at two given points on their respective curves, it is simply a matter of altering the scale of one diagram to bring both to the same absolute standard.

The great advantage of this comparative method lies in the fact that as but one absolute determination of candle-power is made, this one can occupy a good deal of time, and be made with great care, and further, that as the *relative* efficiencies of the different lamps are ascertained by comparing the light of one lamp directly with that of another, while at the same time the relative values of the currents and electromotive forces are obtained by direct comparison, any errors that may be made in the absolute measurements will affect all the lamps alike, and *cannot alter the relative efficiencies.*

It is, of course, impossible in a brief memoir to describe all the details and precautions against error employed in work which extended over a period of about two months. Therefore, having given a sufficient account of the methods used to enable one to form a fair idea of their reliability, we now pass on to consider

The Results.

The first result of the experiments just described was a series of curves, showing for each individual lamp tested the value of the current strength in amperes, and the candle-power, for a range of electromotive forces, from the point where the carbon is barely incandescent to a point where the lamp is given four or five times its normal candle-power. These results were carefully averaged for each class of lamps. The method of averaging was to take lamps of the same kind, not at the same candle-power, but at the same electromotive force, as they are intended to be run in practice, and find, from the curves for the separate lamps, the values of the candle-powers and amperes at intervals of five volts. Then the average of these values was taken at each point, the average resistances being computed by dividing the number of volts by the average number of the amperes. This gives to all the quantities the same mean values which they would have in an actual case where the lamps are run in multiple arc.

The average results have been represented graphically, and are shown by the diagrams hereto annexed. The curves of equal illumination have already been referred to. The next curves plotted were intended to show, for each class of lamps, the relation between the electromotive force, current, and resistance. [Diagrams were drawn to show the results.] Some of these diagrams were constructed on what the author thinks a new plan, which he describes in these diagrams. Electromotive force in volts is laid off on the horizontal scale at the top, and the curve for each lamp is so constructed that the height of any point on it represents on the vertical scale at the right the resistance of the lamp in ohms, under the corresponding electromotive force. It is also desirable to show the current which will flow through the lamp under a given electromotive force, and also the resistance of the carbon when a given current is passing through it.

(TO BE CONTINUED.)

LEGAL.

Metcalf v. the London and Globe Telephone Company.

This case came before Mr. Justice Pearson in the Chancery Division of the High Court of Justice a few days since. It was a motion on behalf of the plaintiff that the defendants might be restrained, by injunction, from carrying out a certain provisional agreement dated the 24th of June, 1884, and made between the United Telephone Company and the defendant company for the purpose of effecting a sale from the defendant company to the United Telephone Company. It appeared that a meeting of the shareholders of the defendant company had taken place on the 16th July, at which it was proposed that the directors should be at liberty to carry out the sale of the company to the United Telephone Company on the terms of the agreement, with such modifications as they should think beneficial under the circumstances. After a long discussion, an adjournment of the meeting was moved till the following Monday. This motion was put to the meeting by the chairman, and, on a show of hands, was declared to be carried. A shareholder then demanded a poll upon the question of adjournment, and this having been put into writing was carried out, when there appeared in favour of the motion 6,505 votes against 16,640 votes. The chairman thereupon declared that the motion for the adjournment of the meeting was negatived, and a resolution was then carried in favour of the proposal to carry out the sale. The present motion was resisted upon the ground that the meeting of the 16th July was irregular, and that the resolution approving of the sale was not legally passed.

Mr. Everitt, Q. C., and Mr. T. L. Wilkinson appeared in support of the motion; and Mr. Higgins, Q.C., and Mr. Beale for the defendants.

Mr. Justice PEARSON, after discussing the technical objections which had been raised to the validity of the course taken at the meeting of the 16th of July, came to the conclusion that the resolution had been legally passed, and that the defendants—the directors of the London Telephone Company—were at liberty to carry out the agreement for sale to the United Telephone Company. The motion was therefore refused, with costs.

The United Telephone Company v. Graham.

In the Chancery Division of the High Court of Justice, on Friday, the 1st inst., on the application of Mr. Fletcher Moulton, the Vice-Chancellor granted a perpetual injunction against the defendant's manufacturing, selling, supplying, letting on hire, or using any carbon telephone transmitters, or Blake telephone transmitters, or any other instrument manufactured according to, or in a manner only colourably different from the specifications of the plaintiff company's various patents.—The defendant appeared in person, and offered no opposition.

United Telephone Company v. London Globe Telephone Company.

In the High Court of Justice, Chancery Division, before Vice-Chancellor Bacon on the 4th inst., an action was brought by the plaintiff company for an infringement of the Edison patent.

Mr. Moulton appeared for the United Telephone Company, and informed his lordship that the defendants had agreed to the minutes of the judgment with the exception of one slight verbal admission which the Registrar was to decide.

Judgment was given accordingly.

In re the Great Western Electric Light Company.

On the 6th inst., in the Chancery Division of the High Court of Justice, Mr. Justice Day made an order for the reduction of the capital of this company (£250,000 in shares of £5 each) by in effect turning the £5 shares into shares of £2 10s.

Mr. Phipson Beale appeared.

COMPANIES' MEETINGS & REPORTS.

Anglo-American Telegraph Company (Limited).

The ordinary general half-yearly meeting of the proprietors of this Company was held at the City Terminus Hotel, Cannon-street, on Wednesday last under the presidency of the Right Hon. Viscount Monck.

The SECRETARY (Mr. T. H. Wells) read the notice convening the meeting and the minutes of the last meeting.

Mr. T. SMITH (of York) then requested that the report of the directors should be read paragraph by paragraph, which was accordingly done by the secretary.

The CHAIRMAN afterwards said: Gentlemen, it now becomes my duty to propose to you the only resolution that the Board will submit to you at this meeting: "That the report of the directors with the accompanying statement of accounts to the 30th of June, 1884, submitted to this meeting be and the same are hereby received and adopted." Gentlemen, before I proceed to say anything upon that resolution a melancholy task devolves upon me. You have heard in the report that we have sustained the loss of one whose countenance at these meetings had become a familiar feature, and who exercised a great and a justly great influence upon the proceedings of your Board. The late Hon. Robert Grimston was no common man. His almost unrivalled experience in the management of telegraph companies gave him a grasp of the general principles upon which they should be conducted. His uprightness and honesty of purpose and his exactness in the transaction of business insured for his opinions a favourable reception even on the part of those who differed from him, and his energy and force of character enabled him to put forward his views on every subject with vigour and effect when it was necessary to do so. Gentlemen, if it had been thought expedient on other grounds to appoint a director in his place, it would have been difficult if not impossible to find one who would adequately fill the position that he occupied at this Board. Having paid this unavailing and imperfect tribute to the memory of one for whom, after a long period of association with him on your Board, I entertained a profound respect and a deep personal regard, I now come to deal with the subjects mentioned in the report. The first matter to which I will allude is the condition of your property. We are, as you know on the eve of another of those great competitions which have exercised so baneful an influence upon our interests, but whatever the result of that competition may be, we, at all events, embark on it under good auspices. Your property is in perfect order, and although the earnings of the last half year do not compare favourably with those of the corresponding half of last year, the diminution is not due to any inefficiency in the performance of the functions of the Society, but rather to the depression in trade which still exercises its injurious influence upon all undertakings of this description. Gentlemen, with regard to one resolution which was proposed, but not adopted, at the last half-yearly meeting, namely, with reference to economy, I am glad to inform you that what was said by my noble friend on my right (the Marquis of Tweeddale) on that occasion has been realised and practised during the half year of which we are now discussing the results. The expenditure of that half year is £4,805 14s. 11d. less than that in the corresponding half of 1883. I do not for one moment mean to say that you are to look forward to anything like a corresponding reduction of expenditure in future half years, because that would land us in a *reductio ad absurdum* in the end of managing our affairs without any expenditure whatever. But I think it shows you that your Board are attentive to the question of economy, and desire by every means in their power to reduce the outlay at which your work is done. Well, gentlemen, I do not think there is anything else of what I may call non-contentious matter with which I need trouble you. I now come to what I suppose I may say will be the great bone of contention at this meeting, namely, the amount which should be laid by to the renewal fund. Now, gentlemen, I have been for a great many years chairman of this Company, and I think I have lived my life during that period to some discredit if I cannot call upon you to admit that I have always been ready whenever I could see my way clear to do so consistently with my duty to the Company to consult the wishes of the shareholders in all matters which they brought before me. But gentlemen, with regard to this matter of the amount to be laid by to the renewal fund, I cannot bring myself to concur with the resolution, or recommendation rather, that was passed at the last meeting ["Resolution"]. I hope you will hear me patiently, and give me credit for sincerity in stating the reasons why I should have come reluctantly to that conclusion. Now it sounds almost like a truism to say that in order to earn a dividend, or to earn money, you are bound to take proper measures to keep your plant in order. That is a truism, of course, in reference to all undertakings. But let me say that, looking to this matter merely from a shareholder's point of view, you are bound as a natural law which applies to all enterprises to be perfectly certain that you are in a position to maintain not only plant sufficient to earn a dividend, but an amount of plant equal to retain the income which you now possess. Gentlemen, you are all aware that you are operating not as an ordinary company. You do not receive your income direct from your customers. You receive only a share of the gross income derived from telegraphy across the Atlantic by what is technically termed the "pooling" of three companies. Now, the conditions upon which you obtain that income are that you should maintain in full efficiency not merely a cable but a particular number of cables, the same number which you had when you entered into that agreement, and if you take any step which will prevent you from carrying out that arrangement, and a catastrophe should happen which you would be unable to meet, your income would fall beyond what any competition could deprive you of. Well, gentlemen, that is looking at the question from merely a shareholder's point of view, and with reference to dividend. But you must forgive me for saying that your directors are compelled to look at this question from another point of view. You are bound by your interests, as I said before, to keep your property in such a condition as to earn money for you. Your directors are bound by the law of the land so to manage your income that the first object attained should be the maintenance of your property as a going concern in proper order. Now, gentlemen, that I believe is law. I have beside me our legal adviser, who will tell you so, and that I believe is sound law; and let me add that it is sound law in a manner which is very disagreeable to directors, because recollect the majority of the shareholders by a vote cannot shield the directors. If such a catastrophe as that which I have alluded to should take place any shareholder might bring an action against the directors, and make them personally responsible for the dividend which they had declared in prejudice to that contribution towards the renewal fund which on reasonable grounds is so necessary to maintain your plant in a proper condition. Any shareholder who was discontented, on finding that either the revenue derived from the joint-purse arrangement was reduced or that you were obliged to raise money by debentures or otherwise for the renewal of the plant, might bring an action against the directors ["No, no"] and make them personally liable. It is all very well to say "No," but the highest authority at our English bar has advised that that is the law of the land, and I do not expect that any body of shareholders will call upon directors to put themselves in such a position as that. Gentlemen, we have anxiously and carefully, and with the utmost desire to comply with the wish of the shareholders, looked into this question. I entirely decline to commit myself to any statement as to what is the proper life of a cable for this simple reason, that we have only had the experience of 19 years in deep sea Atlantic cables, and that during that period we have had only one cable which has reached the age of 15 years, and that that cable has cost us a large sum of money to maintain it in its present position. With only these facts it would be absurd for me to attempt to give you any definitive statement as to the life of a cable. All that we can do is to obtain the advice of the best experts we can find. We have some members on our own Board who, I believe, have as good an opinion on the subject as any man living, and we have taken the advice of others outside who are equally competent, and the advice they gave us is embodied in this paragraph of the report:—"After very careful consideration of the proposed reduction in connection with the condition of the cables, their present age and probable life, and taking the most reliable opinions which could be procured on the subject, the directors have arrived at the conclusion that, for some time to come, no diminution can be made without great injury to the prospects and property of the Company, and seriously jeopardising the proportion of gross receipts accruing to the Company under the existing joint-purse agreements." After the most careful consideration, do you think it is possible that we could maintain in a court of law that we had exercised reasonable discretion in the amount which was set aside to the renewal fund if the question was raised that we had not set aside enough. I do not think we could, and we have come deliberately to the conclusion that we cannot reduce that amount for some time to come which we have hitherto set aside to the renewal fund. Now, gentlemen, let me say that has been the decision of your Board, and by that decision the Board and myself are prepared to stand. But, gentlemen, that is not only the decision of your Board. There is a phrase that has lately been brought into use, "legislation by pic-nic," and "legislation by consulting the polls." Now we do not attempt legislation by pic-nic, and we do not want to consult the polls; but we have an intermediate system by which we can very easily ascertain the opinions of the great body of our constituents. Nothing can be plainer, I submit, than the manner in which the issue on this subject is stated in the report. We state, as I have already read to you, that we cannot faithfully reduce the amount that has been hitherto set aside for the renewal fund, and we say "the directors look with confidence to the great body of the proprietors for their co-operation and support in the maintenance of the renewal fund, upon the sufficiency of which the whole existence of the Company depends." Gentlemen, we have put that report before the shareholders. We have asked them to send us their opinion of it in the shape of proxies, and this is the result [showing list of proxies received]. Under these circumstances, gentlemen, backed, as we feel we are by the great body of the shareholders of this Company, we cannot refuse to give effect to their wishes and to our own determinate conclusions, and though I reluctantly differ in opinion from any body of shareholders of the Company, I am bound to say that the Board and I myself are steadily resolved to maintain at present the amount hitherto set aside to the reserve fund.

The Most Hon. the Marquis of TWEEDDALE seconded the motion.

Mr. A. J. BAKER wished to ask how much the proxies that had been received represented, and whether the holdings of the Globe Company and the Submarine Trust were included amongst them?

The CHAIRMAN replied that the amount of stock represented by the proxies was about two and a-half millions, and begged to suggest to the hon. proprietor that it was a very invidious sort of thing to lead it to be inferred from what he said that the Globe Company had not as great an interest as anyone else in maintaining the dividend.

Mr. BAKER dissented from this view on the ground that the Globe Company made up its dividend from a number of other stocks.

Mr. MOON asked whether it would be desirable to give the meeting an estimate of the probable cost of a new cable, supposing that one of the present ones fell into disuse? It might be of use to answer the question in considering the amount necessary for the renewal fund.

Mr. PRUST wished to remind the shareholders that the renewal fund was now £640,000, and it would soon be over a million. Now, the stock of the four cables stood in the market at about two millions, although the original price would have been about seven millions. That no doubt was

Digitized by Google

a very deplorable state of things. It was a fact, he thought, that it was their enormous reserve funds which caused the stocks of banks to stand so high in the market, and therefore, considering the competition that was likely to take place, there was no doubt that the reserve fund would be their best friend. He really thought, however, after all was said and done that £3,000 a year for directors did appear a very large sum for the personal attention they occasionally gave to the affairs of the Company, and more especially when he observed that they were all wealthy men. When the majority of the shareholders were getting nothing, and their property was disappearing, the amount was too large.

Mr. JACKSON thought that it was a most important question to the majority of the shareholders to know what was the limit they intended to fix the renewal fund at. The sixth paragraph said, "The Company's system of cables is in good working order." He thought that under these circumstances, and as a matter of justice to the proprietors, the time had now come when some return should be made to them on so large a proportion of the capital as was represented by the reserve fund. The last paragraph which the Chairman had quoted from the report said, "The directors look with confidence to the great body of the proprietors for their co-operation and support in the maintenance of the renewal fund, upon the sufficiency of which the whole existence of the Company depends." Now he regarded that as a rather exaggerated statement, and one with which the shareholders would hardly agree. If that were so where would be the railways and other undertakings which had no reserve fund or renewal fund? He did not mean to say that the telegraph business exactly resembled these, and admitted that there was a necessity for a renewal fund; but in view of the present condition of this Company he thought it was about time to limit it, and give the shareholders some return on their capital. He did not hesitate to say he was most anxious to support the Board, and was opposed to any division of feeling between the Board and the shareholders if it could be avoided. Nobody would regret more than he would that an eminent directorate like theirs, containing as it did gentlemen of the greatest experience and standing, and having a long connection with telegraph business, should be interfered with in their conduct, as most assuredly would be the case if the policy of the Board was insisted on. It was a monstrous assertion to say that upon the sufficiency of the maintenance of the renewal fund the existence of the Company depended. Did it not depend on the enterprise and development of the resources of the Company? It was an insult to men of business in the City of London to say that was the foundation of all success in business. The position of the Company was unsatisfactory, and a better result ought to be shown. He did not say he could do it, but that was no answer to him. The fact remained that the business had steadily declined for years.

Mr. T. SMITH (of York) moved "That, inasmuch as the directors of the Anglo-American Telegraph Company have failed to carry out the resolution passed by a majority of the proprietors at the annual meeting held in February last, this meeting rejects the report now submitted so far as relates to the sum of £75,000, set apart to the renewal fund." At that meeting in February the shareholders were told that the directors had nothing but the interests of the Company at heart, and that if he withdrew the amendment he then proposed, which was similar to that which he had just read, the directors would give effect to the resolution with regard to the renewal fund which was passed by a majority of proprietors at the large meeting he referred to. [Voices: "It was only a recommendation."] He begged to say that it was stated to have been passed. He understood then, and the shareholders also believed, that that resolution would be carried out. But to his surprise, in the middle of April he thought it was, they had carried forward £37,500 to that account. The directors spoke about having the interest of the Company at heart. Was that their way of expressing it? It was the very thing that sent the stock down, and the price of stock was a barometer of the credit of a company. In that very room their worthy chairman, the Marquis of Tweeddale, told him when he brought the matter forward on that occasion that the purport of the resolution was a valuable suggestion, and would have the attention of the Board. He thought they would have had some result from that promise before now, but no result had followed. The directors asked for the confidence of the shareholders. He had come to London for many years, and he had heard many reports about the "confidence trick," but the way the Board were dealing with the renewal fund beat all the "confidence tricks" he had ever heard of. There was just now a confidence trick, consisting of a renewal fund of £640,000. He did not see how they got it, but it was there. It was put down in the accounts. Well, some fine morning they would find it would have gone over to their friend the Maintenance Company. They would find that they would require some new cable laid or some extraordinary cable mending, and that was where it would go. They had paid the Maintenance Company, he believed, £600,000 within the last few years. The Maintenance Company were not satisfied with a poor 3 per cent. They must have their 20 or 30 per cent., with a bonus besides. This Company formed a sort of feeding ground for it—nothing else. One of their directors was the Chairman of the Maintenance Company, and he had very grave doubts whether he had authority to sit at the Board as a director. The Companies Act of 1862 said that the directors were the servants of the proprietors, partners, or shareholders of a Company.

The SOLICITOR: What clause is that?

Mr. SMITH replied that he did not know. He was not a lawyer.

The SOLICITOR said that he was, and that that was not in the Act at all. He then read Article 104 of the Articles of Association, specifying the powers of the directors in regard to setting aside such sums as might be necessary in their judgment to meet any claims that might arise, or to provide for new works or other purposes.

Mr. SMITH said that the directors were locking up too large a sum of money, and they ought not to put by more than £100,000 per annum at the very most, which would amount in a very short time to a million of money. He concluded by formally moving his amendment.

Mr. BLUMENTHAL seconded it.

Mr. VEARS thought that if the Board acted on the suggestion of the previous speaker they would be taking a step in the right direction.

Mr. RAMSDEN begged respectfully to propose that the amount of the renewal fund should be limited to £700,000, and that no addition be made to it, except by way of interest, until the deferred shareholders had received 12 per cent. interest.

The CHAIRMAN: I am afraid you must wait till the other amendment is disposed of.

Mr. GRIFFITHS thought that the argument advanced by the Chairman as to the legal responsibility of the Board in this matter showed a somewhat unfortunate bias in the minds of the directors, and one not altogether correct from a legal point of view. The directors were not responsible for a fair exercise of their judgment. They were responsible only for fraud and gross missmanagement—amounting to fraud—nothing more. That point of law was clear, and he hoped the directors would not from any personal desire of keeping themselves free from legal proceedings be restrained from fulfilling their duty to the shareholders, or adopting a course which might be injurious to the property of the Company. One shareholder asked what would be the cost of a new cable. He thought he would not be wrong in saying that it would be about £500,000.

The SECRETARY: Much more. It is close on £600,000, and that is only to Newfoundland.

Mr. GRIFFITHS went on to say that he had ascertained from a Post Office authority that the duplication of the cables that now existed might be multiplied indefinitely, and as a matter of fact they had more cables than were sufficient to carry on the business. Then they had the direct cable they must remember, and they had £600,000—a sum more than was sufficient. Where, then, was the necessity for paying that large insurance premium every year which they were now doing, and which was really putting their money below water, and throwing it away for 3 per cent., when it might be divided as profit among the proprietors. He would vote for the amendment.

A SHAREHOLDER thought the cables were in such good working order that the Company might now go on without adding more to their reserve fund.

Mr. BUTT, in a speech of considerable length, defended the action of the Board and the soundness of the policy they were pursuing, which, he said, was unquestionably in the interests of the permanent holders of the Company's stock, though not, perhaps, in those of speculators. If the judgment of the directors was that they ought to set aside a certain amount to the renewal fund, and they acted in a manner contrary to that belief, they must necessarily be liable to the proceedings brought against them in a court of law. He thought, moreover, that the Board were as much bound to abide by the wishes of those shareholders all over the country who had sent in their proxies as they were by the behests of the shareholders present at the meeting.

Mr. NEWTON asked whether the legal opinion to which the Chairman had referred had reference to the keeping up of the capital of the Company or of its property? That was, he considered, a question of some importance. The shareholders had been given to understand at the last meeting that a new cable from shore to shore would cost about £400,000. Was that so? Because it was necessary to have some basis to go upon in estimating the amount that was necessary for the reserve fund.

Mr. MOON thought that the feeling which animated a good many of the shareholders present was not that of the shareholders who were permanently interested in the prosperity of the Company, and he was quite sure that if a poll of the whole of the shareholders of the Company were taken it would endorse the policy of the directorate.

Mr. STOCKDALE asked whether it would not be better, instead of putting a large amount to the reserve fund, to appropriate it in reducing their present inflated capital.

Mr. BLUMENTHAL said he concurred in the view expressed by the previous speaker.

The CHAIRMAN, in reply, said: Now, gentlemen, before I proceed to notice in detail the questions that have been put to me, there is one question, which as our American cousins say covers the whole ground, which I should like to notice. We have been told by a gentleman on that side of the room that the directors are the servants of the shareholders. To that principle I entirely subscribe, and I rejoice that the question which that principle involves has been raised from that side of the table, and that you have not driven me as the spokesman of the Board of Directors to make this question a question of confidence. In the ordinary relations of life, when a servant disobeys his master's orders, or when he fails to carry into effect what his master considers best for his interest, the ordinary course is to dismiss him, and my advice to the shareholders is this—if they consider that the Board of Directors are not carrying out what they believe to be for the interests of the Company, my advice to them is to dismiss them, and put others in their place. But, gentlemen, this Board, if I know anything of their opinions or their intellectual fibre, will not at the threat of any body of individuals act contrary to what they have already described to you as their deliberate opinions and as their final judgment on the facts submitted to them. We cannot go back from what we have said. We have considered this question in all its bearings. We obtained all the assistance which we could command in considering it. We have arrived at a definite conclusion, and as I have already stated to you by that definite conclusion we must stand. Well, gentlemen, having said so much on that point, I will just allude briefly in detail to the questions that have been put. A great deal has been said about the amount which has been laid by to the reserve fund, and we have been asked what limit we could put to the

Digitized by Google

contribution to that fund. Well, gentlemen, we have four cables. We are told we have cables quite sufficient to carry the whole of the correspondence across the Atlantic. And so we have. But that is not the question which you have to consider. It is not whether we can carry the whole of the correspondence across the Atlantic, but the question is this: if we allow our carrying power to diminish we shall not receive under the joint-purse arrangement the same proportion of the whole earnings as we are now getting. It is quite plain that we should not, and I venture to state to you—if I was not able to convey my meaning in the observations I made at the beginning—that there are additional obligations on you beyond that which binds the shareholders of other companies to keep up their plant in perfect condition. As to the limit to be placed on the contribution to this reserve fund, I have told you that we have one cable that is fifteen years old, the French cable from Brest to St. Pierre. That cable, we may reasonably suppose, will break down first. The cost of replacing that would be between £800,000 and £900,000. Now, the question is, are we legally bound to keep it up? I say we are, and if we do not keep it up we shall lose all the benefits we get under the joint-purse arrangement. That is a sufficient answer to the question as to the limit of the renewal fund ["No, no."] I say that that is an answer to the question of limit, because if that cable were to break to-morrow we have not the means of replacing it, and if we have not the means of replacing it we suffer in our position in reference to the joint-purse agreement, and we render ourselves liable to any shareholder who may choose to bring an action against us for not taking the proper precautions ["No, no."] You say "No, no," but you have no responsibility, and we have.

The SOLICITOR: And that makes all the difference.

The CHAIRMAN: I confess that I was rather surprised at, and I regret to hear the spirit in which some observations were made with regard to the remuneration of the directors. I do not want to make any invidious comparisons, but I do not believe there is any company of such magnitude in London managed at so small expense to the shareholders as this Company, and in this very report, in consequence of the diminution in the Board by two directors, they have voluntarily surrendered £500 a year of what was set apart as their remuneration. The sum set apart for the remuneration of the directors was £3,000; by this report that is reduced to £2,500. We have voluntarily reduced the amount. Well, now, gentlemen, we have heard something of the claims of the deferred shareholders. Now it is rather a remarkable fact that people in the same position take different views of their interests. We have heard a great deal of complaint on the part of some of the deferred shareholders that they are getting no income; but many of those proxies to which I referred in my opening observations came from gentlemen of the same class. It is a curious fact to state that I have the proxies in support of the Board of a gentleman who holds £95,000 of deferred stock. The directors certainly derive some support in the policy they adopt from such a fact as that. Mr. Smith, in proposing his amendment, used some strong language about the conduct of the directors, and said that a resolution had been carried by a very large meeting, which meeting consisted of individuals 29 of whom were opposed to Mr. Smith's motion, so that there was a majority of 17 in favour of the resolution. There are 5,500 shareholders in this Company, and you all know that the words "great" and "small" are relative terms. A meeting of 75 would be a larger meeting if the whole body consisted of only 100, but I submit that a meeting of 75, 29 of whom were against a resolution adopted, is a very small meeting when compared with 5,500. We were asked by a gentleman to make some statement to raise the value of the stock. Well, I wish we could make such a statement, but I do not believe it is within the bounds of possibility for the Board to do so, and if we rejected the element of truth I am afraid the increased value of the stock would be of a short-lived character. Mr. Griffiths spoke of conciliatory measures, and said he hoped we would adopt some plan by which we should not have this continual wrangling going on, and another gentleman used an expression which gives a certain meaning to the word conciliation which probably Mr. Griffiths did not mean to apply to it. We were told that the directors must change their discretion; that is to say, that the conciliation must be all on one side, and that the directors—who, as I told you and maintain, are legally responsible for their acts, and may be made responsible in damages—must change their deliberate judgment in order to adopt the views of those who have no such responsibility whatever. Mr. Aston proposed that we should have some new directors. If this were a mere question of expediency and not of active principle there might be some force in it. But no addition to the Board could possibly change the deliberate opinion of the existing directors, and it would only add to the difficulty of the Board in the way of making any progress. Mr. Newton asked a question with reference to the legal opinion I quoted, and he asked whether it referred to the keeping up of the capital or the property. The legal opinion has nothing to do with the capital. We must keep up our property to meet all the obligations which the possession of that property entails on us. Some gentleman put into my mouth words which I certainly never used. He said that I quoted a legal opinion to the effect that the directors cannot use the renewal fund for any purpose except renewal. I never said anything of the kind. The legal opinion I quoted was not with reference to the application of the renewal fund, but with reference to providing a sufficient renewal fund. I should be very glad to see the capital reduced, but it is practically impossible in the present state of the law, as I am advised, to do so. We cannot go on the Stock Exchange and buy our own stock. That would be clearly illegal.

Mr. BAKER rose to speak, but was ruled out of order.

The CHAIRMAN: You can do anything by Act of Parliament, but I doubt very much if the shareholders would sanction the application of their hard earned reserve fund to buying stock in the market. It is not within the range of practical politics at the present time. With these observations I will now put the amendment to the meeting, the effect of which is practically to eliminate the third paragraph in the report. As many as are of opinion that this amendment be carried. Twenty-one. As many as are of the contrary opinion. Thirty-four. The amendment is therefore lost. He then put the original resolution, which he declared carried.

In further reply to Mr. Moon the CHAIRMAN said that the Direct Cable Company was carrying its full proportion of messages to America, and that each Company mutually bound itself to keep its cables in good condition.

Mr. BAKER suggested that a circular should be sent to the shareholders asking their opinion on the subject of the renewal fund.

The CHAIRMAN replied that it was not a point as to which the Board were at all disposed to lend their assistance, seeing that the non-contents were clearly in the minority.

Mr. WM. ABBOTT gave notice that he would move at the next meeting that Mr. Cyrus Field be requested to retire from the Board.

A vote of thanks was, on the motion of Mr. JACKSON, seconded by a SHAREHOLDER, cordially passed to the Chairman, who briefly returned thanks, and the proceedings terminated.

The Submarine Telegraph Company.

An ordinary general meeting of the proprietors in this Company was held at the Company's offices, 2, Throgmorton-avenue, London-wall, on Friday, the 1st inst. The Chairman, Sir Julian Goldsmid, Bart., presided.

The SECRETARY (Mr. S. M. Clare) read the notice convening the meeting, and the Company's seal was thereafter affixed to the register of the shareholders.

The CHAIRMAN then said: Gentlemen, in pursuance of a practice which has been established for many years in this Company, and which, since I have been your Chairman I have endeavoured to comply with, I should like to supplement, by some information which I can give you, what is contained in the report. You will all have observed that the amount which has been received for messages has somewhat decreased as compared with that of the corresponding half year. I think that those of you who were present at the last meeting will bear in mind that I then pointed out that the decrease up to that date was mainly owing to the system of condensation of messages which was prevailing, and which prevailed for several years before. I pointed out to you on that occasion that, whereas in the year preceding the average number of words in every message was over 13, during the period which was then under review it was 12·33, and I told you that in my opinion we must come to an end of the process of condensation at some fixed point or other, but what the point was I could not indicate. I have to report that during the last half year a further decrease in the number of words per message has taken place, but I am glad to say it is not so great as it was in the previous half years to which I have referred, and it rather looks as if we were coming near the end of this condensation, if we have not arrived there already. I find that up to the 30th of June, 1883, we had, as the number of messages, transmitted 1,337,009; and up to the 30th of June, 1884, we had actually an increase, though a small one, namely 1,377,419; therefore, practically, an increase of 40,000 messages. Now, the number of words was as follows:— Up to the 30th of June, 1883, it was 16,925,163, whereas during the half year just elapsed it was 16,583,147, showing a difference roundly of 380,000 against the half year which is now under review. Or, to put it in another form, in which you may understand it better, that whereas the average length of messages to the 30th June, 1883, was 12·65 words, it was in the last half year 12·04, showing a decrease of ·61 in comparing the two periods. But I said it appeared to me—and I hope that I am not deceived—that we are coming near the bottom of this decrease, and, therefore, the increase which occurs in the number of messages may benefit us. Taking month by month, in January the average length of messages was 11·92 words; in February it was 11·99; in March it was 12·15; in April it was 12·07; in May it was 12·08; and in June it was 12·02. The consequence of that, you will see, is that in January we reached the lowest point we have ever attained; and since then there has been a rise in the number of words per message, so that I hope we have reached the lowest limit. If that is so, any legitimate increase in the number of messages will redound to our credit to the extent of the increase in the receipts from the extra number of words we transmit. As I showed you on the last occasion, and I venture to repeat it now, this is a thing which is absolutely beyond the control of any board of directors. They have no power to dictate to the public what length of message they should send. Well now, to take the other side of the accounts, you will see that, notwithstanding there has been some decrease in the number of words carried, we have still had an increase in the payments which we have to make. That is a thing which the Board and myself have very carefully examined, and that again is absolutely beyond our control. Under our convention with France there are certain clerks in France who are paid by the French Government. Their salaries and their numbers are fixed by the French Government, and we have no control over one or the other, excepting by memorial or representation, which may or may not be attended to. We have recently, for instance, had a considerable increase in the pay of some of the clerks employed by the French Government in our behalf as well as a slight increase to their number. A larger number was proposed, and we respectfully addressed the French Government on the subject. Our representations were attended to, but, notwithstanding that, the result so far as the last half year is concerned is that we have had to pay £670 for salaries more than in previous half years. With regard to the increase to the Company's staff we have paid nearly £600 more. I have gone into the matter with great care, and I discovered that our rate of wages to clerks, porters, &c., is certainly not above what is paid by the Post Office. We cannot expect to get services

Digitized by Google

of this kind at a lower rate than is current throughout the country. But we have established a system of grades with regard to clerks by which the oldest men if they are capable go into a higher class and get higher wages. Then there is a lower class, and as the numbers of the upper class are from time to time reduced by death or resignation, those men in the lower class who are capable are promoted, and in each class we are giving a gradual increase according to a scale, and it is in consequence of that that we have had to pay more for wages. But I may say that I believe this is a necessity. It is essential to pay the men a proper scale of wages. If we do not we shall not get our work well done, and that would interfere with our traffic, so that in that respect we should as shareholders greatly suffer. The Board are quite alive to this matter, Mr. Clare looks after it very carefully, and I have spent a good deal of time in examining the details myself. Now, I come to another subject which affects us very considerably, and which is of constant interest to the shareholders—that is, the expenditure upon the cables. We have expended as you will observe on the repair of cables very nearly £5,000—£4,958—which is a large sum of money. I have pointed out to you at every meeting that a constant source of trouble and anxiety to us has been the condition of what we generally call the Dutch cables. Those are cables which belong to the English Government, but which by an agreement with the Government are worked by us on their behalf. Amongst other things in that agreement as long as they were in decent repair we had, if they were broken, to repair the breakages. We had to do this on many occasions, and long before I was chairman I used to jocosely point out that as every autumn was approaching we must make arrangements for the Dutch cables to be broken; that really represented the actual facts of the case. They always did get broken, and I was under the opinion that there was something defective in the cables to be so ill-treated by the storm. We had the matter examined, and it was reported upon by our able engineer with the result that last year I came to the conclusion that it was perfectly ludicrous for us to go on endeavouring from time to time to keep them in decent repair or to undertake to mend them. They were old cables of a bad type, which none of us would lay down in the present day, and they were totally unfit to carry on the traffic. In addition to that, I was well aware that the Dutch Chamber of Commerce were making repeated representations that the Dutch traffic was frequently interrupted, and they did not think proper attention was paid to the subject. In fact, I was appealed to by the Dutch Minister, who was an old friend of mine, and I assured him that I was well aware of the fact, and that we had made strong representations to the English Government on the subject, and that we had made two alternative proposals to them, which it is unnecessary for me to trouble you with to-day, by which the difficulty might be obviated. I must say I was exceedingly well received by the Post Office authorities and the Chancellor of the Exchequer, and after a great deal of discussion and negotiation the Post Office finally decided that they would put down one absolutely new cable themselves, and would thoroughly repair the other. With regard to the first part of the promise it has been redeemed. An absolutely new cable has been laid down. It has not been completed many weeks. They accepted the offer which I made to them of giving them the assistance and advice of our engineer in laying it, and he has reported to us that it is in excellent condition. It is laid on the line across the channel that he advised, and he believes it will add materially to the traffic between Holland and England. The other cable is to be put in order by the Government by inserting a considerable extent of new mileage of wire. That being so, I believe the Dutch cables will be put in a thoroughly satisfactory condition. They have cost us, I may say, a very large sum of money. I find for instance that the communication was totally interrupted between the 13th November, 1882, and the 14th March, 1883, and again from 12th November, 1883, to the 15th March, 1884—that is to say, the two successive years—in consequence of the condition of those cables. We had our steamer out the greater part of the time endeavouring to find the ends and set them right; but until the better weather came in March it was practically impossible to get them into working order. So that from 1882 to 1883 those cables were interrupted 123 days, during most of which we were at work with our steamer, whereas during the half year ended June, 1883, the French and Belgian cables were not interrupted at all. During the half year ended 30th June, 1884, the total period of interruptions in these different cables was sixty-nine, and there was never any interruption in the traffic. That shows the difference between having good and bad cables. The expenditure therefore has been always considerably increased by the condition of the Dutch cables, and I venture to predict that in future half years we should show more satisfactory figures. Because not only is the actual cost of such work very expensive, but there is this also to be remembered—that we have to pay heavily for insurance on our steamer when she is out of harbour. The more days of course that she is looking after the cables there is less rebate on account of the insurance. I can honestly say that last year I devoted a great amount of time and attention to this matter, and I believe it is now on a satisfactory footing, and that we shall be able in future half years to give more gratifying accounts. With regard to all the other ordinary items there is nothing to be said. We have paid about the same under almost every other head except this. The steamer has been kept in good repair, but the Board are considering at the present moment the question of renewing the cylinders which have been in ever since the vessel was built. Apart from that, I do not think there is any other novelty connected with this Company. One gentleman has asked me to make an observation with regard to the investment of the reserve fund. I remember that our late respected Chairman, Sir James Carmichael (and I myself on two or three occasions touched on it) made some remarks here with regard to this matter, and I am very happy to repeat the purport of the observations made—I should say at least twenty times—and that is that the power of investment by the directors is very properly limited. They can only take debenture stock or Government Consols. That being so it is not worth while to discuss whether it is a wise and proper limitation or not. It exists, and a great deal is to be said in favour of it. All that the directors are able to do when they have money to invest on account of the reserve fund is to endeavour to get a good debenture stock or similar stock at the lowest price to be had in the market. The price of debentures has risen of late, and it does not require to be a prophet to say that they are likely to continue to rise. I should say they are. All that we can do is to get the lowest price at which we can purchase them, and that is practically what we have done. We took some South Metropolitan Gas Company debentures some time ago, because we found they would pay as good a rate of interest as we could reasonably expect. Considering all the facts that I have pointed out, I do not think that we can be surprised that we should have had a considerable diminution in the receipts, and therefore that the rate of interest which we are able to return you on your capital is not quite as large as it was; but though that is so it is still a return not to be despised, and one with which I for one, as a large shareholder, desire to express my own individual satisfaction. If the directors had been able to do anything by which they could have increased it they would have been glad to do so, but the income of the Company is beyond the control of the Board. Having made these observations, I have now to propose "that the report and accounts which have been submitted be received and adopted."

The Hon. Ashley Ponsonby seconded the resolution.

The Chairman, in reply to Mr. Dolman (who asked whether, in view of the somewhat diminished revenue, the directors were prepared to exercise their liberality by foregoing part of their fees) said that personally he did not care what salary he received. He did not get much more than the rest of the directors, and it certainly did not recoup him for the trouble he took in connection with the Company. But, as a matter of principle, it was the very worst thing shareholders could do to pay their directors badly, because, if they did so, they would not get first-class men to attend to their work. In further reply to shareholders, he said the insurance of the steamer was arranged with one of the best insurance offices in London, and the amount depended on the number of days the vessel was out of harbour. The more days it was out the less rebate was received from the insurance. The steamer, buildings, and stores fund stood at £17,024, and, as they would see from the accounts, "this amount was taken from the reserve fund of both Companies, and includes £15,105 5s. 11d., the cost of the steamer, which is in course of repayment by half-yearly instalments, in accordance with the terms of the resolution passed by a special meeting of proprietors on the 10th May, 1870." As to the renewal of the concession nobody could be more gratified than he if it were renewed, but it was impossible to say what would be their position at the end of the concession. They had, however, three advantages. They had a priority of claim over anybody else to carry on the service, and should the worst come to the worst they had been increasing the amount of the reserve fund in order that a considerable portion of the capital might be represented by it, in addition to which they had the value of the cables which belonged to the Company, which would be a considerable amount, as well as the steamer and buildings which were part of the reserves.

The resolution was then put and carried unanimously.

The Chairman next moved, and the Hon. Henry R. Brand, M.P., seconded, "That, in accordance with the recommendation of the Court of Directors, a dividend for the half year ended 30th June, 1884, at the rate of 13 per cent. per annum, less income-tax, upon the capital of the Company, be declared, and that it become payable on and after the 1st September next," which was also carried unanimously.

Sir Julian Goldsmid and the Hon. Ashley Ponsonby, the retiring directors, were re-elected to their seats at the Board. The Company's auditors were also reappointed, and a vote of thanks having been passed to the Chairman, the proceedings terminated.

Eastbourne Electric Light Company.

The general meeting of the above Company took place on Thursday, at the Gildridge Hotel, Eastbourne, under the presidency of Mr. Alderman Boulton, of Torfield. We take the following report of the meeting from the columns of the *Eastbourne Standard* for Saturday last:—

The minutes of the last general meeting and the notice convening the present meeting having been read, the report of the directors, a copy of which had been sent to each shareholder, was taken as read.

The Chairman said the report was so exhaustive and had been so extensively circulated that it left him little to say; nevertheless, there were one or two points to which it might be as well that he should direct their attention. (1) As to the arrangement with the Hammond Company. It would be seen that for the past two years they (the Eastbourne Company) had been working at a loss. Of course that was a mode of business which could not go on long. Rather than attempt to wind up the Company, they decided, in view of the strong opinion expressed by scientists as to the future of electricity, to negotiate with the Hammond Company, with a view to their taking over the working of the Company. It was ultimately agreed that they should take the management for a period of two years, that they should pay all outgoings and charges, and in return receive all rentals and profits which might result from the sale of electricity, while they should bear all the risk in connection with the matter. This the directors considered a very good arrangement. They could not, they felt, be worse off, while by the aid of the new plant which the Hammond Company would put down they might and probably would be in a position at the end of the two years to earn money and pay a dividend. What the directors asked them to do was to be patient a little while longer. He would refer them to the last clause

Digitized by Google

but one, which had reference to their determination of the contract with the Town Council for the public lighting. In the starting of all new concerns it was impossible to calculate exactly the cost of supplying a commodity. They (the directors) thought they had made a good contract with the Local Board, but experience had shown them that they were not receiving enough, the light really cost more than they got for it. Acting, therefore, under the advice of Mr. Hammond, they had given notice for the determination of the contract, and at the same time issuing an invitation to the council to confer with them as to amendment of terms, and to see whether, in the face of the public, they would put out the electric light and go back again to gas. Of course, after all, the council was only a representative body, and if the ratepayers desired that they should go on with the existing light, he did not see that they could take any other course than to comply with the request. What they (the directors) were anxious to do was to push the incandescent light in the shops and private houses. Many shops were already lighted with it, and so far as he could ascertain it had given every satisfaction. He inquired the other day of Messrs. Lavis, and they said it answered perfectly, and on no account would they be without it. With this object in view they were endeavouring to secure the services of a good canvasser, and he had no doubt before long the engagement would be completed. They hoped before many weeks were passed to have numerous orders for the incandescent light for shops and private houses. If the council declined to renew their contract, then the machinery could be utilised to supply the incandescent, while, if the parade service should be retained, they would still have machinery sufficient to deal with the increased business. The Company had had no slight difficulties to contend with, a good deal of ill-natured abuse had been levelled at them, while they had been spoken of even by friends in that suggestive way in which friends were sometimes given to speak. They had not, however, been discouraged, but, on the other hand, with the assistance which the Hammond Company would be able to give them, they hoped to achieve success. One point in conclusion he ought to mention, and that was that since the 12th of February, to which date these accounts were audited, they had been able to pay off all, or very nearly all, the liabilities of the Company, with the exception of course of the interest on the debentures. He moved the adoption of the report.

Mr. LANGHAM said it would not be necessary for him to do much more than echo the statements of the chairman. It was scarcely necessary for him to say much about the Hammond Company, because the ratification of that agreement would come before them later on. He should like, however, to refer to one point. It was not merely the fact that they were not earning a dividend—that was often a difficulty with a new company at the outset—but the Electric Lighting Act, although it pretended to give the electric light protection against the gas company, in reality secured to the gas companies an increased monopoly, while it stopped the application of capital for the purposes of electric lighting. This, as a matter of fact, was the way in which the matter had operated as regards the Eastbourne Company, and as he believed it had done with other companies. Their Company had put out one or two notices inviting additional capital, locally, but without success, and that led to their negotiations with Messrs. Hammond and Company and the Anglo-Brush Company. He thought the result had been satisfactory; they had been arranging with those companies to supply them with additional plant, and take all the risk, and to effect that arrangement at a juncture when they (the directors) had a balance in hand to pay off their own liabilities with. He had no doubt the press, who were in a position to arrive at the opinion of the public on the question, would be able to say whether the ratepayers and visitors were in favour of the retention of the light or otherwise, and thus, as the voice of the public, represent that opinion to the council. They (the Company) only asked for the renewal of the contract upon fair terms, and fortunately they had a precedent. At Hastings they shut off the light at eleven o'clock at night, but at all events they (the Eastbourne Company) were prepared to deal with the council here on the same terms as the Hastings Company with their corporation. By way of strengthening that observation he might mention that the council was prepared to respond to their invitations to consider the matter. He believed Mr. Hammond would be willing to come down and go into the whole question carefully. Continuing, the speaker said the Company had almost unsurmountable difficulties to contend with, besides which they were called upon to spend a large sum of money on posts and lamps, which latter, in the case of the gas contracts, had always been found by the local authority. He, however, believed that under the new arrangements the result would be satisfactory to the shareholders, and place the Company in the position of earning in future a substantial dividend. He had much pleasure in seconding the chairman's proposition.

The adoption of the report was unanimously agreed to.

Mr. Routledge having been re-elected as a director, and Mr. Hammond's name having been added to the directorate in place of Mr. Diplock, deceased, the meeting was made special to consider the agreement with the Hammond and Anglo-Brush Companies, by which the management of the Company for two years from 2nd Feb. last, the provision of all necessary service and the payment of all working expenses and charges, including debenture interest, is undertaken by the Hammond Company at their sole risk, the understanding on which this agreement is based being that the Hammond Company shall take all profits as remuneration, and bear all losses should such occur. By the agreement with the Anglo-Brush Company, this Company accept payment by debentures for the plant supplied by them to the Eastbourne Company.

It was unanimously agreed that this agreement should be ratified, and a meeting was fixed for the 18th of the present month for the special purpose.

The proceedings terminated with a vote of thanks to the directors and officers, which was duly acknowledged.

National Telephone Company (Limited).

The report of the directors of this Company for the year ending the 30th of June last states that the annual gross revenue on the 30th of June was £57,271 15s. 2d., against £43,111 5s. 6d. at the end of the previous year, showing an increase of £14,160 9s. 8d. After providing for the accrued interest on the debentures, the usual dividend of 6 per cent. on the preference shares, and having paid a dividend for the first half of the year at the rate of 1 per cent. per annum on the ordinary capital, £6,672 9s. 9d. will remain as the balance of profit. Out of this the directors propose to allot a further sum of £3,375 to the payment of a dividend at the rate of 1½ per cent. per annum on the ordinary capital for the second half of the year, and to carry forward £3,297 9s. 9d. The loss on trunk wires has increased, and for the year amounted to £986 7s. 3d. This large loss has been in some measure due to the protracted negotiations with the Post Office with relation to the new trunk wire agreement, which extended from November, 1882, to April, 1884, when it was settled upon its present basis. The directors desire to acknowledge the general courtesy of the permanent officials of the Post Office Department, and to state that the operations of the Company have been facilitated within the official lines laid down. Each day's experience, however, proves that those lines are so narrow as practically to deprive the public of the major portion of the advantage it is entitled to expect from the telephone.

Cuba Submarine Telegraph Company (Limited).

The half-yearly report of the directors of this Company shows a gross revenue of £19,918, including £594 brought forward. After providing for expenses, and adding £1,266 to the reserve fund, which is thus raised to £58,000, and meeting the interest on the Preference shares, there is a balance of £7,567, out of which it is proposed to pay a dividend on the Ordinary shares at the rate of 9 per cent. per annum, tax free, leaving £367 to be carried over to the accounts of the current half year.

NOTES.

ELECTRIC LIGHTING IN A GASWORKS.—A French paper says that Pilsen arc lamps are used to light the Municipal Gasworks at Prague.

ELECTRIC LIGHTING IN AMERICA.—The United States Electric Light Company are fitting up a central station at Portland, Oregon.

WESTERN AND BRAZILIAN TELEGRAPH COMPANY.—The traffic receipts of this company for the week ended 8th August were £2,398.

COPPER.—The total production of copper in Arizona State this year is expected to be nearly 50 per cent. greater than last year's yield, which amounted to 17,000,000 pounds.

SAFETY LAMPS.—It is said that the Viennese fire brigade have been supplied with electric lamps to enable them to enter rooms where gas is escaping without incurring the risk of an explosion.

GULCHER ELECTRIC LIGHT COMPANY.—The petition for the reduction of this company's capital from £300,000 to £150,000 is to be heard before Mr. Justice Pearson on the 20th inst.

AN ELECTRIC EEL.—A large *gymnotus electricus*, said to be nearly six feet long, is to be seen in the Zoological Society's Gardens at the present time. It has recently arrived from South America.

DEVON AND CORNWALL ELECTRIC LIGHT COMPANY.—The creditors of this company should send their names and claims to Mr. H. T. Edwards, 66, Coleman-street, E.C., on or before the 1st October.

BOOK RECEIVED.—"The Electrician's Pocket-Book," by E. Hospitalier, translated from the French, with additions, by Gordon Wigan, M.A. Published by Cassell and Co., London, Paris, and New York.

ELECTRIC LIGHTING IN MILLS.—The mill of Messrs. Pia and Co., at Brandizzo, Italy, is lighted by 85 Edison lamps. The installation has been carried out by the Societa Generale Italiana di Electricita.

TELEGRAPH RECEIPTS.—The receipts from the Postal Telegraphs from 1st April to 9th August were £595,000, against £590,000 in the same period of last year. The estimate for the year 1884-5 is £1,800,000.

THE NEW ATLANTIC CABLES.—The cable ship "Faraday" picked up and spliced the shore end of the second Bennett-Mackay cable on Wednesday. The laying of it is proceeding satisfactorily, the weather being very fine.

ELECTRIC LIGHTING FOR WAR PURPOSES.—Similar experiments to those recently carried out at Aldershot with Sautter, Lemonnier and Co.'s portable electric light apparatus have just been conducted at Berlin by the German staff.

TELEGRAPH INSTRUMENTS IN FRANCE.—*L'Electricité* says that there are at the present time 7,702 Morse instruments at work in France. The Bandot apparatus which works between Paris and Marseilles transmits on the average 1,800 messages per diem.

ACCIDENT FROM LIGHTNING IN SWITZERLAND.—During a recent storm a house in the village of Villard-Lurin, near Brides-les-Bains, was struck by lightning and set on fire. The conflagration spread rapidly, and ninety houses were attacked by the flames.

TENDERS WANTED FOR LIGHTING.—The Walthamstow Local Board want tenders for lighting their district by oil or otherwise. Tenders are to be sent in by the 21st instant. Specifications can be obtained of the Surveyor, at the Town Hall, Walthamstow.

NEW METEOROLOGICAL OBSERVATORY.—Lord Mount-Edgcumbe laid the foundation-stone of a new meteorological observatory at Falmouth on Tuesday. Magnetic observations will also be taken, the instruments for that purpose being supplied by the Royal Society.

ELECTRIC LIGHTING IN BERLIN.—The central station of the Edison Company in Berlin is nearly finished. It will contain four 500-light Edison dynamos, and the necessary boilers and engines for driving them. This gives the station a capacity for lighting 2,000 sixteen candle-power lamps.

ELECTRIC PROPULSION OF BALLOONS.—A very successful trial was made in France a few days since by Captain Renard, of the Engineers, with a balloon steered and to a certain extent propelled by a kind of screw actuated by an electric motor. At present we have no details of the apparatus used.

ELECTRIC MOTORS FOR TRAMWAYS.—An American paper says:—"A successful experiment in the application of electric motors to street railways is reported to have been made by the East Cleveland, Ohio, Railroad Company, July 26. The company was sufficiently satisfied to contemplate the extension of electricity to their whole service."

THE TELEPHONE AND THE POST OFFICE.—We give this week a report of the discussion which took place a few days since in the House of Commons on the policy of the Post Office with regard to the telephone companies. It will be found interesting reading. We have discussed the whole matter in our leading article this week.

BUSINESS NOTICE.—We are informed that Messrs. Shaw and Connolly, of Manchester, have finally removed their offices from 10A, Victoria-buildings, to their works in Alexandra-street, Oldham-road, Manchester, having made the necessary additions to meet the extra accommodation required. They are also adding considerably to their plant.

THE GASLIGHT AND COKE COMPANY.—The receipts of this company for the half year ended June 30 last reached £1,552,644. At the half-yearly meeting, held last week, it was resolved to declare a 12 per cent. dividend, and carry forward £188,929. Last year they paid 11 per cent. Surely they can afford to reduce the price of their gas again.

ELECTRIC LIGHTING EXHIBITION AT BRUSSELS.—The committee of organisation in connection with this exhibition, which it is proposed to hold next year, have met to consider the necessary details for its promotion. Sub-committees have been appointed to choose a site, to organise the exhibits of electric lighting apparatus, and those devoted to heating and lighting by gas.

GRAVESEND.—At a meeting of the corporation on Wednesday the town clerk announced that the Board of Trade had revoked the provisional order granted some time since to the Brush Company, owing to the company not having executed the work within the time allowed them by the order. The corporation are now free to recommend the granting of the required powers to another company.

ELECTRIC LIGHTING AND GAS.—One of the first gasworks erected in the North of England was that put up to supply gas to Messrs. Duff and Rowntree's establishment at Bishop Auckland, nearly fifty years ago. The same firm were among

Digitized by Google

the first, if not the first, to adopt the electric light, and the electrical plant now stands within a few feet of the gasmaking apparatus which it is doing its best to elbow out of its place.

BRIGHTON ELECTRIC RAILWAY.—Mr. Magnus Volk's electric railway seems to be as popular as ever to judge from the number of passengers it carries. He has fitted up some Maxim incandescent lamps to light his Aquarium Station. We are surprised that other sea-side resorts do not imitate Brighton in this matter. There are dozens of places where such a line would prove useful and might be made to pay well also.

PROVINCIAL BRUSH COMPANY.—A notice in the *Gazette* says:—"A petition for confirming a resolution reducing the subscribed capital of the above company from £99,205 to £54,562 15s., making the total capital £155,357 15s., was, on the 10th July, 1884, presented to the High Court of Justice, Chancery Division, and is now pending; and the list of creditors of the company is to be made out as for the 30th August, 1884."

A WANTON ACT.—Some of the inhabitants of South Uist, Scotland, have lately been committing themselves to some foolish and wanton acts of destruction to show their hatred of landlords. Amongst other things, they cut down the telegraph wires near the village, and twisted them across the road, in the hope of upsetting vehicles or horsemen. It appears that this is the second time within a very short period that this has occurred. Verily political passion indulges in strange freaks.

POSTAL TELEGRAPHS.—The competitive examination for the vacant appointment of technical officer in the engineer-in-chief's department has resulted in the success of Mr. Hartnell, of Nottingham. The following gentlemen also competed at the examination, and obtained positions in the order named, viz.:—Messrs. Slingo, Stubbs, Hinton, Moon, Probert, Morgan, and Ferguson. Mr. Hartnell, it may be remembered, obtained the highest number of marks in last year's technological examination in connection with the City and Guilds' Institute.

TELEGRAPHIC COMMUNICATION IN SOUTH AFRICA.—The Free State and Transvaal capitals were expected, says *The Colonies and India*, to be in telegraphic communication before the end of August. The fact is not without some significance that the Transvaal Government have deliberately neglected to re-establish the broken line of telegraphic communication with Natal. The circuit will be *viâ* Winburg, Cronstadt, Heilbron, the Coal Fields, thence to Heidelberg, and on to Pretoria. The line from Heilbron to the Coal Fields has been finished, and is only awaiting the junction with the Free State line.

EARTHQUAKE IN ITALY.—A telegram from Rome, dated August 7, states that an earthquake shock occurred on the morning of that date at 2 a.m., and was followed by another at 3:15 a.m. The direction taken by the wave was through Velletri, Nemi, Ariccia, Albano, Castel Gandolfo, and Rocca di Papa and Frascati. The shocks were most severely felt at Rocca di Papa, but no damage was done beyond the felling of two chimneys at Ariccia. At half-past three a severe shock, quickly followed by another, was distinctly felt at Rome, and that which shook the Alban hills extended also as far as Porto d'Anzio, on the coast.

PEROXIDE OF LEAD CELLS.—Mr. F. Maxwell-Lyte writes to us, pointing out that the lead peroxide mentioned in *The Electrician* of 26th ult. as used in the De la Rive battery must be prepared by the usual process of acting by means of nitric acid on the red lead of commerce. A far less expensive method, patented by Mr. Maxwell-Lyte, consists of adding to lead chloride dissolved in hot water a sufficiency of bleach solution and the right proportion of calcium hydrate. By this means lead peroxide of from 90 to 100% may be produced and sold, with a fair margin of profit, at about 3½d. per lb. This could not contain the nitric acid complained of.

TRAIN LIGHTING.—A trial of incandescent lighting is now being made on the London and North Western line. A locomotive running one of the trains between Liverpool and Manchester has been fitted with a Brotherhood engine and a dynamo, the latter supplying the requisite current to a Swan lamp in each of the compartments of the train. A duplicate lamp is also provided and so arranged that it would be switched into the circuit directly the other lamp went out. The current is regulated by a switch from the footplate, a pilot lamp indicating to the driver the candle-power at which the lights are burning. We heard some time since that Mr. Webb was making experiments in this direction, and trust that the results will be satisfactory.

TESTING ALLOYS.—"The possibility of ascertaining the standard fineness of alloys by the aid of electricity," says Professor Chandler Roberts, F.R.S., in his Cantor lectures now being published in the *Journal* of the Society of Arts, "long ago occupied the attention of physicists. In 1823 Becquerel suggested that trustworthy indications might be afforded by the electromotive force developed when the alloy to be tested is placed in an exciting fluid together with an alloy of known composition. The subject was partially investigated by Œrsted in 1828, and its practical importance was further pointed out by Gay-Lussac in 1830. In 1878 the use of magnetic induction for indicating the composition of alloys was suggested by Professor Hughes, who showed incidentally that the induction balance affords a ready means for detecting counterfeits, and I have elsewhere pointed out the degree of accuracy of which this instrument is susceptible."

TELEGRAPHIC COMMUNICATION WITH MAURITIUS.—A curious illustration of the isolation of the Island of Mauritius from the rest of the world by reason of the non-existence of telegraphic communication with that colony, reference to which was made in our leading article of last week, appears in the following paragraph taken from the *Standard*:—"In connection with the stoppage of the Oriental Bank some curious questions have arisen. The bank had a branch in the Mauritius, with which island there is no telegraphic communication. The winding-up petition was presented on May 3rd, and between that date and the 14th, when the news reached the colony, moneys were paid in to the branch, and bills drawn to the amount of three hundred and forty thousand pounds. The legal questions involved were mentioned in Mr. Justice Chitty's court on Saturday, and the decision was postponed until after the Long Vacation."

OVERHEAD WIRES.—At the last meeting of the St. George's (Hanover-square) Vestry, Sir A. Hobhouse moved that Her Majesty's Government be requested to bring the erection and maintenance of overhead wires under due control by some adequate local authority, a resolution which was passed after some discussion as to the words "adequate local authority," which it was thought were too vague. The St. James's Vestry (Westminster) having written to the Local Government Board asking that a law should be passed giving local authorities some power over the erection of wires, have received a reply stating that it would be impossible to deal with the subject by legislation this Session, and the Govern-

Digitized by Google

ment cannot now say what Bills they will introduce next year, but there would probably be an advantage if a select committee were appointed to inquire into the subject, and that the Board would consider whether steps should be taken early next year with this view.

Electric Lighting at Craig-y-Nos Castle.—The electric light has been introduced into Craig-y-Nos Castle, the Welsh residence of Madame Adelina Patti, by Messrs. Paterson and Cooper, and their agent, Mr. John Legg, of Swansea. The installation consists of 70 twenty candle-power incandescent lamps, distributed in the winter garden, conservatory, dining hall, drawing room, billiard room, boudoir, &c. In the winter garden and conservatory the lamps hang by twisted silk cord from the roof, and have tinted green lilies over them. The effect amongst the various climbing and other plants which are festooned about the roof is charming. In the dining, drawing, and billiard rooms and the boudoir the lamps are partly attached to the existing gas fittings and partly hung by silk cords from the ceilings. The lamps are all covered by tinted opalescent ruby and other shades. The lamps are worked by one of Paterson and Cooper's phœnix compound shuntwound dynamos, driven by one of Crossley Brothers "Otto" gas engines.

Arc Spectra.—In a recent number of *The Chemical News* Mr. Hartley stated that the short lines in some arc spectra are lengthened by moistening the electrodes with water; and, moreover, it is suggested that this phenomenon is due to the cooling action of the water on the negative electrode, since heating the electrodes produces a reverse result. Herr Wiedemann takes exception to this explanation, and has offered the following in its place, the pith of which is given in the Chemical Society's *Journal* for this month :—"When the electrodes are moistened, the discharge produces oxygen and hydrogen gases, which re-combine at some distance from the electrode with great development of heat, consequently increasing the temperature of the metallic vapours, and also the length of the lines. By directly heating the electrodes, however, the potential available for the production of spark is lowered, with the result that the amount of matter dispersed at each discharge is diminished, as well as the temperature of the spark, the ultimate effect being shortened lines in the spectrum."

Magnetism.—M. Duter presented the following note to the French Academy of Sciences at a recent meeting. With tempered steel plates 1mm. thick and varying in diameter from ·040m. to ·005m. he formed cylindrical piles; in some of these piles the plates were directly in contact, in others they were separated by strips of pasteboard the thickness of which varied from extreme thinness up to ·001m. The piles were placed in the centre of a very powerful magnetic field, and after having been withdrawn, were found to constitute perfectly regular permanent magnets. The closer the contact between the plates the greater was the carrying power of these magnets. In a pile of 100 plates directly in contact and pressed close together in a brass cylinder, the carrying power at each end was 30 grammes. This result obtained, he took down the plates one by one, taking care to mark the upper and lower faces of each one. Each of the plates retained in this condition but little magnetism. Each, however, constituted a flat magnet, the two faces of which formed the poles. For, on re-forming the pile, it again formed a perfectly regular magnet, but was weaker than at first.

The Telephone in Aberdeen.—We have received the latest edition of the list of subscribers to the Aberdeen Exchange of the National Telephone Company, which has been brought up to date. The first telephone was set up in Aberdeen in 1881; at the present time there are 400 instruments at work there. The number of connections with the exchange is 355, and there are 20 private lines, the two together representing nearly 230 miles of wire. The longest line is that to Culter Paper Mills, which measures 8¼ miles. The exchange is in telephonic communication with the police and fire station, whence also telephone lines run to the firemen's houses, so that on an alarm being given the men can be summoned with the least possible delay. The company also offer to establish automatic fire and burglar alarms in subscribers' houses, by means of which the police or fire brigade can be at once apprised of fire or burglary. It should be mentioned that the exchange is open day and night, Sunday included. The list is divided into various heads ; first we have the subscribers' names in the order of their exchange numbers; then a similar list arranged alphabetically; then a list in which the subscribers are classified under their various trades and professions. The list is extremely well got up, and has been neatly printed by Messrs. John Avery and Co., of Aberdeen, who are well deserving of a word of praise. We notice that the Exchange is still under the able management of Mr. J. D. Miller.

Reducing Bromide of Silver Residues.—M. Scola communicates to the *Bulletin* of the French Photographic Society an easy method of reducing waste bromide of silver to the metallic state, and not only obtaining the bromide in a useful form, but also generating an electric current at the same time. To separate the bromide of silver from the waste emulsion, M. Scola recommends that two or three per cent. of sulphuric acid should be added, and the mixture should be boiled for some minutes, after which the bromide settles rapidly to the bottom of the vessel. It is now washed and dried, when it is ready to be cast into sticks for use in the battery about to be described. The battery in which the reduction is effected is constructed on precisely the same principles as the chloride of silver battery of Warren de la Rue, and one form of this, as is well known, consists of a rod of amalgamated zinc immersed in acidulated water, and opposed to a similar rod of fused chloride of silver, a platinum wire being embedded in this latter to serve as a conducting terminal. When the plates of the battery are connected by a conducting circuit the chloride of silver becomes reduced to the condition of metallic silver, while the chlorine unites with some of the zinc to form chloride of zinc. If the negative plate of the battery is made of fused bromide of silver, reduction takes place quite readily when the terminals are united ; and when the battery is exhausted it is merely necessary to fuse the resulting spongy silver in order to obtain it in a convenient condition for use in making a fresh supply of nitrate, while the whole of the bromine takes the form of bromide of zinc, and remains in solution.

The Theory of Magnetism.—Professor A. K. Eaton writes in the *Electrical World* for July 26 :—Allow me to correct a misapprehension on the part of Professor Hughes as to the scope of the statement quoted from Faraday, in the article reproduced in your last number. The statement is as follows—"Faraday remarked that the magnetic qualities of iron disappeared at yellow-red heat (1050° C.), reappearing gradually when cooled to red-heat (700°C.)." *Vide Electrician*, p. 430, Vol. XII. Professor Hughes adds that he has found that "if we heat steel to yellow-red the whole previous structure disappears and does not reappear on cooling." He is quite right

Digitized by Google

in this, but has entirely misapprehended the meaning of Faraday's words. Faraday did not mean that a magnet having lost its magnetism by heating to a yellow-red would recover its magnetic character by cooling to a red heat. What he meant was that a piece of iron which, when cool was attracted by a magnet, ceased to be at all attracted when raised to a yellow-red heat, but would again be, in a measure, attracted when cooled to a red-heat. Many years since, wishing to determine the effect of tempering steel while the magnetic current was circulating through it, I heated the steel to a cherry-red, and taking it up by the poles of a strong horseshoe magnet immersed it in water while in this magnetic condition. In this way I obtained unusual magnetic intensity in the bar of steel. But on one occasion, having raised the steel to a yellow heat, I found that my horseshoe magnet would no longer lift the bar, and it was necessary to wait until it became cooler. Briefly, then, any piece of iron or steel when heated to a yellow-red becomes insensible to the action of a magnet, but becomes capable of magnetisation again when cooled down.

THE ELECTROLYSIS OF SOLID GLASS.—Herr Warburg has made some experiments in this direction, the results of which he has communicated to *Wiedemann's Annalen*. We take the following summary of his paper from the *Phil. Mag.* for August:—"In the electrolysis of lime-soda glass, heated to about 300° between mercury electrodes, a badly conducting layer of silicic acid is formed on the anode side of the glass, which soon reduces the strength of current to a fraction of its original value. This layer has a greater or less thickness, according as a greater or lesser electromotive force has acted in the circuit in a definite time. It is visible, showing the colours of thin plates, diminishes the surface-conductivity of the glass in the cold to a fraction of its original amount; and at a high temperature, when the mass of the glass has become a conductor, it acts like the dielectric of a condenser, whose coatings are the conducting mass of the glass, and the mercury of the anode. The capacity of this condenser was found to be independent of the difference of potentials of the coatings, between 1 and 20 Bunsen's elements, and for a square centimetre of the glass used it varied from ·021 to ·041 microfarad, according as the layer was formed by 30 or 15 Bunsen's elements acting for several hours at 300°. The formation of this layer may be avoided by using sodium amalgam as anode; the result of the electrolysis may then be quantitatively determined. In this a quantity of sodium is given off at the cathode and absorbed at the anode, so that the weight of the glass does not vary; the weight of the sodium is chemically equivalent to the silver which is deposited at the same time in the silver voltameter. During electrolysis the glass remains perfectly clear, and it was found that all the properties of the glass were not appreciably altered by electrolysis."

EARTHQUAKE IN AMERICA.—A Reuter's telegram, dated New York, Aug. 10, says:—"At two o'clock this afternoon a shock of earthquake passed along the Atlantic coast, from Philadelphia to Portland. It lasted about ten seconds, and was distinctly perceptible in New York and the district." *The Times'* Philadelphia correspondent, telegraphing from that city on the 11th, says:—"The earthquake yesterday suddenly moved along the Alleghany Mountains and their eastern slopes, from Virginia to Vermont, in a direction from south-west towards north-east, extending over the entire country from the mountains to the ocean. The most southerly city in which the shocks were noticed was Washington, and the most northerly Brattleborough, Vermont. Two distinct shocks, each of about two seconds' duration, with an interval of about four seconds, were generally felt, while in New York and further eastwards a slight third shock was experienced a few minutes afterwards. The earthquake was observed at nine minutes past two o'clock in the afternoon at Philadelphia, and somewhat later to the eastward of this city. It was most severe in New York city, Connecticut, and Boston. The vibration was slighter elsewhere. No loss of life was caused, except that one convict was frightened to death in Hartford Gaol." The *Daily News* New York correspondent says that the shock was most severely felt at Hartford, Connecticut. He also states that it is reported from Boston that six distinct shocks were felt there. He gives the duration of the earthquake wave as from 10 to 15 seconds. *The Standard's* New York correspondent states that the shock was first felt in New York at seven minutes past two, and that the vibration continued for 20 seconds; in other respects he corroborates the other correspondents. Later information says that the shock was felt seven miles out at sea from Sandy Hook, and that another slight shock was felt in New England and at Long Island on the 11th instant.

THE INVENTIONS EXHIBITION.—The classes into which the exhibits are to be gathered together at South Kensington next year in the buildings now occupied by the "Healtheries" have been arranged. Electrical machinery and apparatus is to be classified as follows:—Class 66. Generators.—Dynamos, primary and secondary batteries, thermo-electric batteries. Class 67. Conductors.—Submarine cables and apparatus for laying them, aerial wires, and underground cables, insulators and poles, insulating and coating materials, joints and connections, underground conduits, pipes, tubes, troughs, &c., electric light leads. Class 68. Testing and measuring apparatus.—Galvanometers, magnetometers, dynamometers, voltmeters, current-meters, methods of testing. Class 69. Telegraphic and telephonic apparatus.—Needle instruments, A B C instruments, Morse instruments, type-printers, relays, duplex and quadruplex apparatus, keys, recording instruments, automatic transmitters, electric bells, indicators, telephones, microphones, lightning protectors. Class 70. Electric lighting apparatus.—Lamps, resistance coils, cut-outs, safety catches, switches, fittings for glow and other lamps. Class 71. Electro-metallurgy and electro-chemistry.—Methods of depositing and coating various metals, electrotyping, galvano-plasty, vats, cleaning and polishing apparatus, materials, tools, and appliances. Class 72. Distribution and utilisation of power.—Electric railways, electric motors, electrically-driven boats, tricycles, and other conveyances, systems of distribution. Class 73. Electric signalling.—Fire and burglar alarms, railway, ship, and time signals, water level and wind indicators, tell-tales, electric clocks, chronoscopes, &c. Class 74. Lightning conductors. Class 75. Electro-medical apparatus. Class 76. Electrolytic methods for extracting and purifying metals.—Copper, zinc, lead, iron, refining the precious metals. Class 77. Electro-thermic apparatus.—Electrical apparatus for war, mining, blasting, and other purposes.

A WHALE CAUGHT BY A CABLE.—Mr. Robinson Kendal, chairman of the West Coast of America Telegraph Company, has communicated the following extracts from letters received from that company's officials on the west coast of South America to the papers. The captain of the company's repairing steamer writes:—"Having picked up 21 knots of cable, and while continuing picking up, an immense whale came up to the bows entangled in the cable. It seemed to be about 70ft. in length. In its struggles to get free the cable cut right into its side, the

Digitized by Google

whole of its entrails coming out, and great streams of blood. In its last dying struggle it parted the cable on the bow sheaves and floated to windward of the steamer. The cable was twisted up in the form of a wire rope for about two fathoms, and in six different parts it had the appearance of having been bitten through sufficiently to stop all communication. There is no doubt the whale has been the cause of the interruption." Their manager also writes:—"The cause of the breakage of the cable, as has been pointed out to you in Captain Morton's report, was a huge whale, which became entangled in the turns of the cable, and was held prisoner for seven days; the interruption was unfortunate, but it is, at least, satisfactory to know that the cable did not give way naturally, and that where picked up, the sheathing, yarn, and core were found to be in an almost perfect state of preservation, in fact, looked as good as on the day the cable was first laid." Mr. Kendal gives no dates, but the facts, as related, are interesting to cablemen. It is satisfactory to find that the cable is fully up to such a heavy strain as was put upon it, and also to have another instance of careful fault-finding and rapid repairing. Shareholders in cable companies well know that the quicker a fault is found and repaired the less money it costs, and the less the traffic is impeded. The India Rubber, Gutta Percha, and Telegraph Works Company are also to be congratulated upon the excellence of their work, they having laid the whole of the cables for the West Coast Company. This little incident shows the wonderful strides that have been made in cable making and repairing of late years.

THE LARTIGUE ELECTRIC RAILWAY.—A model of this railway is now to be seen at the Rouen Exhibition. It is a single rail line, with supports in the shape of an Λ. The carriages are of wicker work, with metal framework. They weigh about 1,600 kilograms each, and can carry eight persons, four on each side, sitting back to back. The train at Rouen, says *L'Electricien*, consists of three carriages and the motor. On the latter is a Siemens dynamo, type D^3, which is used as the motor. The current is produced by a D^2 Siemens series machine. This makes 1,400 revolutions per minute, and is connected to the non-insulated rail of the Λ-shaped supports, and to a return. The current is taken off the rail by laterally placed rollers, which also assist in preserving the balance of the carriages. The motor makes 1,000 revolutions per minute. This speed is reduced to 125 by gearing. The total resistance of the circuit, comprising the generator, conductors, permanent way, and motor is 1·5 ohm; that of the conductors and the permanent way is less than ·1 ohm. By the aid of commutators on the motor it is possible to run the train backwards or forwards. Resistances gradually introduced into the circuit enable the speed to be slackened as required. The permanent way at Rouen is in the form of a closed ring, 111 meters long, and with very sharp curves and gradients. The whole distance is traversed twice in two minutes. The change made is ·15 fc. per person, and the railway is fairly popular. M. Boistel has published the following data. A train, composed of three carriages and a motor, weighs when empty 2,400kg. Taking the weight of each traveller as 45kg., the total reaches 3,480kg. The speed is 1·30m. per second. At starting the E.M.F. of the generator was 165·5 volts, that of the motor 105·7 volts, and the current 48 amperes. The electrical work absorbed was therefore 7,944 watts, or 10·8 horse-power. The work utilised was 5,073 watts, or 6·9 horse-power. The electrical return was therefore 63·8 per cent. In normal working the E.M.F. of the generator was 139·9 volts, that of the motor 98·4 volts, and the current 22·35 amperes. The electrical work expended was therefore 3089 watts, or 4·2 horse-power. The work utilised was very nearly 3 horse-power, and the electrical return was therefore about 71 per cent. There were no experiments made with a brake to determine the mechanical work and duty, but there is every reason to suppose, says our contemporary, that in the two cases above mentioned the mechanical duties were respectively 50 and 57 per cent.

UNDERGROUND WIRES FOR NEW YORK.—In the last number of the *Operator* Mr. G. M. Coggeshall discusses the subject of overhead and underground wires in New York. He concludes as follows:—"We will now discuss the various kinds of conductors needed for the different systems. The telephone, being the most easily affected by induction and requiring connections at every building, necessitates the use of separate insulated conductors. The various automatic systems and the messenger service require the same. The telegraph companies, owing to the long distance between offices, could use any of the cable systems, allowing one or more to each company. For the electric light some sectional system of large conductors is necessary, preferably those wound with cotton dipped in compounds of wax, resin, &c., and encased in lead. The use of conductors encased in iron pipes would not be advisable. The selection of insulated conductors and the construction of conduits are matters that our electricians and engineers are fully competent to determine. Having decided upon a feasible plan, we will next arrange for the construction and management of the conduit. Evidently it would not do for a private corporation to build or manage it, therefore the electric companies should organise a separate company managed by a Board of Directors chosen from each company, the stock to be equitably divided among the various companies, the underground company to make all connections, repairs, tests, &c., and do all work connected with its department. As to the cost of such an undertaking, from actual experiments made recently in Boston, and from careful approximate calculations made here in New York, a system such as we have mentioned, for the down-town district, would cost about 1,500,000 dollars per square mile; the residence section would cost about 1,000,000 dollars per square mile, meeting all the present and prospective wants of all the electric companies. The people who are served are asking too much when they demand that all wires shall go underground. This is probably the dividing line between the people and the electric companies. As an illustration of what I mean I would say that the heaviest business carried on by telephone is between the various commercial houses and exchanges, and the railroad, steamboat and steamship docks, and yet the telephone company get for this the rent from only one, or at the most two instruments on each dock. The cost of putting conductors under ground to these distant points would be immense. The same objections hold good for all the outlying residence and manufacturing sections. It will apply equally to the messenger service and to the electric light companies. The just and proper thing to do is to let this unreasonable cry, "The wires must all come down," cease, and cause to be placed one or two conduits through from the battery to the Harlem River for all the trunk lines. That would do away with all the heavy poles and the bulk of all the wires. Then put the wires in the business and dense residence section underground. A committee could be appointed composed of representatives of the city and the electric companies to decide upon the boundaries of the districts. Other sections to be placed underground as fast as the business warrants it. The foregoing, of course, would require intelligent and careful legislation."

THE ELEMENTS OF ELECTRIC LIGHT ENGINEERING.

BY E. C. RIMINGTON AND C. W. J. CRAWLEY.

(CONTINUED FROM PAGE 295.)

As the accuracy of Ayrton and Perry's ordinary ammeters and voltmeters depends on the permanent horse-shoe magnet retaining its power, it is important that the keeper should never be left off for longer than necessary. On the other hand, if by accident the instrument be used with the keeper

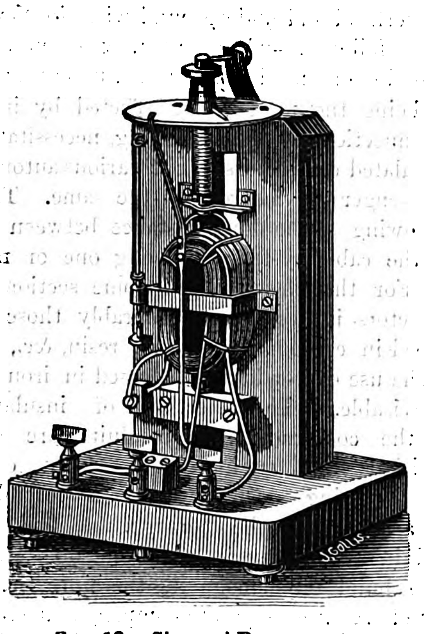

FIG. 12.—Siemens' Dynamometer.

on, the needle is liable to be injured by being swung violently against the side. In most cases it is inadvisable to leave the current running through the instruments when not in actual use for fear of heating the wires. A make and break key is therefore generally introduced into the voltmeter circuit, and only depressed when a reading is required. The ammeter is usually either cut out or short circuited.

Another convenient current-measurer is the Siemens electro-dynamometer, Figs. 12 and 13. Here the coils act, not on a

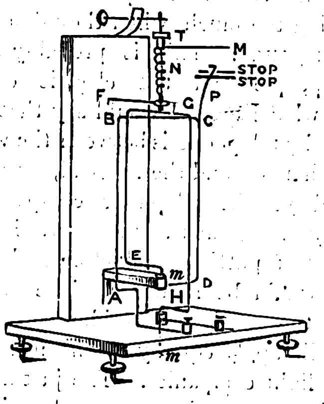

FIG. 13.—Diagram of Siemens' Dynamometer.

magnetised needle, but on a suspended coil, through which, as well as through the fixed coil, the current passes, thus obviating the variation due to loss of magnetism, to which most instruments are liable. Fig. 13 gives the arrangement of the instrument, only one turn of the fixed coil being shown for the sake of simplicity. The current enters at the left-hand terminal, passes through the fixed coil A B C D to the upper mercury cup m', thence through the swinging coil E F G H to the lower mercury cup m, and out at the right-hand terminal. Then since the current in G H is parallel to and in the same direction as that in C D, there will be attraction between G H and C D, and the latter being fixed, G H will move towards it, and the pointer P will turn towards the right-hand stop. It will easily be seen that the currents in all the other parts of the coils have a like effect in making the pointer move to the right.

If the current be reversed, P will still turn to the right-hand stop, for the currents in G H and C D are still parallel and in like direction. This instrument therefore gives no indication of the direction of the current, as is done by instruments with a magnetised needle; but, on the other hand, it can, for the same reason, measure an alternating current, which no instrument with a magnetised needle can do.

Fig. 12 shows an instrument with two fixed coils; one consisting of a few turns of thick wire starting from one terminal, the other having more turns of finer wire, for small currents, starting from terminal No. 3, the other end of each wire being connected to the upper mercury cup, so that whichever fixed coil is employed the current passes through the hanging coil and out by the centre terminal, which is common to both. The current is measured, not by the angle of deflection of the swinging coil, but by the amount of torsion which has to be put on the coiled spring N (one end of which is attached to the hanging coil, the other being fixed to the milled head T) to exactly counterbalance the effect of the current and bring the coil back to its original position, as shown by the pointer P returning to zero. The current is then proportional to the square root of the angle of torsion.

The force of attraction between two parallel wires traversed by the same current varies as the square of the current when the distance between them remains constant. Conversely the current varies as the square root of the attractive force. Now, the force of torsion varies as the angle of torsion; when, therefore, the attractive force due to the current and the opposing force of torsion are exactly equal, the current varies as the square root of the angle of torsion.

The current is therefore equal to the $\sqrt{\text{angle of torsion}}$ multiplied by a constant. This constant is given at the head of the table supplied with each instrument, the table itself being the product of the constant into $\sqrt{5}$, $\sqrt{10}$, $\sqrt{15}$, &c. —that is, the number of amperes corresponding to 5°, 10°, 15°, &c., of torsion as shown by the pointer on the top of the dial.

The constant should be verified occasionally by passing a current of known strength, C amperes, through the instrument, noting the angle of torsion D° ; then the constant $K = \frac{C}{\sqrt{D^\circ}}$.

Should the table be lost or K be found to differ, a new one should be made of the values of $K\sqrt{5}$, $K\sqrt{10}$, $K\sqrt{15}$, &c. Or a table may be worked out for the values of $\frac{C^2}{K^2}$, where C = 1 ampere, C = 2 amperes, and so on; thus giving the number of degrees corresponding to 1, 2, 3, &c., amperes. To use the instrument, it is first levelled by the three levelling screws, till the point of the plumb wire hangs exactly over the fixed point. If there is no plumb wire on the instrument an ordinary spirit level can be used, or for rough work the position of the ends of the moving coil in the mercury cups can be used as a guide, the instrument being altered by means of the screws until each end of the coil is exactly in the centre of its mercury cup. At the back of the base board will be found a milled headed screw working through a brass spring plate. This must be screwed down to free the moving coil.

(*Be careful always to release the spring again* by unscrewing the milled head before moving the instrument or when it is not in use.)

The pointer P should now swing freely between the two stops shown, the point which is bent over being just clear of the surface of the dial. If it is too high or too low it should be adjusted by carefully turning the milled head, on which the suspending fibre is wound. Pointer M (Fig. 14) is now set to zero by the milled head T, when, if the instrument is properly levelled and in order the end of the pointer P will also swing to zero. The instrument is now put in the main circuit and the current turned on, the pointer P immediately swings

over to the right-hand stop and remains there. The pointer M is now turned by means of the milled head T in the direction of the hands of a watch until the needle again returns to zero. The angle of torsion as shown by M on the scale is now looked out in the table where the current equivalent to it is found. If the current is not quite steady the needle P, of course, cannot quite be brought to rest at zero, but must be made to swing evenly on each side of it. Being now enabled to take measurements, and E.M.F. at the terminals, it is advisable to draw a characteristic curve for the dynamo employed, *i.e.*, a curve giving the relations between the total E.M.F. and the current.

The machine is run at a constant speed through a certain external resistance, the terminal E.M.F. and current are observed and noted down, the external resistance is then changed, the speed being maintained the same as before, and

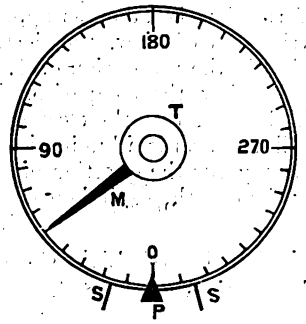

Fig. 14.—Siemens' Dynamometer Dial.

the terminal E.M.F. and current again noted down. About twenty or more observations are made in this manner, the external resistance being varied gradually from being so great that hardly any current is generated by the machine to being so small that the greatest current consistent with safety, as regards the heating of the wire on the armature and field-magnets, is produced. With each variation of the resistance the terminal E.M.F. and current are carefully noted down, the speed being constant throughout. Two lines O X and O Y (Fig. 15) are then drawn at right angles of one another. O Y is divided into a number of equal parts representing volts; O X into a number of divisions on the same scale representing amperes. Next draw a line O D so that tan D O X or $\frac{DX}{OX}$ equals the internal resistance of the dynamo in ohms. Now mark off O m on O X, the number of divisions

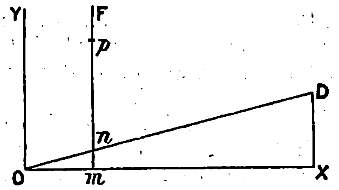

Fig. 15.

representing the current in amperes from one of the observations. Draw mF parallel to O Y, cutting O D in n. From n mark off, along n F, $n p$, the number of divisions representing the terminal E.M.F. in volts for the observation corresponding to the current O m; this will give p as a point on the curve. From the other observations other points can be obtained, and the curve joining all these points is the characteristic curve for that dynamo at the particular speed at which it was run in taking the observations. It is often advisable to make the divisions representing amperes two or three times as large as those representing volts, for by doing this we obtain the curve of a more convenient shape, but it must be remembered that in this case the internal resistance is no longer equal to the natural tangent of the angle representing it as measured, but equals $\frac{DX}{OX}$ where D X equals volt divisions and O X equals ampere divisions.

Thus, supposing the machine had an internal resistance of half an ohm, we mark off on O X, X =, say, 20 amperes, and X D = 10 volts, then join O D.

To use a characteristic curve.

To find what current we shall obtain through a given resistance at a given speed,

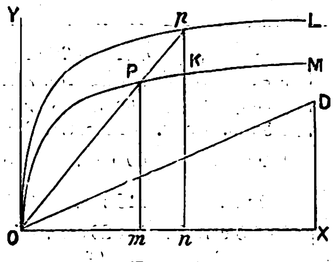

Fig. 16.

Let the speed be that for which the characteristic curve O P K M (Fig. 16) is drawn, and let tan. P O m or $\frac{Pm}{Om}$ represent the total resistance from the point where O P cuts the curve; drop the perpendicular P m, then O m represents the current in amperes gained through the given resistance.

(TO BE CONTINUED.)

A NEW HAND DYNAMO.

Messrs. C. and E. Fein, of Stuttgart, have lately modified their hand dynamo, and rendered it more effective from a double

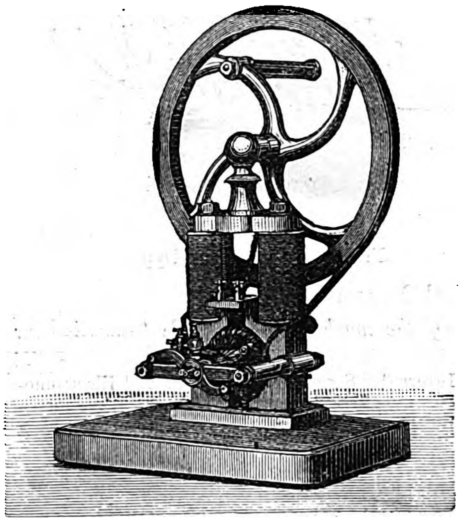

Fig. 1.—Fein's Hand Dynamo.

point of view. In the first place the new machine is cheaper than the older forms made hitherto. Then it is simplified and made less weighty, so as to be easily transported, as well as smaller, features of great importance for small physical laboratories. Figs. 1 and 2 show the machine, made in two forms (with simple and with double transmission). Fig. 1 shows the fly-wheel with crank erected on the top of the machine driving the motive pulley directly by a driving belt; this arrangement is preferable to the use of toothed wheels, as it is almost noiseless. In order to always have the right tension two tension rollers are fitted.

In the other form, Fig. 2 (with double transmission), the fly-wheel is erected on a cast-iron pillar, which has on the top a second axle for pulleys. By this arrangement a greater velocity and thereby a multiplied effect is obtained. The machines are erected on an oaken base which can be fixed upon any table by means of screw-clamps.

The machine is also made without gearing, so that it can be actuated by a prime motor, lathe, or such like.

Digitized by Google

Notwithstanding its small proportions, this machine, which only weighs 22 kgr., gives the following results :—

	With simple transmission.		With double transmission.	
	Coarse wire.	Fine wire.	Coarse wire	Fine wire.
Heats to redness a platinum wire ...	400mm. long. 0·5mm. thick.	900mm. lg. 0·1mm. thk	500mm. lg. 0·5mm. thk	1000mm lg. 0·1mm. thk
Melts a steel wire.	200mm. long. 0·5mm. thick.	350mm. lg. 0·2mm. thk	250mm. lg. 0·5mm. thk	580mm. lg. 0·2mm. thk
Decomposes water per minute	120 cm³.	60 cms.	150 cm³	75 cm³.
Deposits copper per minute	230 mg.	115 mg.	280 mg.	170 mg.
Works Swan lamps.	6 of 5 carcels. or 1 of 2·5 carcels.	1 of 20 carc. or 2 of 10 carc.	8 of 5 carc. or 10 of 2·5 car	1 of 20 carc. or 2 of 10 carc.

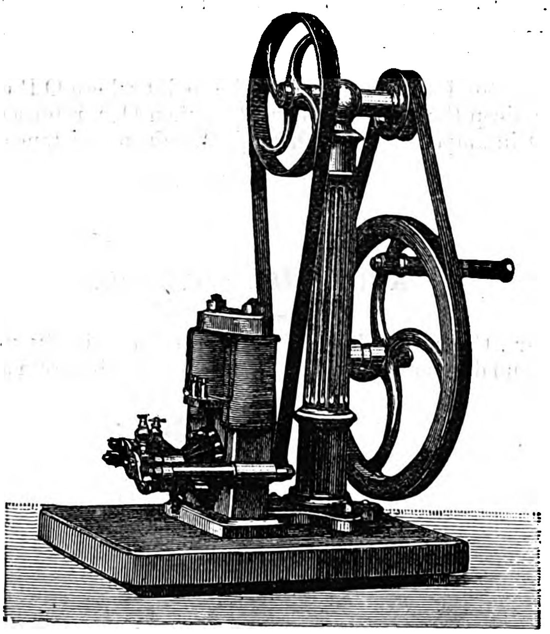

Fig. 2.—Fein's Hand Dynamo.

The Electrical Measurements are :

(*a*) *Of the machine with simple transmission* :—

	Internal resistance.	Strength of the current.	E.M.F. at terminals.	Electromotive force.	External resistance.
Thick wire	0·5 ohm	5 amperes	10 volts	12·5 volts	2 ohms
		8 ,,	8 ,,	12 ,,	1 ,,
		11 ,,	5·5 ,,	11 ,,	0·5 ,,
Fine wire..	12 ohms	1·3 ,,	40 ,,	54·6 ,,	30 ,,
		2 ,,	30 ,,	54 ,,	15 ,,
		3 ,,	15 ,,	51 ,,	5 ,,

(*b*) *Of the machine with double transmission* :—

	Internal resistance.	Strength of the current.	E.M.F. at terminals.	Electromotive force.	External resistance.
Thick wire	05· ohm	7 amperes	14 volts.	17·5 volts	2 ohms
		10 ,,	10 ,,	15 ,,	1 ,,
		13 ,,	6·5 ,,	13 ,,	0·5 ,,
Fine wire	12 ohms	1·6 ,,	50 ,,	71·4 ,,	30 ,,
		2·5 ,,	37 ,,	67·5 ,,	15 ,,
		3·6 ,,	18 ,,	61·2 ,,	5 ,,

These figures show the current of this machine is equal to 20-30 Bunsen cells, 20cm. high, connected in series with a resistance of 0·24 ohm, and an electromotive force of 1·8 volt. Therefore the current is sufficient for all ordinary experiments in a course of lectures on physics that require an electric current. These machines will be found very useful.

CORRESPONDENCE.

THE ELECTRIC LIGHT FOR LIGHTHOUSES.

TO THE EDITOR OF THE ELECTRICIAN.

Sir: Among the "Notes" of your valuable paper of the 9th August I see a paragraph taken from the *Daily Telegraph*, in reference to the lighthouse experiments at South Foreland. You very wisely point out that it would be rash to draw conclusions from such a paragraph, and give it as a piece of news only. The following facts, therefore, may possibly interest some of your readers :—

Instead of the comparison between the electric light, gas, and oil being unfavourable to the former, the following figures, I have good reason to believe, may, in lack of any better authenticated information, be taken as approximately correct. From a photometric point of view, the electric light, gas, and oil compare together in the proportion of 5, 1, and ·95. From a financial point of view the comparison is as 4, 11, and 1, from which it will be seen that the electric light is far ahead of either gas or oil as regards illumination, while it stands between the two as regards the question of cost. I should add that in calculating the cost the capital outlay has of course been included.—Yours, &c.,

J. F. Albright.

The Edison and Swan Electric Light Company,
London, 14th August, 1884.

IMPROVEMENTS IN ACCUMULATORS.

TO THE EDITOR OF THE ELECTRICIAN.

Sir: In the last number of *The Electrician* you quote from the *Rêvue Industrielle* that M. Paul Gadot has "made several improvements in the Faure-Sellon-Volckmar accumulators, which have considerably increased their capacity."

Will you allow me to state that the accumulators made by the Storage Company of London two years ago for the purpose of propelling the launch "Electricity" gave a "duty" (if this term is acceptable) of 15 ampere hours per kilogram of lead whilst working at the high rate of 42 amperes discharge through the motor driving the screw. The actual storage capacity of these cells was 13,576 kilogrammetres per kilogram of lead, with a mean E.M.F. of two volts.

M. Paul Gadot's figures are 13 and 9,400 respectively; the improvements, therefore, are not in the direction of large capacity with small weight.

The Electrical Power Storage Company are now constructing cells for motive power purposes, from which I expect to obtain a higher "duty" per kilogram of lead than has ever been attained in any practical application.

I have so frequently referred to the above results, notably before the British Association, the Society of Arts, and the Institution of Naval Architects, that I must apologise for this repetition and trespass upon your valuable space.—Yours, &c.,

A. Reckenzaun.

60, Queen Victoria-street, E.C., August 11, 1884.

CONSOLIDATED TELEPHONE COMPANY'S MEETING.

A CORRECTION.

TO THE EDITOR OF THE ELECTRICIAN.

Sir: I observe in your report of the above meeting of my few remarks that I am reported as having used the word "roguery." What I did say was "irregularity." As I disclaim having used the former word, I must ask you to put the matter right in your next issue.—Yours, &c.,

J. H. Buckingham.

ELECTRIC LIGHTING.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: The accompanying correspondence may, we think, be interesting to your readers.

To avoid possible misconception, it may be better to state, in reference to the last paragraph but one of Mr. Gordon's letter, that this company have not yet concluded finally with the Metropolitan Railway Company, but I hope a contract will be passed shortly.—Yours, &c.,

J. E. PICKERING, Secretary.

The National Company for the Distribution of Electricity by Secondary Generators, 18, Warwick-street, Regent-street, W., Aug. 13, 1884.

(Copy.)

The National Company for the Distribution of Electricity by Secondary Generators (Limited), 18, Warwick-street, Regent-street, London, W.,
Aug. 8, 1884.

To J. E. H. Gordon, Esq., B.A., M.S.T.E., Manager of the Electric Light Department of the Telegraph Construction and Maintenance Company (Limited), 38, Old Broad-street, E.C.

Dear Sir: In your interesting work entitled "A Practical Treatise on Electric Lighting" you are good enough to devote a chapter to our system of electrical distribution by secondary generators.

We are much indebted to you for the very comprehensive manner in which you have treated the question, and we feel sure that you will pardon us for drawing attention to some points which we think you will see upon reflection require further explanation in order to do justice to the subject.

A portion of the remarks we propose to offer are necessitated by circumstances which have arisen since the publication of your book.

On page 185 you say, "The Gaulard-Gibbs apparatus consists essentially of an induction coil, of which the primary coil consists of a long thin wire, and the secondary a short thick one."

This description does not apply to either the form we had in use at the time your book was written, or to the improved form which we now employ. In both forms the same length and cross section of copper are employed for the two conductors, and in the present form these conductors are absolutely identical in all respects, and similarly situated relatively to the iron core. We have adopted this latter design after a long series of experiments.

In effect the apparatus employed on the Metropolitan Railway was composed of columns formed of a cable rolled in two superposed layers of spirals round a cylinder containing iron wires, the cable being formed as follows:—

An insulated copper wire of four millimetres in diameter (No. 8 B.W.G.), through which the primary current passed, was surrounded parallel to its axis by 118 wires (No. 21 B.W.G.) individually insulated, and constituting the induced circuit. Thus the sum of the sections of the secondary circuit was obviously equal to the section of the inductor, and it followed from the central position of the inductor that the mean distance of the two circuits from the central core was the same.

The type of secondary generators now adopted is composed of copper discs of $\frac{1}{2}$mm. in thickness, furnished with earpieces allowing of their being connected so as to form two independent circuits, insulated from one another by means of discs of paraffined cardboard. This apparatus, simple in construction and far less costly than the original model, gives even a higher percentage of effective work, and cannot in any way be said to resemble an ordinary induction coil.

2. On page 187 you say, "In order that the plant which we can now afford may be able to supply the required quantity of electricity, the efficiency of the induction coils must not be less than

$$E_1 = 100 \frac{18000}{14500} = 89\%.$$

I fear that it is not likely that the efficiency will be anything like so high as this."

As a matter of fact, Dr. Hopkinson, after the most careful tests, found the efficiency of our secondary generators to be, singularly enough, precisely what you had considered necessary, viz., 89 per cent., as per his report dated 14th of March last, a copy of which we have the pleasure to hand you herewith.

3. On the same page (187) you make a comparative estimate between the ordinary 100 volt system and a system where the E.M.F. could be increased to 1,000 volts. You admit that the copper in the latter case (our own) would cost £500 only as against £5,000 in the former, but you add £4,000 in the case of employing a current of 1,000 volts for "insulator" as against £2,000 under the 100 volt system. Now, in fact, on the Metropolitan Railway we had a current of nearly 2,000 volts passing over a primary conducting wire 4 mm. in diameter (7·16 B.W.G.) and 15 miles in length; the paraffined tape (used for giving partial insulation to the primary conducting wire) when once saturated by the humidity in the tunnels furnished no insulation whatever, yet the naked primary circuit at the terminals of our secondary generators could be touched without any perceptible derivation.

This installation on the Metropolitan Railway worked without a hitch from dusk till 8 a.m. during five winter months to the entire satisfaction of the company, and we are now treating for the lighting of their entire system from a central station at Neasden over a circuit thirty miles long, the total electrical energy to be distributed being equal to 200 horse-power.

On page 188 you justly remark that, "In very scattered districts (as, for instance, the stations on the Metropolitan Railway, which are now being lighted on this system as an experiment) the proportion of the cost of the copper to that of the cost of the plant in a 100 volt system might be much greater than in the typical one which we have suggested, and in such a case the system might be useful."

We would venture to add that in such a case the cost of copper in a 100 volt system would be absolutely prohibitive, and we take this opportunity of stating, as we mentioned to you recently at a personal interview, that we do not wish to compete where other systems can be employed, but that our special province is to aid all, and commence where previously known systems cease to be operative. In doing so we offer the additional advantage of being able to furnish currents of varying potential, thereby enabling consumers to supply any type of lamp, whether incandescent or arc, as well as motive power. We propose publishing this letter, to which course, as affording us an opportunity of correcting errors, we presume you will have no objection.—We are, sir, your obedient servants,

(Signed) Lucien Gaulard, J. Dixon Gibbs, } per J.D.G.

Electric Light Department, Telegraph Construction and Maintenance Co. (Limited), E. Greenwich,
Aug. 11, 1884.

The National Company for the Distribution of Electricity.

Dear Sirs: I thank you for your letter of Aug. 8, and am much interested in what you tell me as to the improvements that you have recently made in your generators.

Whenever I commence to prepare a second edition of my book I shall not fail to write to you, and request you to give me full particulars of all improvements that you have made up to that date.

I should, both as a scientific man and as a manufacturer of alternating current machines, be much pleased to see your system successfully tried on a large scale.

I hope that the lighting which you tell me you are about to carry out from Neasden may be complete in time for me to give an account of it in the next edition of my book (the first edition is about half sold).

I shall of course have no objection to your publishing your letter to me and this reply.—I remain, dear sirs, yours faithfully,

(Signed) J. E. H. Gordon.

ANSWERS TO CORRESPONDENTS.

ENQUIRER.—*The operation you mention is not usually classed among electrical work, and we imagine the ordinary method of procedure is far cheaper than by electro-deposition.*

P. HOWELLS.—*So far as we know the small dynamos you require are not to be found in the market. Perhaps, however, some reader may be able to help you to find "a dynamo of the smallest possible dimensions that would be of sufficient power for one Swan lamp." The purpose for which the lamp is required renders a battery unsuitable. Do you require a 5, 10, 20, 40, or 100 c.-p. Swan lamp? How do you intend to drive the dynamo if you are successful in obtaining one?*

MR. FAWCETT AND THE TELEPHONE COMPANIES.

The concessions which Mr. Fawcett has offered to the Telephone Companies surprised nobody so much, perhaps, as the companies themselves. Great as is the political power exercised by the telephone interests and by the crotchetmongers who take every opportunity of damaging the State telegraph in the supposed interests of the public, a surrender so instant and so complete was scarcely dreamed of. Mr. Fawcett explicitly exonerates the permanent officials from responsibility for the regulations complained of but now altogether abandoned; he might, we should imagine, exempt them from the responsibility of sweeping those regulations away. To the permanent officials, and to them alone, the decision of the Postmaster-General has probably caused no surprise. Uniformly to yield to noisy clamour is the rule with which they have grown familiar during his administration, and a sacrifice of their own convictions once again at the expense of the Department is rendered easy by the accommodating broad shoulders of its parliamentary chief.

Mr. Fawcett's language partly justifies these observations; but they are based chiefly on our inability to believe that the permanent officers of the Department—men who have large practical experience of the telegraph, of its traffic, its tariff, and its management—could have concurred in framing the recommendations which were announced in the House of Commons last Thursday week. But this is comparatively a small matter. The concessions are made, and will be eagerly accepted. The really important point now is their effect upon the telegraphs belonging to the State, as well as upon private telephone enterprise. The companies have obtained for their property what, in the language of the day, may be called an "unearned increment" of very considerable dimensions; they are now placed on a footing of almost practical equality with the Post Office telegraphs, and all they have got to do to make the balance perfect is to push their advantage on the lines kindly indicated by their official competitor. On the other hand, the Postal Telegraph has now to suffer to the extent of its rivals' newly-acquired gains. But this is by no means all. Mr. Fawcett has made it next to impossible to refuse those further concessions, which will, to all intents and purposes, undo what the law courts, at great cost and labour, secured, namely, the inviolable monopoly which the country had bought and paid for.

This at least is our opinion after considering the situation with as much impartiality as can be given to it. Indeed, it would not otherwise be worth while to criticise the decision were it not for the consequences which are almost certain to follow on it, but which seem to have been entirely overlooked or set aside. The recipients of Mr. Fawcett's bounty were quick to perceive this the moment they recovered from their first astonishment, and forthwith demanded all or nearly all that remained to be given up. The concessions were exceedingly fair, they were even generous—but only "as far as they went;" and *The Times* next day spoke of the "worst evils of official monopoly" being "mitigated" but "not removed," and of Mr. Fawcett's concessions as an instalment of reform which must shortly be followed by measures of a more liberal character. These measures, *The Times* thinks, are to be made practicable by the process familiar to electric lighting companies—the wiping off of capital. With a blank page for its capital account—the purchase money for the telegraphs being struck out—the Post Office could afford to treat the Telephone Companies as if they were "in the position they occupied before the Government laid violent hands on them." So say *The Times* and Dr. Cameron. It happens that it was the companies that laid violent hands on the Government's property; but let that pass. What we have to note is that, much as they have obtained, the companies expect to get more, and we think they will get it.

For example, after virtually cancelling the distinction between telephony and telegraphy, is it possible to retain it in respect to the traffic? We are inclined to agree with Mr. Gray that the restriction forbidding the companies delivering written messages is "unworthy of the right hon. gentleman;" unworthy of anybody who seriously desires, after what has happened, that a distinction so artificial should last. Again, will it be practicable, in view of the 10 per cent. royalty, to permit free competition, much less for the recipient to actively compete on his own account? And while demanding this royalty in all circumstances, how can the Government decline to assist—nay insist—that wayleaves shall be given their clients who have to pay it? Holders of licences will have a stronger case now than ever for demanding protection, and for regarding the Government as a sleeping partner in their business, and as a sharer of its risks so long as a share of its profits is accepted. The royalty we hold to have been a mistake from the very first, and it is now pretty

Digitized by Google

plain that this, too, will have to go, when there will be absolutely nothing left to take its place. Its maintenance has made freedom from all restrictions a logical necessity; free competition will similarly relieve the competitors from the burden of the Government tax.

This we think is certain, especially in the face of Mr. Fawcett's astounding confession that he was at first "considerably attracted" by the offer of the companies to guarantee the Government against any loss of local revenue consequent on complete immunity from regulations and royalty. A more impertinent offer was never made to any respectable Government—at all events on this side of the Atlantic; and that an English government official should for a single moment entertain it is a sufficient measure of that official's squeezability, to say nothing of his self respect. We heartily share in the public congratulation that the telephone will now have free play; but what we fear is, that the public will not be so well served under this extreme latitude of freedom as they might have been under a well regulated and united system. In one respect certainly the public must suffer—by the uncontrolled and indiscriminate multiplication of overhead wires, all sort of control over which the postal authority has now completely abdicated. Sixpenny telegrams, too, were almost an accomplished fact, and the public are said to be eagerly demanding this reform. It is obvious that the financial difficulties in its way will be increased by the sacrifices now made to a competing system of telegraphs, the revenue from which will not go into, but rather come out of the postal telegraph purse.

DYNAMO-ELECTRIC GENERATORS.

(CONTINUED FROM PAGE 305.)

*Siemens' Continuous Current.**

This is known, perhaps, more familiarly by the name of its makers, but should be called by the name of the designer of its very ingenious system of winding, Herr Von Hefner Alteneck. It rivals the Gramme for compactness and efficiency, and is a type of many of the best known and most powerful machines. The field-magnets are of the form I have briefly described above as being used in the Maxim machine. They may be either vertical or horizontal, wound with the field coils in series in the circuit, on a shunt, or a combination of the two methods. The armature is cylindrical, the coils being wound in diametrically opposite divisions along the elements of the cylinder and across the ends.

In an earlier form of machine there was no moving mass of iron. The coils were wound on a German silver drum, which rotated outside a fixed iron cylinder carried by a shaft extending through the sleeves of the drum and fixed in position.

A strong magnetic field existing between the poles of the field-magnets and the iron cylinder, the drum, in rotating, caused the coils of wire to cut the lines of force, and thereby developed currents. This has now been superseded by the armature, in which the coils are wound on an iron cylinder direct.

It is curious how many people, and prominent ones, too, have fallen into the mistake which is thus stated in a recent work:—"Actual method of winding up the cylindrical drum armature of a Siemens generator, the method invented by Hefner Alteneck, is an unsymmetrical one . . . . . There are, in fact, a large variety of ways of winding coil upon a longitudinal armature, of which that adopted by Siemens is one, and not the best one."

Herr Frölich, a German engineer, and M. Antoine Breguet both thought they had discovered a new system of winding a drum armature, a more symmetrical one, when trying to describe the Siemens armature. Both of these gentlemen and those who quote them were, I think, wrong, and were led into their mistake by an inspection of the patent drawings of the Siemens machine, or by drawings which were copied from these. . . . . . . Let any one take a single wire, and after reading a description without drawings attached of the Siemens armature, and attempt to wind such an armature, or let such a one attempt to draw a plan of the winding on paper, and he can scarcely avoid making precisely the same thing as is illustrated by Herr Frölich. In other words, he will wind a Siemens armature as it is now and has been wound, but will make a better diagram than that given in the Siemens patent. In short, the last mentioned drawing does not correctly in one sense represent what it is intended to. It is to be remembered that there are the same number of complete coils as there are divisions of the cylinder; that two coils shift polarity at the same instant, and that consequently there must be in each pair of sections two independent coils occupying the same radial position.

In fact, where there are two poles of wide extension, and coils are wound in such a manner as to occupy symmetrical positions with regard to the neutral line of the field, there is but one real way of winding double coils in diametrically opposite divisions, and when properly connected they must be joined in one way only—there is no other. The methods proposed by M. Breguet are, electrically considered, unsymmetrical, because the two active parts of a coil are at times on the same side of the commutator line—that is, in the same field, and hence antagonistic. Reference to Fig. 15, and also to the development, will explain the method of winding with a single wire. I will take Fig. 15, speaking as "down" the plane of the paper when winding along an element of the cylinder away from the spectator, and calling the ends face and back.

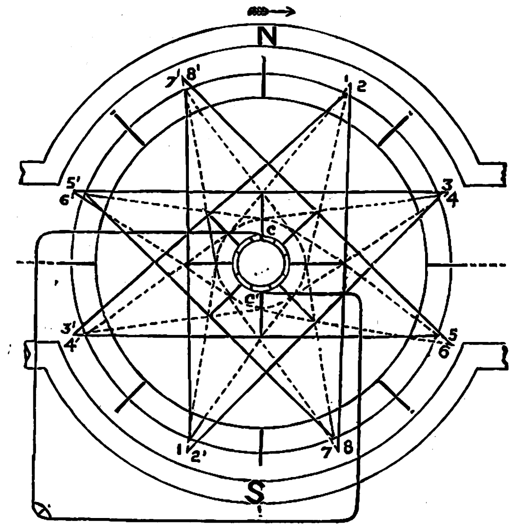

Fig. 15.—Winding of Siemens' Armature.

Starting with 4, wind down 4, across back, up 4′, across front to 2; down 2, across back, up 2′, across face to 8′; down 8′, across back, up 8, across front to 6′; down 6′, across back, up 6, and across front to 3′. Four coils have now been wound, and the eight divisions are all occupied. We now continue in regular sequence, but since we have gone half way round, and all divisions are occupied, we must put the remaining coils on top of the first, and we really wind in the reverse order, because starting on opposite elements of the cylinder. Hence we wind down 3′, across back, up 3, and across front to 1′; down 1′, across back, up 1, and across face to 7; down 7, across back, up 7′, and across face to 5; down 5, across back, up 5′, and across face to join 4, the first coil end, to which it is joined. There is now a double set of coils wound with geometrical and electrical symmetry, and forming a closed circuit. Now join the lights in seriatim to the strips of the commutator. If the circuit which is now established be followed, it will be seen that entering, say, at C, the current splits, passes over two equal paths, and that it leaves at C′, after having traversed every element. It would further

* Vide *Electrician*, Vol. X., p. 256

Digitized by Google

be seen that the currents in all the elements on one side are in one direction, and on the opposite side of the cylinder they pass in the reverse direction. In practice a single wire is not used, but enough to wind the proper amount in each coil, the ends being thus connected in a proper manner. The coils may be wound either singly or two at a time, the whole or only half of the winding being completed at once. This last will give a range of coils of practically the same resistance. When wound as described with a single wire the banking up of the wire on the ends of the cylinder produces an irregularity of resistance and length of coils, provided the same number of turns are laid on. The banking up of the wire on the ends is not avoidable, and causes some heating of necessity. The cylinder may be solid, or built up of rings or discs. There is a distortion of the lines of force and formation of transversal poles in this machine, as in the Gramme, and the brushes must therefore be given a lead. I believe the brushes are set at a given lead, but I think movable arms better. The machine is very compact, well made, very efficient, and powerful. It converts about 90 per cent. of the absorbed mechanical power into electrical energy.

*Weston.**

This machine has an armature wound on the Hefner-Alteneck plan, although its invention, considerably later, may have been perfectly novel with its maker. The cylinder is built up of a large number of the rings cut from soft iron, and having a range of widely spaced projections on the outer periphery. These rings are built up to form the main part of the armature coil, spaces being left between for ventilation. The ends are formed of iron heads with projecting pieces in wake, or in extension of the ribs which are formed by the ring projection. Several slight modifications have at times been made in the method of laying on the turns of wire, the coils being wound singly, in twos, and also side by side in the same divisions of the surface, but the connections are always those of the Hefner-Alteneck system. The connections to the commutator plates are by wires passing through a hollow shaft, this arrangement being made necessary by having the commutator outside the bearing. The commutator strips are cut obliquely, so that the line of contact, which is parallel to the axis of the spindle, touches upon two of these strips at once, insuring continuous contact and very slight sparking. The brushes are curved, so as to give end contact only, and are built up of ten or twelve thin strips, each cut into three tongues. This gives elasticity and pliability. They are mounted on a swinging frame to allow of change of position. Compound field-magnets are used, but each is made not of two large coils, but of six smaller ones, three on a side, and enclosing three circular legs, which are detachable. The part which embraces the armature is grooved or cut into tongues, and the edge of these form an elliptical outline. This form is adopted because it is claimed that the induction at different parts of the cylinder is not the same, but extends from the centre outwards.

The breaking up of the surface affords more room for ventilation, and cuts off the Foucault current set up by the reaction of the armature on the field. These machines are finely designed, run very quietly and smoothly, and are of high efficiency, probably second to none of their class. The mechanical work is of high character.

Edison.†

Of this make there are two distinct classes, one the central station dynamos, and the other embracing those designed for isolated systems. The Edison machines were designed to form part of a distinct and complete system of lighting, and, as such, they possess some peculiar features not noticed in other machines. Since heavy currents are necessary for supplying incandescent lamps in parallel circuit, and a fixed difference of potentials must be maintained at the terminals, armatures of very low resistance were adopted, and the field-magnets, which were of an unusual mass of iron, excited by a shunt current passing over a over a path of high resistance. In the smaller machines the field-magnets are wound with a large number of turns of wire, with an aggregate resistance of about 40 ohms. This, with a terminal potential of 110 volts, would give a current in the field of 2¾ amperes, and require but two-fifths of a horse-power of electrical energy. These magnets stand on a zinc plate, which is bolted to a cast-iron bed-plate, with grooves in the lower side to take slide-bars.

Wire Armature.

The armature is built up of a large number of exceedingly thin discs of soft iron, separated by tissue paper, and strung upon a wooden core. They are firmly bound together by tie-bolts, and outside of the cylinder so formed are wound the coils. Of these there are a large number; they are wound on a modified Hefner-Alteneck system, and firmly bound in place by wire bands to prevent the strands from flying out. The ends are covered with a wrapping of cloth, and the field-magnets are similarly protected. The commutator is very wide and thick, and hence is adapted for long runs. The brushes are formed of alternating layers of wire and thin strips of copper, are a third of an inch thick, and are the best I have seen for heavy currents. They are mounted in a swinging frame to allow of proper adjustment, and this is so well effected that the sparking is remarkably slight. The armature is mounted with outside bearings, and all end-strain thus avoided, although making it a little inconvenient for the belting. The circuit is closed by a switch. This machine, the Z, is designed for 60 to 65 lamps, the resistance of the armature is 20 ohms when warm, and the consequent loss is about one-half a horse-power. The machine runs quietly, steadily, and is highly efficient.

The use of such large masses of iron in the Edison machine was at one time looked upon as ridiculous, but, as pointed out also by Marcel Deprez, this is conducive to economy and efficiency. The reason is easily explained, and it is because a much more powerful field can be obtained where large masses of iron are used than where small ones are, because the saturation point is not so easily reached.

Other sizes of these machines are made for 150 and 250-light, and these are in general appearance like a combination of two and three of the Z machines—that is, there are two and three sets of field-magnets of precisely similar construction, ranged side by side, and with larger armatures of similar build. The field-magnets are coupled in parallel circuits, two legs in series.

Bar Armature—Central Station.

Another armature has been used with the Z, which is called the bar armature. The body of the cylinder is the same, but instead of using wire thick rods of copper are laid on, and the requisite connection made across the ends by copper discs; that is a coil is formed of two bars and two copper discs. This is a highly economical armature, and the resistance is very low. This form has been abandoned for the smaller machines, but is used for the central station dynamos. These are intended at the present economy to supply 1,000 to 1,200 lights of full power, 16 candles.

These armatures are very heavy, weighing four or five tons, and the bars, of which there are from 90 to 100, of large cross sections. The resistance is consequently very low, being, when cold, less than ·004 of an ohm. The connections are plated with gold to prevent oxidisation. The field-magnets are horizontal, have twelve legs (eight at the top and four at the bottom), and the pole-pieces are very heavy. The armature is driven direct from a high-speed engine, with coupling between. The speed is about 350 revolutions for the single dynamo. It is proposed to drive two armatures with a single engine of 400 horse-power, and at a somewhat lower speed. These machines can be coupled in parallel circuit, but in the case of the double armature the two will be connected in series, and the sets in multiple arc for a proposed new system of distribution. The very heavy currents taken off by sets of ten thick brushes, and the commutator blocks are removable.

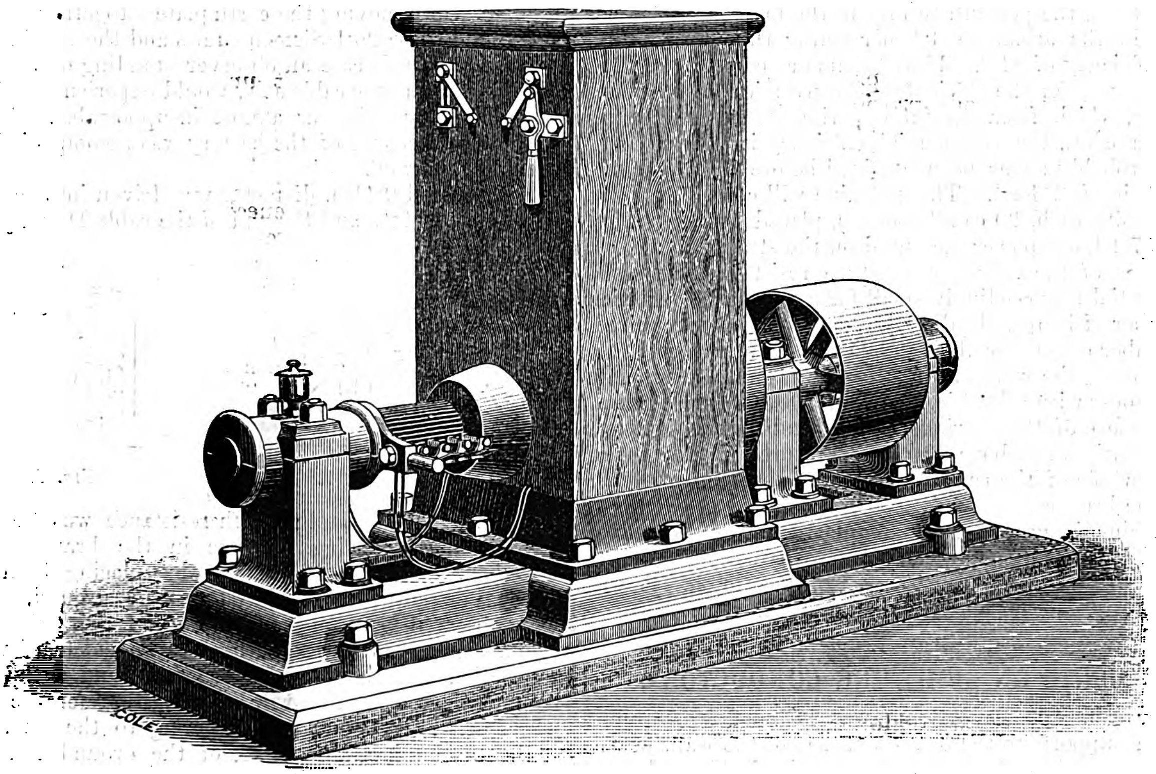
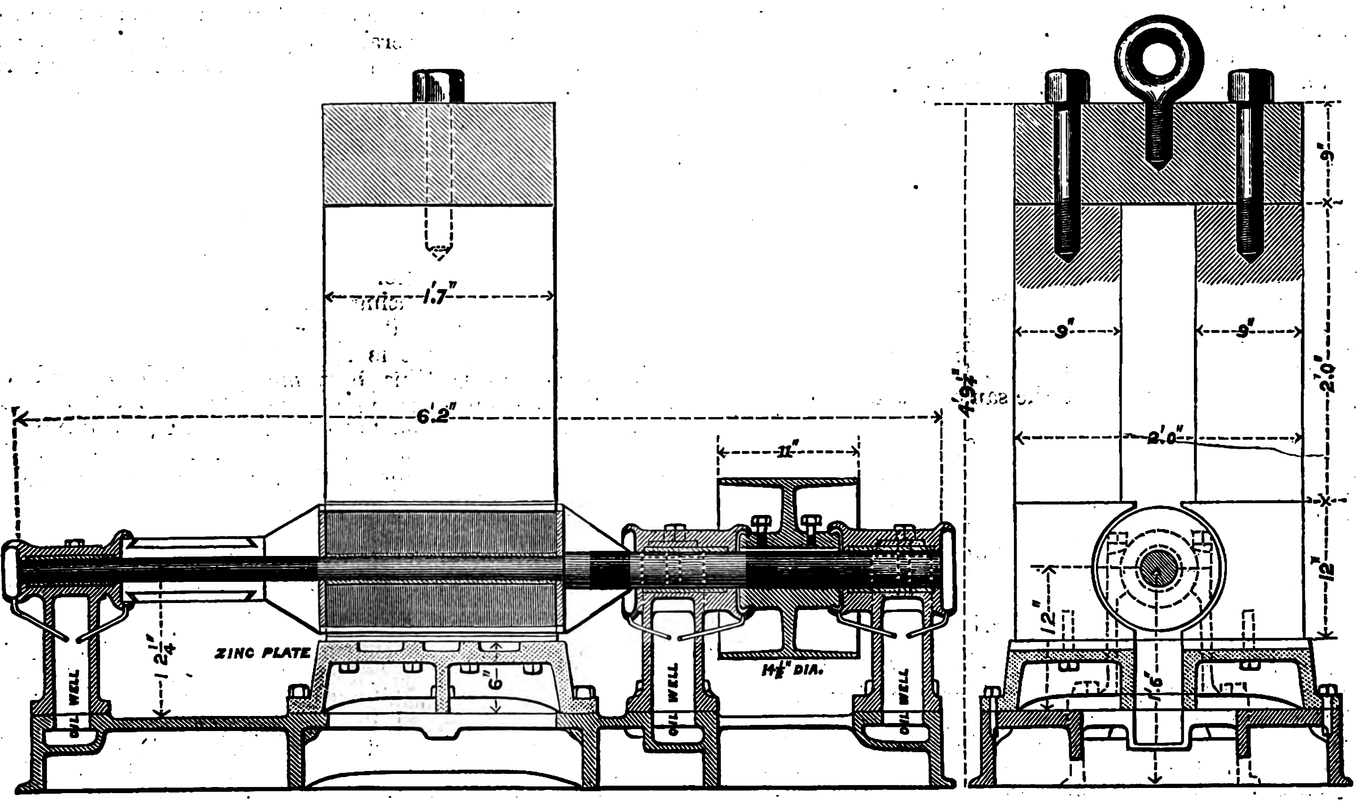
500 LIGHT 10-INCH DYNAMO.

This machine is the first that has been constructed on the Edison-Hopkinson plan to carry 500 Edison A lamps, and possesses several points of interest. The general dimensions strong current of air is automatically drawn between the armature and the fields of the magnets by the rotation of the armature. For the sake of protection, and to add to the external



500 Light Edison-Hopkinson Dynamo.



LONGITUDINAL SECTION TRANSVERSE SECTION

500 Light Edison-Hopkinson Dynamo.

of the dynamo are the same as those of the 250 light, namely, slow speed machines. The driving pulley is provided with an outside bearing, and the length of the bearings increased. A appearance of the machine, the pole pieces of the magnets and the yoke are cased with polished wood. The upper casing is convenient for fixing the switch and magnet connections. For

Digitized by Google

110 volts and 350 amperes in the external circuit the dynamo runs at 820 revolutions per minute.

The resistance of the armature is 0·0108 ohm, and of the magnets 16·4 ohms. Hence, when working with its full load, there is a loss of only 737 watts in the magnet coils, and 1,374 watts in the armature, while 38,510 are available outside the machine. Thus, the percentage loss in the magnets is 1·8 per cent., and in the armature 3·4 per cent,; this gives a total electrical efficiency of 94·8. If we assume as correct Mr. F. S. Sprague's figures for the efficiency of conversion of machines of this type, which from careful experiments he deduced as also 94·8 per cent., the commercial efficiency is 90 per cent., which has probably never been attained before in a machine working at its full load. The machine will carry 640 Swan lamps (55 volts each, 20 candle-power), placed two in series, absorbing 57·4 horse-power measured on the strap.

On account of the very low armature resistance, the variation of potential is exceedingly small for a very large variation in the number of lamps. If absolute compensation is required, a small number of series coils is sufficient for the purpose.

Before leaving the works the machine was run continuously for twelve hours with a load in excess of 500 Edison A lamps. The temperature of the bearings at the end of the run was only 12° centigrade above the temperature of the room. During the whole of the run there was no sparking whatever visible at the brushes.

The machine is now working regularly, driven by one of Mather and Platt's engines, with its full load of lamps, at the mills of Messrs. Wright, Turner, and Co., Pendleton. It was made by Messrs. Mather and Platt, of Salford.

EXPERIMENTS ON LIGHTNING CONDUCTORS.*

A copper cable, 65 yards long, was fastened by 13 uninsulated iron supports to the outside of one of the walls of the Polytechnic School in Dresden. One end of this cable was carried into a well 16 yards from the building, and containing water to a depth of 6 yards, and could there be joined on to earth plates of various dimensions. By means of a connection leading from the cable into the laboratory strong discharges from a battery of 74 Leyden jars could be sent into the cable,

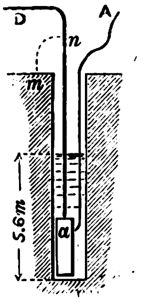


FIG. 1.

the spark being transmitted between two metallic balls kept at a constant distance. The arrangement will be understood by reference to Figs. 1 and 2, the first showing the well with cable D and earth plate *a*, the second the battery B, cable D and electrodes X. The outer coatings of the jars were in metallic connection with the water-mains W by a very stout copper wire, and might therefore be taken to be always at the potential of the earth. A branch circuit, A Z w_1, joining the earth plate with one of the branch pipes connected with the water-mains, and having at Z two smaller metallic balls, served to illustrate by the spark passing between them the principle of lateral discharges from a lightning conductor. Every time a disruptive discharge took place between the balls X in the primary circuit another discharge occurred between the balls Z in the secondary circuit, and this took place notwithstanding that the earth plate, which measured 13ft. by 1ft. 7in., was entirely submerged in the water of the well.

For the purposes of comparison the sparking distance at X was kept constantly at 0·4in., that at Z was varied to get its maximum for each arrangement. With an earth plate of the size mentioned above the earth resistance between *a* and W was found to be 2·3 Siemens units, and the maximum sparking distance at Z 0·021in. With an earth plate half as long the resistance was 3·0 Siemens units, and the sparking distance 0·027in. On removing the earth plate altogether the resistance was found to be 26·1 Siemens units and the sparking distance 0·128in. In this case an observer standing on the ground at *m*, and touching the cable at *u*, would experience a shock which the author describes as almost insupportable. At the same time each discharge of the battery was accompanied by a loud report in the well.

An iron rod 0·41in. diameter was driven into moist ground to a depth of 6ft., and the end of the cable D was joined to it

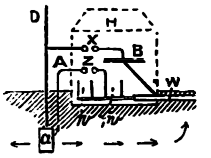

FIG. 2.

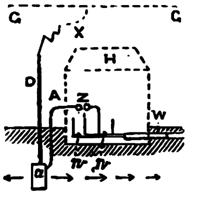

FIG. 3.

(Fig. 4). In this case the earth resistance was 30 S.U., and the maximum sparking distance in the branch circuit was 0·138in. Shocks could be felt by placing both hands at unequal distances from the rod on the ground, and sparks were observed between the electrodes of two wires, *b* and *c*. The analogy between the author's arrangement of a battery in connection with the lightning conductor and a thunder cloud hanging over a building will be seen by reference to Fig. 3, where G G is the cloud corresponding to the internal coating of the Leyden jars, the surface of the ground containing the water-mains corresponding to the outer coating, and X the stroke of lightning corresponding to the spark from the battery. The lateral or secondary discharge through Z must therefore be expected to take place in all cases where large metallic masses connected to earth come near to the lightning rod

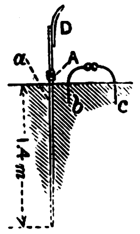

FIG. 4

without being in actual metallic connection with it; and the author considers it a most important condition for the safety of a building that all metal about the building should be in the best possible metallic connection with the system of lightning conductors. The town mains for gas and water should also be included in this connection.

* From a paper by Professor Dr. Toepler, published in the *Elektrotechnische Zeitschrift*, June, 1884.

ELECTRO-MAGNETIC ORE-DRESSING AT OBERLAHNSTEIN, GERMANY.

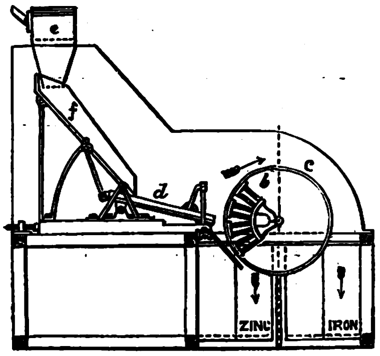
A few years since the announcement was made through the technical press that a system of electro-magnetic ore-dressing had been tried in Germany. The plant, which has now been at work for three years at the Friedrichssegen mine, near Oberlahnstein, has been recently described in greater detail by Herr Otto Heberle, at a meeting of the Verein Deutscher Ingenieure. The Friedrichssegen mine produces ore containing a good deal of iron ore and zinc-blende, which are difficult to separate, because their density is nearly the same. Two classes of ore are mined, cobbing ore, from which some pure saleable ore is separated by hand-sorting and smalls. That part of the cobbing ore that is rejected in sorting goes to the electro-magnetic separators, while the smalls are dressed in the usual manner. Middlings, containing blende and iron ore, are

Digitized by Google

obtained also in this dressing, and they too go to the electro-magnetic plant. The material for that process obtained by sorting ranges in size from 40 to 120 millimetres, while the ore from the ordinary dressing plant is 6-millimetre stuff. It is worked by first roasting, separating by means of the electro-magnets, and then jigging.

The object of the roasting is to prepare the material for the subsequent process by converting the iron into magnetic oxide. The picked lump ore is roasted in a shaft-kiln, with coke-dust as fuel. The consumption of fuel is slight on account of the sulphur in the blende, not being greater than 110 pounds to 8 tons of ore, which are daily put through one furnace. The furnace requires the labour of two men. The roasted ore goes to a rock-breaker and to a pair of rolls below it, which reduce the rock to 5-millimetre grain, and deliver it to an elevator that takes it to the electro-magnets.

The fine middlings obtained in the wet dressing are worked in one reverberatory furnace with a hearth 12 feet wide and 38 feet long, provided at each side with a fire-place, 5 working doors, and a discharge opening, and in one small reverberatory, the hearth of which is 6 feet wide and 22 feet long, and which is provided with one fireplace, two working doors, and a discharge opening. Roasting takes an hour and a half. These two furnaces have a capacity of from 18 to 20 tons in twenty-four hours; but of course the cost of fuel and labour is much greater, being fully three times as large as that of roasting the lump in kilns. After being roasted, the ore is spread out on a cooling-floor, is then passed over screens to get out sintered lumps, and is then delivered by a bucket elevator to the hopper into which the crushed and calcined lump ore goes. In this hopper, the ores are put through a screen with 4-millimetre mesh, the fines falling through chutes to the magnetic separators, while the coarse is crushed by a small set of rolls.



The dressing is done by 16 electro-magnetic apparatus arranged in sets of four in pairs above one another. The upper pair receives the ore from the chutes, and partially separates the blende from the iron. The products obtained are worked over once more in the lower apparatus. They are, 1st, a mixture of blende and quartz; 2nd, iron ore; 3rd, blende middlings; and 4th, iron ore middlings. The middlings are treated over again. As there is a good deal of dust in working, all the apparatus are connected with an exhaust-fan. The apparatus, which is shown in the accompanying diagram, is constructed as follows:—The electro-magnets are attached to a solid stationary shaft. In front of the brass cylinder *c*, which revolves around the magnets, is a shaking-table *d* and a distributor *f*. The ore drops from the chutes and through the funnel *e* upon the distributor and the shaking-table, which delivers it on to the brass cylinder *c*. As soon as the ore reaches the vicinity of the cylinder, the particles of magnetic oxide are retained, while the blende drops by. By the rotation of the cylinder in the direction indicated by the arrow, the particles of iron finally escape beyond the action of the electro-magnets and fall off at the other side of the cylinder. By adjusting the distance of the shaking-table from the cylinder, different sizes of ore may be treated. The electric current is generated by dynamos, one machine that requires a motive power of one horse-power being sufficient to supply four separators. With two sets of four apparatus of the plant now at the Friedrichssegen mine, 24 metric tons of ore, running from 12 to 15 per cent. of zinc, and from 20 to 22 per cent. of iron, can be treated for each set in twelve hours, yielding a product of 7 tons of blende and 18 tons of iron ore. The former contains about 33 per cent. of zinc, and the latter from 36 to 38 per cent. of iron and 10 per cent. of manganese. The iron ore is sold as such. The zinc ore is worked further by screening to obtain 1, 2, and 3-millimetre sizes and jigging. The object is to get rid of the gangue in the product, and to obtain the lead in it. In this manner, the percentage of zinc in the ore is carried up to 38 per cent., while the lead ore carries about 65 per cent. of lead and 0·004 per cent. of silver. The fine dust is washed in buddles, yielding lead beadings carrying 55 per cent. of lead, and zinc beadings containing 32 per cent.—*Engineering and Mining Journal.*

THUNDERSTORMS.

Once again within the past three or four weeks the intense heat we have been experiencing has terminated in a series of violent thunderstorms, which have been more than usually destructive to life and property. To detail every instance of buildings or animals struck by lightning would, judging from the pile of clippings from the provincial and daily press now lying before us, fill several pages of *The Electrician*, and serve no good purpose. We therefore propose to pick out only a few instances of destruction of property or life where the details have been recorded more fully than usual. Surely the Meteorological Office might institute inquiries into the surroundings of the spots on which Lord Lauderdale, the painter at Ripley, and the labourer at Ormesby met their deaths. Could they not obtain the evidence given at the inquests, and supplement it by examination of the locality where the lightning stroke occurred? We should have thought so. The details collected with considerable pains from various papers, which are given below, are interesting as news, but are almost valueless for scientific purposes.

The first series of storms broke over the British islands on Saturday last. In the Rossendale Valley, between Haslingden and Accrington Moors, in Lancashire, the storm was marked by a very heavy fall of hail, the stones being of unusual size, variously stated as from one to three inches long. That they must have been unusually large, and have fallen with considerable force is proved by the immense destruction of windows and greenhouse glass which is recorded. On the same day at Darwen a man named William Marsden was killed, and another man named Richard Farnworth injured by lightning whilst playing football. A stoker named Carrington, employed at Messrs. Craik's Collieries, near Barnsley, was struck by lightning whilst in the firehole, and seriously hurt. At the Chapeltown Railway Station, according to the *Sheffield Independent*, a ball of fire dropped in the midst of the passengers, but without doing them any injury. The wires in the signal box were, however, destroyed. The following details of lightning strokes and their results are from the same paper:—"In Barnsley the lightning struck a house in Somerset-street, occupied by Mr. Darham. Passing down the chimney it filled the house with soot, set fire to a cloak which was on a sewing machine, and spoilt a dress. It was observed to pass through a house on the opposite side of the street occupied by Mrs. Rowse, and burst with a loud report in a back garden. At the same time it struck another house in the same street, occupied by Mr. Hayes. The house was filled with soot. Mrs Hayes was hurled violently to the floor, but was not seriously injured. During the storm a house at Handsworth, occupied by Richard Foster was struck by lightning, the electric fluid coming down the chimney, displacing some of the brickwork and breaking the pictures hanging upon the walls in the room, passed through the wall into the adjoining cottage, occupied by Miss Swann, and disappeared again through the ceiling, doing considerable damage to the plaster, &c. In Foster's house were several children. One of these was cut severely upon the face, and a second was burnt upon the body, and the third was also injured in a similar manner. Foster's wife was in the house at the time. At Clowne the electric fluid struck the chimney of the house occupied by Mr. Thomas Fenton Salvin and family near the Cross. The fluid displaced the masonry work of the chimney, and passed down into the kitchen, causing the utmost alarm, and filling the room with sulphur, soot, smoke, and dust. A gun, which previously hung over the fireplace, was dislodged and hurled across the house, and was found doubled up under the wringing machine, and the large beam supporting the upper chamber was splintered by the electric fluid passing along it into an adjoining washhouse. At Glossop the lightning struck the chimney of the house of Charles Shepley in Surrey-street, where it displaced a number of bricks, and after travelling part of the way down the chimney burst a hole through the brickwork and entered the front room, where it swept the carpets off the floor, and threw them all in a heap. The fluid seemed to have swept round the room, and then found its way out of the window, which was open. The railway station buildings at Worksop were struck by lightning. Fortunately very little damage was done, but as the platform was thronged with people some fright was occasioned among those present. The fluid struck at the east end, and appeared to follow some of the iron rods which form the support of the roof, running along one for some yards, and then exploding with a sharp smack quite distinct from the peal of thunder which followed."

Another paper states that a ball of fire was seen to descend at Stratford-on-Avon, close to Shakspeare's birthplace in Henley-street, but did no damage. The *Newcastle Daily Chronicle* says:—"At Low Staples, the

Digitized by Google

farm of Mr. Wm. White, the chimney of the back kitchen was struck by the fire and knocked to pieces. The electric fluid seems to have divided at the chimney, and to have struck both the interior and the outside of the building. Several articles were damaged; for example, a strong stone whetstone, lying on a shelf in the back kitchen, was split into two portions, one of which was left on the shelf and the other hurled to the floor, and a gun, in cover, had the cover singed and the muzzle rather doubled in. Mr. White himself was standing at the stable door, and was lifted off his feet by the electricity. He experienced a painful sensation, as if his legs were being torn off above the knees, and still feels a peculiar numbness and stiffness about his leg joints. His eldest daughter also seems to have been somewhat affected by it, as she felt pain and stiffness about her ankles. The Dalton Fell, a rough pasture, covered with whins, &c., was set on fire by the lightning."—The *Yorkshire Post* says:—"An inquest was held—before Mr. Bladon, deputy-coroner—on Monday afternoon, at Haxey, near Gainsborough, on the body of Mrs. Louisa Major, the wife of a postman, who was killed on Saturday by lightning in her own house. During the height of a terrific storm the attention of the next door neighbour was attracted by smoke proceeding from deceased's house. On entering they found her dead, and the woodwork of a sewing machine on fire together with other things. The wall was hot and blackened and the room full of soot. A child nineteen months old sitting on the floor was uninjured, although covered with soot. Dr. Eminson said the electric fluid had been attracted by the sewing machine, and the jury returned a verdict to this effect."

M. G. F. Roumieu, coroner for West Surrey, communicates the following to *The Times*:—"I held an inquest recently at Ripley, near Woking, on the body of George Henry Mitchell, a painter, who was killed on Saturday last by being struck by lightning. From the evidence it appeared that deceased, who lived at Battersea, had been employed at Ripley Court, and, having finished his work, was proceeding to Weybridge Station, with the intention of returning home; on his way the thunderstorm came on which appears to have done so much damage in other parts of the country. He was seen by a boy to take shelter under a large tree which stands in a meadow by itself. Almost immediately after the deceased got under the tree a vivid flash of lightning was seen, and deceased was observed to be lying on the ground. A man at once went to the spot and found him lying on his face quite dead. The doctor who examined deceased said his face was perfectly black, all the hair on his face and head singed, and the tympanum of his left ear ruptured. Deceased had on a leather belt with an ordinary metal buckle; the clothes around and under it were burnt and the flesh charred; his felt hat was very much broken in on one side, and his boots, which were nearly new, presented a very extraordinary appearance, the laces were completely charred and broken up almost like tinder; on the inside of each boot, just at the instep, was a rent in the leather large enough to push an egg through, by the exit of the electric fluid into the earth. The tree under which deceased was standing had been struck by lightning a few years ago and very much damaged as it was on this occasion. I know of several instances where trees have been struck by lightning more than once. Can there be any particular attraction for lightning in these various spots?" All the above accidents occurred during the storms of Saturday.

The parish church of Glaurinnes, Banffshire, was struck by lightning on Monday afternoon. The belfry was completely consumed and great part of the roof burned before the flames could be checked, while the bell fell down the shaft, and much damage was done to the interior of the church.

On Tuesday last a fresh series of storms broke over the country, again doing an immense amount of damage. At North Ormesby, near Middlesborough, a very similar accident occurred to that reported in our issue o the 2nd instant as having happened at Nottingham, when a milkman was struck dead in the streets. In this case, however, it was a woman who was struck whilst selling milk, and the report merely says that she was rendered insensible. A man engaged at Old Ormesby in sprinkling lime in a field was, however, struck dead.

The lightning entered a house in the village of Whitlets, in Ayrshire, Scotland, smashed the grate in one of the rooms, passed into the kitchen, and broke a large piece out of the hearthstone. A woman sitting by the hearthstone was uninjured. At Glasgow a flash was observed to strike the steeple of St. Mark's Free Church, cutting away a part of the ornamental stonework and shattering the slates, three large holes being made in the roof. At the same place three men, while erecting a stack, were struck by lightning in Swanston-street, and rendered insensible. One named William Herbert, sixty-three, was so seriously injured that he had to be conveyed home; but the other two shortly afterwards recovered. The roof of the Naval School on the south bank of the Clyde was stripped completely off by lightning. The roof of the Bonnington Sugar Refinery was struck by the lightning, which also entered the police station at Newhaven, near Edinburgh, and ignited the gas, and destroyed the wire communication with the head office. In the Lauder district the Earl of Lauderdale was struck by lightning while on the moors. He was mounted on a pony, which was killed under him, and was proceeding across the Braidshaw Rigg, on the Lauderdale estate, when the storm was at its height. He was struck on the forehead by the lightning, which made a deep wound on his forehead and breast. The fluid melted his watch and chain, and also part of the case, but did not stop the watch, and then, being diverted into two currents, ran down each side of his left leg, the course being plainly traced by the scorched mark which was made. His clothes were also burnt. The deer-stalking hat which the earl was wearing at the time was torn to shreds, and was thrown by the shock in one direction, while the pony and its rider fell in another. The earl was taken to the nearest farmhouse, where he regained consciousness after a time. During the afternoon he continued in a very dangerous condition. He became comatose about eleven o'clock at night, and died in less than an hour afterwards. A man named Taylor was killed by lightning at Little Langton, near Northallerton, a child in his arms escaping uninjured. At Levisham, near Whitby, hailstones fell fully 1½in. in circumference.

Continuing our account of Tuesday's storm, the lightning struck the telegraph wires which cross the Mile End-road, East London, one of the wires being severed and falling across the carriage way. One paper says:—"A terrible thunderstorm prevailed on Upper Deeside. Huge balls of fire were seen rolling down the slopes of Lochnagar, and the buildings at several farms were struck by lightning." Another paper describing the storm at Dundee says:—"The effect of the lightning play was brilliant in the extreme. The lightning sometimes darting in brilliant fire balls, which seemed to burst just over the earth." At Leith a four-storied house in Mitchell-street was struck by lightning, which forced out the firegrates in the rooms on the second and third floors, severed the gaspipes and ignited the gas on the top floor, passed through the ceiling, and stopped a clock. At Bacton, near Norwich, a house belonging to Mr. G. Smith was struck by the electric fluid, which passed through the roof and on to the staircase, where the wife of Mr. G. Little was passing. The woman was killed instantaneously. Her infant, about twelve months old, which was in her arms at the time, escaped, although the hair on one side of his head was burnt off. At Canterbury the lightning seems to have passed through one window of the military washhouse, where a number of women were at work, and passed out of the door, fortunately causing no injury. A chimney stack in the married quarters was also struck. The electric fluid passed down two of the flues, dislodging large quantities of soot and bricks into rooms occupied by Private Barnett, 8th Hussars (up stairs), and Private Mallen, 12th Lancers (ground floor). Fortunately, no one was in the apartments of the former, but a great deal of damage was done, and the place set on fire. Corp Levison, 13th Hussars, was struck and knocked down, while Regimental Serg.-Major Martin received a shock.

On Wednesday morning early, while a terrific thunderstorm was passing over Fylingdales, near Whitby, Yorks., the lightning descended the chimney of a farmhouse at Stoup Brow, near Robin Hood's Bay. The house is occupied by Mr. Robert Stainthorpe, who, with his wife and child, were in bed at the time. The electric fluid entered the room where they were in bed, set fire to the bedclothes, and did other damage. Mrs. Stainthorpe was struck by the lightning and remained insensible for two or three hours, but she afterwards fully recovered and is not seriously hurt. The child also escaped uninjured. Mr. Stainthorpe was not quite so fortunate, as he was struck by the lightning and badly burnt on one of his legs. He is now doing well under medical treatment. It is a remarkable fact that Mr. Stainthorpe's silver watch and chain, which were hung up against the ceiling near the bedside, were destroyed by the lightning, the silver being melted.

THE TELEPHONE COMPANIES AND THE POST OFFICE.

The following is the report of the discussion on the policy of the Post Office with regard to the telephone companies, which took place in the House of Commons on Thursday, the 7th inst. Our report is from *The Times*:—

On the vote to complete £1,734,589 for the Post Office Telegraphs,

Mr. Fawcett said—Knowing the great interest that is taken in the question of telephonic communication by many hon. members on both sides of the House, I think it will be convenient to the Committee, and will save time if I at once explain the decision which has been arrived at by the Government on this subject [hear, hear]. On many occasions I have stated that we have been most anxious to afford every facility for telephonic communication which is compatible with due regard to the interests of the revenue. I am free to confess that during my short official experience no question that I have had to deal with has presented so many difficulties, and I trust the Committee will accept the assurance that, in attempting its solution, I have been actuated by no other motive than a desire to do what I believe would most conduce to the advantage of the public [hear, hear]. I feel that no good would result from occupying the time of the Committee by going over bygone controversies, and therefore I will at once state that, after taking into consideration all existing circumstances, I have come to the conclusion that, in order that the public may enjoy the facilities with regard to telephonic communication which, in my opinion, they may fairly claim, it is desirable to give greater freedom to private enterprise by relaxing some of the conditions contained in the licences which have been granted to private telephone companies [hear, hear]. This being so, we have to consider what are the conditions on which telephonic communication should be supplied by private enterprise in order to secure, as I have already stated, on the one hand such facilities as the public have a right to demand, and on the other due protection for the Revenue. With the view of obtaining all the assistance I could in determining this question, I, some weeks since, asked the telephone companies to furnish me with a statement of their views upon the subject. The United Telephone Company and its affiliated companies shortly afterwards, in response to this request, submitted three distinct proposals, which I will proceed briefly to describe. Before doing so, I may remark that from four telephone companies not affiliated with the United Telephone Company I have also received statements of their views which, except in one particular, do not vary in any important respect from those of the United Telephone Company. The point on which they specially insist is protection from competition within towns in which they carry on telephone exchange business. This is a suggestion which I think ought not for a moment to be entertained [hear, hear]. Reverting to the three proposals received from the United Telephone Com-

Digitized by Google

pany and its affiliated companies, the first is that each company should be allowed to carry on business within the district for which they may hold a licence in any way they may think fit, and that in lieu of the royalty of 10 per cent. now paid to the Post Office on their gross receipts, the companies would undertake to make good to the Department any loss which the local telegraph revenue might suffer from the development of telephonic communication within such district. In estimating the telegraph revenue account was to be taken of its normal growth, by estimating what had been its growth during the previous three years. The second proposal contemplated that the existing royalties should be reduced from 10 per cent. to 5 per cent.; that the same guarantee as that contained in the first proposal should be entered into; that the existing radius for exchange licences, which is now generally fixed at from four to five miles, should be extended to fifteen miles; and that various other restrictions should be removed, which would in almost all essentials give the same freedom as that embodied in the first proposal. Before describing the third proposal, I think it may conduce to a clear understanding of the question if I at once proceed to state why I have come to the conclusion that the existence of such a guarantee as that which I have just described is inadmissible. At first sight I was a good deal attracted by it, and I thought it might offer a solution of the question. When, however, I examined the proposal further I came to the conclusion that with such a guarantee there were associated some very serious and, indeed, insuperable objections. If it were accepted a monopoly would at once be conferred, so far as each locality was concerned, upon the particular company which gave the guarantee, for it would obviously be unfair to accept a guarantee unless the guaranteeing company were secured against competition. I think the opinion will be generally accepted that if there is to be a monopoly it had better be in the hands of the Government, who can be controlled and who are directly amenable to public opinion, than in the hands of a private company [hear, hear]. Besides this objection there was another which, even if it had stood alone, would, in my opinion, be quite sufficient to prevent the idea of a guarantee from being entertained. If the Post Office had once accepted the principle of such a guarantee its discretion would have been fettered in introducing any change in the telegraph tariff. The third proposal of the companies contemplates no guarantee, and proposes that the existing royalty of 10 per cent. should continue to be paid, and that similar modifications to those I have already referred to under the second proposal should be made. I may further state that great stress was laid by the companies in all the proposals submitted to me upon the abandonment of the condition contained in all recent licences that the companies should furnish the Post Office with an unlimited supply of any patented instruments used by them. As already stated, I cannot accept the principle of a guarantee, which is an essential feature of the first two proposals. I have, however, come to the conclusion that the third proposal, an essential feature of which is the continuance of the existing royalty of 10 per cent., affords a basis for a settlement, and the terms the Government have decided to offer are the following:—(1) That the Government should reserve the right either to carry on telephone business itself or to give licences to any responsible persons to carry on such business in any part of the country, whether any previous licence has been granted for such part of the country or not. (2) That the condition that the companies should furnish the Post Office with an unlimited supply of any patented instruments used by them should be abandoned. (3) That as the extension of the radius to 15 miles asked for by the companies would involve in principle just the same objections as fixing the radius as at present at four or five miles, no limitation of radius should be maintained. (4) That with the abolition of any limit of radius and consequent extension of areas the distinction between the conditions on which the companies have hitherto been allowed to use trunk and exchange wires will not be maintained, the companies being in future able to provide themselves with trunk and exchange wires alike. (5) Call offices should be allowed for the transmission of oral communications. (6) Having regard to these concessions, and to the desirability, as far as possible, of securing simplicity of accounts between the Post Office and the companies, the royalty of 10 per cent. now paid on gross receipts should be extended to their receipts from private wires. (7) That the Post Office incurs no obligation to provide way-leave or to erect wires for the companies. (8) That, in order to maintain the distinction between written telegraphic messages and the spoken communications made by means of the telephone the telephone companies shall not accept or deliver any written message at any point. I think it will be seen that, so anxious have I been to redeem the pledge that no unnecessary impediment should be thrown in the way of the public enjoying the advantages of telephonic communication, in some respects I have conceded more than has been asked for either by the companies or by the public [cheers]. I can only say that I hope the terms will be received in the spirit in which they are offered, and if they should be unreservedly accepted as a settlement of the question it is only necessary for me to add that as soon as the existing licences are returned they shall be amended so as to carry out the foregoing proposals; and that in all new licences which may be granted the terms just described will be embodied [cheers].

Mr. JACOB BRIGHT thought that the arrangement proposed by the Postmaster-General, which appeared to be as just as it was generous, would be satisfactory to the persons in Manchester who were interested in the subject [hear, hear].

Mr. GRAY said the statement of the right hon. gentleman was highly satisfactory and exceedingly clear. He quite agreed with the provisos relating to the protection of the public and the Department, and did not think it would be wise to go back over old controversies. If the right hon gentleman, when he said that there was no obligation on the part of the Department to erect trunk wires for the telephone companies, meant that he would not erect them, the result would be such as the right hon. gentleman in his present frame of mind did not contemplate. It was impossible for any company, or any private individual, to run wires from town to town, because the Post Office had obtained a monopoly of way-leaves along the railway lines. If the right hon. gentleman meant that the Post Office would not erect them unless it would be for the convenience of the public he had no objection to that; but if the right hon. gentleman meant that the Post Office would not do so in any case he would shut out the public from a great convenience. The companies were not desirous to secure revenues from trunk wires, but only that those who used telephones in towns should have facilities for communication between town and town. What he wanted from the right hon. gentleman was some assurance that he would not draw a hard-and-fast line which would deprive the public of the United Kingdom of an advantage which the public of every civilised country either had already or were about to have—namely, that of carrying on conversations with people living in towns at a considerable distance. Let the right hon. gentleman make all the profit he could, but let him not, because he had a monopoly, prevent the public from deriving any advantage from a great discovery. The right hon. gentleman proposed, in consideration of the undoubtedly substantial and generous concessions which he enumerated, that the Post Office should receive a royalty upon private wire business. That involved a principle which the companies might have some difficulty in acceding to. The right hon. gentleman might as well ask an individual who ran a private telegraph wire to give him a royalty on it. [Mr. Fawcett: If he got a profit from it.] The right hon. gentleman might as well ask him for a royalty on a house, if he had one and let it at a profit rent. The right hon. gentleman said that telephone companies must not be permitted to transmit anything in the nature of a written message. That was a condition scarcely worthy of the position which the Government had now taken up. At present the Post Office had a certain number of telephone exchanges, and any person subscribing to them had two privileges which the Post Office refused to subscribers to private telephone exchanges, and one of these was the sending of a written message. He did not see why the right hon. gentleman should deprive subscribers to the telephone exchanges of that advantage. The policy of the Department ought to be confined, in the first place, to protecting the public against the evils of monopoly; and, in the next place, protecting the revenue of the Department against loss. But granting these two points the policy of the Department ought to be not to interfere in any way with the services which the public might otherwise receive. He suggested that telephone companies who wrote telegraphic messages for their subscribers should charge the rate which the Postmaster-General himself charged in connection with his own telephone exchanges, for similar services, and that such messages should be held to partake of the nature of telegrams, and that the revenue derived from them should be the property of the right hon. gentleman in his official capacity. Subscribers to the Post Office telephone exchanges could dictate a telegram through the telephone. Why, he asked, should not the same facility be given to all who use telephone exchanges? The charge of five guineas which must now be made before the privilege could be secured was preposterous. The proposals of the right hon. gentleman were, on the whole, very fair, and if fully carried out would be very beneficial to the public.

Mr. ARNOLD, feeling convinced that the use of the telephone would largely increase, hoped that the development of the invention would be entrusted to those who could develop it most cheaply for the public.

Mr. PULESTON thanked the Postmaster-General for the liberal concessions he had made. The right hon. gentleman need not be afraid that such concessions would militate against the revenue of the telegraph service. In America it had been found that in proportion as facilities had been given for the use of the telephone the revenue of the telegraph service had increased. So it would be here.

Mr. MACLIVER also joined in the expression of satisfaction at the Postmaster-General's statement.

Dr. CAMERON did not desire to enter into old controversies. He could not, however, help saying that if the Government had a legal right, they had scarcely a moral right to an exclusive right in the telephones. It therefore behoved the Government to treat the telephone companies so that they might as nearly as possible be in the position that they would have occupied if this right had not been maintained by the law courts. He hoped that before long the Postmaster-General might be able and willing to reduce the royalty of 10 per cent. which the telephone companies were now charged [hear].

Mr. GRAY said that the telephone companies, in asking that the royalties should be reduced from 10 per cent. to 5 per cent., intended immediately to give the amount of the reductions to their subscribers.

Mr. FAWCETT said that nothing could be more kindly than the way in which the hon. member for Carlow had spoken of him personally, but the hon. member appeared to draw a distinction between the Post Office officials and himself. He did not think anything could be more unfair to the heads of a department than that he should let such a distinction be drawn. He took upon himself absolutely and unreservedly the responsibility for everything that had been done [hear, hear]. He did not mean to say that there had been no mistakes and no delay; but his short sketch of the matter would show that it was an extremely difficult one to deal with, and for any mistake or delay he hoped the hon. member would blame the Postmaster-General, who was responsible to Parliament, and not the officials of the Post Office, who worked with great zeal to serve the public to the best of their ability. In saying that no obligation should be imposed upon the Post Office to erect wires, or secure private way-leaves, he did not mean to say that in no circumstances whatever would the Post Office erect wires, or obtain way-leaves at a proper rent; but a public department that had paid a heavy sum for the wires that passed along railways, was bound to consider the public interest, and it was therefore bound to deal with each application strictly on its merits. As to whether any greater facilities could be afforded for allowing messages which were sent in the first instance by telephone to be

Digitized by Google

forwarded by telegraph wire, although he did not see his way to this at present, he would look into the matter. He recognized as a general principle that all he had to do was to afford the utmost possible facilities to the public, with due regard to the protection of the revenue. On the subject of the royalty, he would remark that a Government monopoly must be taken with its disadvantages as well as its advantages; and it was not necessarily an objection to it that any part of the service might be done more cheaply, otherwise it might be alleged that injustice was done if a company were refused permission to deliver letters in London at a halfpenny each. It was not proposed to make any charge for telephone call messages; they would be allowed on the understanding that the companies handed over 10 per cent. of their receipts. The proposal that this should be extended to private wires was pressed, not so much for increasing the revenue as for simplifying the accounts. He did not see his way to making any exception in the case of written messages; the essential distinction must be maintained; it would make a serious difference in the revenue if written messages were allowed. If the companies would accept those terms as a final settlement and unreservedly, there was no reason whatever why their licences should not be amended at once; and equal promptitude would be shown in granting any new licences.

Mr. PULESTON said the right hon. gentleman had disavowed any responsibility in the procuring of way-leaves; but he understood that that was one of the greatest obstacles to telephonic development. Would it not be advisable to consider whether the Post Office might not be authorised to exercise compulsory powers in some cases? ["oh."] There ought to be some plan of reducing the difficulty now experienced in obtaining way-leaves.

Mr. GRAY said that in some cases the only communication between town and town was along railway lines.

Mr. FAWCETT said that while it would be very unwise to give the assurance asked for, he might say that everything would be done on the part of the Department to prevent unnecessary delay. With regard to the important question of way-leaves on railways, the Government were bound not to grant such a number as to cripple the business of the Department. They were therefore bound to proceed with extreme caution, but he could assure the hon. member that each case would be considered on its merits [hear, hear].

Mr. T. O'CONNOR asked whether the right hon. gentleman would have any objection to supply telephonic communication between different parts of that building, because at the present moment it was easier to ascertain what was going on in that House in a newspaper office in Fleet-street than in the library of the House of Commons.

Mr. FAWCETT replied that that was a matter under the control of the First Commissioner of Works, and not of the Postmaster-General.

The vote was agreed to.

LEGAL.

The Postmaster-General v. The Cambrian Railways Company.

This case came before Mr. Baron Pollock and Mr. Justice Lopes, in the Queen's Bench Division of the High Court of Justice on the 7th instant.

The SOLICITOR-GENERAL said this was an action for damages in consequence of the company not having given free passes to the officials of the Postmaster-General, who were required to examine the telegraph wires along the lines. The plaintiff recovered judgment for damages and costs, and there was an order that the passes should be granted, but this order not having been complied with, the present motion was to enforce compliance by sequestrating property of the company. It now appeared that a receiver had been appointed, and therefore a sequestration could not be asked for; but some of the officials of the company might be attached for disobedience to the order of the Court. He should be reluctant to do this, and he therefore asked that the matter might stand over, to see if an arrangement could be come to.

Mr. CHANNELL, for the defendants, said there was no wish to disobey the order of the Court, and he believed there would be no difficulty in coming to an arrangement.

The case was ordered to stand over.

Re South Eastern (Brush) Electric Light and Power Company (Limited).

In the Chancery Division of the High Court of Justice, on Saturday last, Mr. Justice Chitty heard the petition of this company for leave to reduce its capital, which was stated to be £100,000. There had been taken up 400 £5 shares, which were fully paid up, and there were 19,600 upon which £2 a share had been paid. It was proposed to keep the fully paid-up capital in its present position, and reduce the remaining shares to £2 10s. each, which would leave only 10s. at call on each share. This would reduce the capital of the company to £51,000. The creditors of the company had given their assent to the reduction.

Mr. Romer, Q.C., appeared in support of the application.

His lordship said he would assent to the reduction, which was, however, very large; but as all the creditors assented he would not object. He directed the reduction to be advertised, so that the public would know that such a reduction had been made.

COMPANIES' MEETINGS.

The Cuba Submarine Telegraph Company (Limited).

The twenty-sixth ordinary general meeting of the shareholders of this Company was held on Wednesday, at the offices of the Company, No. 61, Old Broad-street, Mr. Joaquin de Mancha (Chairman) presiding.

Mr. JAMES SCOTT (the Secretary) read the notice convening the meeting, and the report was taken as read.

The CHAIRMAN: Before moving "that the report and accounts for the half year ending June last be received and adopted," perhaps I had better call your attention to two or three facts. I have no doubt you have studied the report, as you have received it now for some days, and I hope it is as satisfactory to you as it is to us. The State of Cuba, as you all know, has not been very prosperous. They depend very much upon their sugar, which this year has been at a very low ebb, and consequently all business in the island has suffered. Notwithstanding that, however, we have been able to show you a very good result. Besides this you will have seen that the cables have been very satisfactorily repaired by Mr. Keith, to whom we owe a large debt of gratitude [applause]. We owe him a debt of gratitude for the trouble he has taken with the work. You will see that we have paid the half-yearly payment for the new cable, which amounts to £2,000; and at the same time, in addition to putting to the reserve fund its annual interest of £1,383, we have been able to put £1,266 5s. to the reserve fund, which stands at £58,000, and which I am sure you will all consider satisfactory [applause]. We hope that this will still go on increasing, which will be a source of satisfaction not only to the preference shareholders, but also to the ordinary shareholders, for the more money we have in hand to meet any fault in our cables it makes our shares so much the more secure. The accounts, as you all know, we rather pride ourselves on making explicit, and they require very few words on my part to explain them. At the same time, if any gentleman would like to have any information I shall be very glad to afford it. I shall now move "That the report and accounts now submitted be received and adopted" [applause].

Mr. ALEXANDER F. LOW: I beg to second that.

Mr. GRIFFITH observed that it was usually a good sign that a Company was prosperous when the meeting was small in numbers, because it showed that confidence was felt in the directors. He did not rise for the purpose of criticism, because there was no ground for it, but as he had recommended the Company to his friends, perhaps the Chairman would be kind enough to give him a little information on one or two points. He said that they were paying a rent for their cable, which still continued to be one of the sources of expenditure. He should feel obliged if the Chairman would tell him for how many years they would have to pay rent upon that cable. He thought it was a most fortunate thing that they were able to buy a new cable upon such a system. The next question was—What was the amount of the tax which the Spanish Government still unfairly detained? It had been due to the Company for a long time, and it did not reflect very much credit on so important a Government as that of Spain to avoid paying its just debts. There was a third question, which was, perhaps, of a minor character. There was an item of "Loan on Securities, £1,500." He had no doubt that the securities were very good, and that the interest also was good, but still it would be a satisfaction to be assured that the loan was an advantageous one and the security good. He wished to be well informed on all subjects connected with the Company, so that he might be able to speak favourably of it when opportunity offered.

The CHAIRMAN, in reply, said the cable that they were paying for gradually was originally contracted for at £48,000, and they had to pay every year £4,000 whilst it was working. There were still nine years more to run before the whole was paid, but in case of any defect the contractor was bound to make the cable good, otherwise the payment ceased. They had now paid off £13,457. Therefore there was still outstanding £34,000 odd. They did not take this from the reserve fund, but paid it out of the earnings of the Company. They thus got a new cable, they might say, for nothing, for if the cable were to break down at any moment, the contractor was bound to repair it. In order to secure his doing so, they retained a certain portion of the money that should be paid, so as to form a fund in case of necessity. They had thus reserved £5,000, so that in case he did not do the work himself, and that they should undertake it themselves, they had no further payment to make. The other question was with regard to the tax they were to receive from the Spanish Government. They had fought the matter out both at Cuba and Madrid, and the Government had given orders that the money should be paid. The whole amount was only about £1,000, and they had the last royal order given by the Government that Cuba should pay the money. When they applied at Havannah for the money they were told that the order would be obeyed, but that it was not included in the last year's estimates, so that they were unable to pay it. But they promised to pay it, and the directors had no doubt that as soon as the new estimates came in their £1,000 would be paid. Cuba had not been in a flourishing state last year. They were told that sugar had been so cheap that they were not selling it, but using it as manure. They would see that the price of sugar was as low as 13s. The next question asked was about the £1,500 loan. That was a portion of the money they had on hand that came in from one source or another, and as they did not require it immediately for paying dividends or anything else, they lent it on the Stock Exchange on good security from fortnight to fortnight. The interest they received, he was sorry to say, was not very flourishing. He thought in one case they had not been getting more than 1½ per cent. per annum, but it was better than the money being in the hands of the bankers earning nothing. This

Digitized by Google

money would be called in in a few days to pay their dividends. As they would see by the note, he thought this was the only Company so frank as to give the names of the parties with whom it deposited money. They got 5 per cent. upon all those sums, which he thought was very satisfactory [applause].

Mr. KEENLYSIDE wished to ask a question. Their reserve now stood at the satisfactory sum of £58,000. He had been a shareholder a great number of years, and had always been a steady supporter of increasing the reserve. This sum would soon reach £60,000, which was the amount of their preference capital. He should like to ask whether the directors might not think it safe to allow simply the addition of the 5 per cent. every half year, instead of taking any more out of the profits of the half year [hear, hear]. Of course, if they had a prosperous half year, he would be happy to see a few more thousand pounds added to it. The 5 per cent. would bring it up to within £530 of the £60,000 next half year. And if they were able, as he hoped they would be, to increase the reserve to £60,000 when they met again, he should like to know if the directors would not consider that £60,000, plus the interest, would be enough? There was one other question he would like to ask. He saw in the accounts an item of agents near the Spanish Government. It had always appeared a rather singular way of putting it, and he wished to know whether that was likely to continue.

The CHAIRMAN replied that when the time arrived the directors hoped to take into consideration whether it would be advisable to leave the reserve fund at £60,000 or at any other sum. But they knew that cables were very ticklish things; they were not like other property that they could readily repair. When they had to repair the cable before it cost something like £21,000. Therefore the Board had to consider that the property might suffer great deterioration, and that, perhaps, they might have to relay the whole cable, so that the stronger their reserve fund was the better. They hoped to be able to pay 10 per cent. by and by, and then stop there and add everything to reserve. It was well to have plenty at the bankers. He remembered hearing a tale about Rothschild. He was asked how a man felt when he had six millions of money. He said he felt he could pay his debts in full [laughter]. If then they could pay their twenty shillings in the pound, and have enough money in hand to relay the whole cable through, it would be satisfactory to them. The other question was about the gentleman attached to the Spanish Court. He thought he explained last time that this was one of the charges they were bound to keep up. It was requisite to have representatives in Madrid and Cuba. If there were any difficulty, and they had to make a claim, they pushed it through the offices. It cost a little money to clear the way, so that the thing should be done; otherwise, if they had claims in Spain, as they knew was the case in London or anywhere else, if they had not the entrée to the office, things were put into the pigeon-hole. It was only a small matter of £200, and it was well spent in having representatives to carry the business through.

The CHAIRMAN then put the resolution, which was carried unanimously.

The CHAIRMAN next proposed :—"That dividends for the half year be now declared on the shares of the Company, at the rate of 10 per cent. per annum, subject to income-tax on the preference shares, and 9 per cent. per annum, free of income-tax, on the ordinary shares, payable on and after August 14th inst."

Mr. LOW seconded the resolution, which was put and agreed to.

The CHAIRMAN then proposed the re-election of Mr. Horatio J. Perry as a director of the Company.

Mr. GRIFFITHS seconded the resolution, which was carried.

The auditor, Mr. Greenwood, was re-appointed, and a vote of thanks to the Chairman and Directors, the Secretary and Mr. Keith, closed the proceedings.

The National Telephone Company (Limited).

The fourth annual general meeting of the shareholders of this Company was held at the offices of the Company, 11, Queen Victoria-street, E.C., on Friday, the 8th inst., Colonel R. Raynsford Jackson in the chair.

Mr. W. B. CAMPBELL (the Secretary) read the notice convening the meeting. The reports and accounts were taken as read.

The CHAIRMAN said: Gentlemen, you have all, I think, carefully examined the report, and you will have seen that the business of the Company has during the past twelve months progressed satisfactorily; that there has been a large increase in the revenue, and that we have been enabled to pay an increased dividend to the ordinary shareholders. I see every indication of a further development in the same direction, and there are signs that during the current year there will be a considerable increase of net revenue, which is the important point with the shareholders. I do not intend to dwell upon the past history of the Company, or upon the character of its business. I wish to call your attention, however, to one paragraph in the report, which bears upon our relations with the Postmaster-General, and you will see that the directors made use of the following words :—"They are glad to be able to inform the shareholders that the Postmaster-General is considering proposals made to him on behalf of the companies, and that they indulge the anticipation of a result according with what might reasonably be expected from the well-known breadth and liberality of his views." Last night, in the House of Commons, the Postmaster-General gave his answer to a letter sent to him by the chairman of the United Telephone Company on behalf of the telephone companies who are working in association with that important company. In that letter various requests were made, some of which were alternative. The answer given by the Postmaster-General is satisfactory upon many points, and shows that your directors were not mistaken in assuming that he would deal broadly and liberally with the important questions that were brought under his review. I have, however, to criticise two of the headings of his answer, and to suggest that modifications should be made in them. I recall your attention first to his answer No. 6, which is as follows :—"Having regard to these concessions, and to the desirability, as far as possible, of securing simplicity of accounts between the Post Office and the companies, the royalty of 10 per cent. now paid on gross receipts should be extended to their receipts from private wires." Now, I apprehend that the Postmaster-General has made this suggestion without duly considering all the bearings of the case as they relate to the business of the companies. The Postmaster-General, under the Telegraph Acts, has the monopoly of a certain kind of business, but he has no control over other kinds of business. When he grants to the companies a licence to do that business, which is his monopoly, he has a perfect right to accept a royalty upon it; but, in the case of companies doing business over which he has no control, I think that the Postmaster-General cannot expect a royalty, and for this reason—if the companies who do that business which cannot be done without the Postmaster General's licence pay him a royalty upon the business which any private firm, or anybody not possessing his licence, can do, the effect must necessarily be that the companies holding the Postmaster-General's licence will labour under great disadvantage when they attempt the private wire business which any private person can do without his licence. The private firms, not possessing the license, could do the business cheaper than the companies. Therefore, the effect of submitting to this condition would be that the private and other unlicensed firms would do all the particular class of business which can be done without his sanction, or without infringing his monopoly [hear, hear]. Mr. Fawcett is so fair minded that I think that when this view of the case is put before him he will withdraw that clause No. 6. Then his eighth condition is: "That in order to maintain the distinction between written telegraphic messages and the spoken communications made by means of the telephone, the telephone companies shall not accept or deliver any written message at any point." I think the wants of the public can be met without in any way infringing the Postmaster-General's condition which I have just read; but no scheme will be complete, or can be ultimately satisfactory to the public, which does not provide for exchange subscribers of the companies being able to send telegraphic messages through the Postal Telegraph Office; and therefore I suggest that the Postmaster-General should allow the various exchanges erected by private enterprise to be connected with the Postal Telegraph Office, and that the subscribers should be permitted to send, through wires which could be switched into operation when required, messages to the Postal Telegraph Office to be transmitted as telegrams, so that there would be no delivery of written messages by the companies, but there would be a great increase of business to the Postmaster-General through the instrumentality of the various companies' exchanges. In addition to giving subscribers the privilege of sending Post Office messages through the Postal Telegraph Office, the Postmaster-General should also, when he receives such messages for the Telephone Exchange subscribers, deliver these messages through the exchange to the subscribers. That would be an immense boon to the mercantile community and to all those who desire rapid communication with their connections in the various business centres; and I do not think that unless a provision is made to supply this particular want the general scheme of the Postmaster-General can be considered complete [hear, hear]. Speaking for myself, and as representing our own Company, I have no other criticisms to make upon the scheme of the Postmaster-General, and it must be distinctly understood by the shareholders that I speak for no one else. I have had no means as yet of communicating with the representatives of the other telephone companies, but I cannot think that their decision will be very different to my own. There is no doubt, as I said before, that the Postmaster-General has aimed at dealing liberally with this question, and has shown an earnest desire to enable the public to derive that benefit from the telephone to which it is justly entitled. I trust that the effect of the correspondence which is going on between the Postmaster-General and the representatives of the companies will be finally to satisfactorily solve this very difficult problem. To make my meaning more distinct with reference to the disadvantage of paying royalty upon private wire business, I must explain that my remarks do not apply to all kinds of private wire business. There is a certain branch of private wire business which forms part of the Postmaster-General's monopoly, and there is another part which does not. That part which falls under the Postmaster-General's monopoly he is entitled to royalty on, but it is that part of the private wire business which does not infringe the Postmaster-General's rights that the remarks I have made apply to. I think it unnecessary to say more, and I will now move the adoption of the report and accounts.

Mr. JOHN P. BIGELOW (the vice-chairman) seconded the motion, which was put, without discussion, and carried unanimously.

The CHAIRMAN moved the re-election of Mr. Peter Garnett, of Thirsk, Yorkshire, as a director.

Mr. W. A. SMITH seconded the motion, and it was carried.

The CHAIRMAN also moved, in succession, the re-election of the other retiring directors, Mr. Samuel H. Sands, of Nottingham, and Mr. John Frederic Harrison, of Rawdon, Yorkshire.

The motions were seconded by Mr. SMITH and Mr. BIGELOW, and were adopted.

The CHAIRMAN: I wish to make an observation with reference to the auditors. The United Telephone Company has the right to appoint an auditor to audit the accounts of all the subsidiary companies. Mr. Blease is the auditor so appointed, and he has, on behalf of the United Telephone Company, examined our accounts and expressed his satisfaction with them. In future his name will appear with those of Messrs. Quilter, Ball, and Co., in our report and accounts.

Digitized by Google

Mr. Bolland proposed the re-election of Messrs. Quilter, Ball, and Co., as auditors.

Mr. Smith seconded the proposition, which was carried.

A vote of thanks was passed to the chairman, who, in acknowledging the compliment, expressed the belief that when they met again he would have a much better record to place before the shareholders, although the present one was not unsatisfactory.

The meeting then closed.

The Lancashire and Cheshire Telephonic Exchange.

The third annual general meeting of the shareholders of the Lancashire and Cheshire Telephonic Exchange Company (Limited) was held on Monday, at the offices of the Company, Faulkner-street, Manchester, Mr. Charles Moseley, Chairman of the Board of Directors, presiding. The following is the report:—The Directors have the pleasure to submit herewith their third report and statement of accounts, and trust the results shown therein will be satisfactory to the shareholders. The subscriptions and rentals (including those of the out-districts) pertaining to the financial year amount to £53,256 3s. 4d., as compared with £45,544 12s. 2d. for the year ending 30th June, 1883. The amount of income carried forward to next year's revenue, as representing sums received in advance for periods extending beyond 30th June, 1884, is £26,101 6s. 11d., against £23,391 5s. in last year's balance-sheet. On the past year's working, and after deducting £496 0s. 6d. loss of rental on Trunk lines between towns, the net profit is £18,655 17s. 7d., which, with a credit balance of £2,073 4s. 6d. remaining from last account, makes a total fund of £20,729 2s. 1d. Out of this sum an amount of £8,613 10s. 2d. has already been absorbed in the payment, in January last, of an interim dividend; and the directors now recommend a further dividend of a like amount, making a complete dividend of 6 per cent. for the year ending 30th June, 1884. After providing for this dividend there will remain at credit of profit and loss account a balance of £3,230 15s. 4d., which is carried forward to next year. On 30th June, 1883, the total number of subscribers to the various exchanges was 2,359 and of private renters, 697; this year, on the same date, the figures were 2,734 and 828 respectively. As regards the money value of this increase, it may be stated that on 30th June, 1883, the business (including work not finished) represented orders on the books equalling a gross income of £54,498 3s. 8d. per annum, and on 30th June, 1884, £61,149 0s. 6d., showing a nett increase of new business to the extent of £6,650 16s. 10d. When comparing this progress with the year ending 30th June, 1883, it should be remembered that during the past 12 months considerable reductions have been made in the charges at several of the district centres, with a view to encourage their development. There is a steady increase in the average of daily "calls" made by subscribers, which may be taken as evidence that the many facilities offered by the telephone system are being appreciated more and more for business and domestic purposes. With a view to improve the service at Liverpool, an entirely new switching apparatus has recently been purchased, subject to a three months' trial; and it is believed that the exchange system in that town is now the most rapid and efficient which has hitherto been practically applied for telephonic purposes. The retiring directors are Messrs. Moseley, Heyworth, and Agnew, who are eligible for re-election. The accounts have been audited by Mr. C. R. Trevor (Trevor and Pilling) on behalf of this company, and by Mr. R. S. Blease (John S. and Robert S. Blease and Sons) on behalf of the United Telephone Company. The Company's auditor, Mr. C. R. Trevor, retires, but offers himself for re-election, for which he is eligible.

The Chairman, in moving the adoption of the report and statement of accounts, said it was a matter of great satisfaction to the directors that, in spite of all the difficulties they had had to encounter, the result of the year's working left them a fair profit, and enabled them to declare a dividend, while at the same time they confessed to a feeling of disappointment that they had not been able to extend their business and increase their profits in the proportion they anticipated from the important property over which they had control. The difficulties with which they had had to contend arose principally from the restrictions which had been imposed upon them by the Post Office. The Post Office had, of course, to consider from an official point of view the interest of the telegraphs, but in the opinion of men who had a knowledge of the subject, and who were fairly competent to anticipate what the result of the development of the telephone would be upon the revenue of the telegraphs it would appear that the conclusions of the Department and the anticipations of the officials were altogether wrong. The telephone itself was used in a sphere altogether out of the action of the telegraph. It supplied a want to business people which it was impossible to obtain by the telegraphs, and yet the Post Office had not hesitated up to the present time to hamper the telephone companies, to restrict them and to tie them in their operations and extensions in every possible way that suggested itself to their ingenious minds. The question had been laid before the Post Office in every conceivable form, and the Directors had been in negotiation with that Department continuously; in fact, one-half of the time of the Board had been taken up in discussing the subjects which formed the bones of contention between the Company and the Department, instead of using their energies for the development of the business. After long and harassing correspondence and negotiations, in which the Directors had not been influenced by selfish motives, but by the interests of the public, no relief could be obtained from the Post Office officials, and the Directors then determined to submit the whole case to the House of Commons. The city and county members of Parliament gave them their assistance in putting questions to Mr. Fawcett, the Postmaster-General, and the result was that that gentleman requested the telephone companies to put their proposals in a definite and practical form, when he promised that they shoul[d] receive his careful consideration. A letter of proposals agreed upon b[y] the various companies was accordingly submitted to Mr. Fawcett, and o[n] Thursday last he gave his reply to the proposals and what he thought wa[s] a solution of the vexatious questions at issue. That these proposals of Mr. Fawcett were extremely liberal as compared with the previous policy the[re] could be no doubt, but one of his proposals, to place a royalty of 10 p[er] cent. on private wires which did not come under the jurisdictio[n] of the Post Office, would operate most unjustly, and the telephon[e] companies hoped that he might be induced, on further consider[a]tion, to withdraw it. Referring to the report, the Chairman sa[id] the gross income during the year had been £61,149 0s. 6d., a[n] increase of £6,650 16s. 10d. over the previous year. The amoun[t] of new business for the year was £9,750. The revenue was £53,256 3s. 6d. and after carrying forward £26,101 6s. 11d., and meeting sundry losse[s] this left a net profit of £18,655 17s. 7d., which, added to a sum o[f] £2,073 4s. 6d. carried forward from last year, gave a sum of £20,729 2s. 1d. at the disposal of the directors. Out of this they recommended the pay[-] ment of a dividend of six per cent., leaving a balance of £3,230 15s. 4d. in hand. The maintenance of lines during the year had cost £5,716 4s. 8d. and £21,869 had been spent on plant account, including an expenditu[re] of between £4,000 and £5,000 on the establishment of a new route fro[m] Manchester to Liverpool. The total number of exchange subscribers [is] now 2,734, an increase on the year of 475; and of private subscribers 828, an increase of 131. During the year 748 miles of additional wire ha[d] been fixed, making the total length of the company's wires 3,628 miles. The number of messages passing through the company's switch room[s] had increased during the year by 1,076,610, and the total number for th[e] year was 5,812,634. The whole of the lines and property of the compan[y] were now in as good condition as they could possibly be. In conclusion he moved the adoption of the report and accounts.

Mr. Turner seconded the motion, which was unanimously agreed to.

The dividend recommended by the Directors was declared, and th[e] retiring Directors and officers of the Company having been reappointed, a vote of thanks to Mr. Moseley for presiding brought the meeting t[o] a close.

The resistances in the above Table are calculated from Dr. Matthiesson's standard (1 mile of pure copper wire of $\frac{1}{16}$in. diameter equals 13·59 ohms or B.A. units at 15·5° C.).

The resistance of pure copper wire increases as the temperature rises about 0·38 per cent. for each degree C., and 0·21 for each degree F.

The **Diameter** (d) of any copper wire equals the square root of its weight (w) in grains per foot multiplied by 6·872

$$d = 6{\cdot}872\sqrt{w} \quad . \quad . \quad . \quad \text{mils.}$$

The **Weight** (w) o any copper wire per foot in grains equals the square of its diameter (mils.), divided by 47·22

$$w = \frac{d^2}{47{\cdot}22} \quad . \quad . \quad . \quad . \quad \text{grains per foot.}$$

The **Resistance** (R) of any pure copper wire per mile at 15·5° C. equals the square of its diameter (mils.) divided into 53085·9

$$R = \frac{53085{\cdot}9}{d^2} \quad . \quad . \quad . \quad \text{ohms at 15·5° C. per mile.}$$

The **Conductivity** (C) of any copper wire is obtained by multiplying its calculated resistance (R) by 100 and dividing the product by its measured resistance (r).

$$C = \frac{R \times 100}{r} \quad . \quad . \quad . \quad . \quad \text{conductivity per cent.}$$

[* *It will be noticed that several of the figures in the decimal places differ slightly from figures given in other tables, but some of these differences may be accounted for by the differences of temperature at which the measurements were taken.*—Ed. *E.*]

NOTES.

THE LAW COURTS.—During the vacation some alterations will be carried out in the electric light machine room at the Royal Courts of Justice.

NEW ZEALAND.—We notice that Sir Julius Vogel, well known in connection with electric lighting, is to be the new Colonial Treasurer and Postmaster-General of New Zealand.

TELEGRAPH REVENUE.—The total receipts from Postal Telegraphs between 1st April and 16th August were £675,000, against the same amount for a period of two days longer last year.

ELECTRIC LIGHT EXPERIMENTS.—The Royal Engineers at Cork have lately made some interesting experiments with torpedoes and the electric light at the entrance to Cork harbour.

EARTHQUAKE.—It is reported by telegram from Rome that a slight shock of earthquake was felt at Cosenza at 7 a.m. on the 19th inst. It was more severely felt at Rossano, but no damage was occasioned.

THUNDERSTORM IN PARIS.—A severe thunderstorm is reported to have occurred in Paris on Sunday night. Many houses were struck, but only one woman appears to have been injured by lightning, and that slightly.

EASTERN ELECTRIC LIGHT COMPANY.—The creditors of this company should send their names, &c., before the 15th December, to the liquidators, Messrs. Heywood, Bull, and Clark, at 19, Great Winchester-street, E.C.

DEATH OF MR. ARNOUX.—It is announced from New York that Mr. Anthony Arnoux, a pioneer of electric lighting business in that city, recently committed suicide. He was treasurer of the Arnoux-Hochhausen Electric Company.

THE NEW ATLANTIC CABLE.—The Waterville correspondent of the *Daily Chronicle* telegraphed on Saturday last :—"The 'Faraday' still proceeds satisfactorily with the second Bennett-Mackay cable. The weather is fine but cloudy. The alterations at Cable House are approaching completion."

"H" AT PARIS.—M. Mascart has found, using Gauss's method of calculation, that the mean value of the horizontal component of the earth's magnetism at the observatory of Parc Saint-Maur was, on the 1st July last, $H = \cdot 19414$ in C.-G.-S. units. The probable error was less than ·0001.

TELEGRAPHIC COMMUNICATION WITH GREECE.—According to a telegram from Vienna telegraphic communication between all the Greek islands and the mainland has just been completed, thus establishing direct communication by telegraph between the islands in question and all parts of Europe.

BUSINESS NOTICE.—Mr. Thomas H. Harrison, who for over twelve months has had charge of the Gülcher Electric Light Company's works at Battersea, and has carried out some of their largest installations, has been appointed agent to the company. His offices are at 5, Lawrence Pountney-lane, E.C.

DEATH OF AN ELECTRICIAN.—A French paper announces the death of M. B. Meyer, a well-known electrician and author of several works. M. Meyer invented a multiplex telegraph, which bears his name. He was a Chevalier of the Legion of Honour. For some years past he had lived in retirement at Malzéville, near Nancy, where he died.

AN ELECTRIC BRAKE.—A trial of the Walcker electric brake, which is in use in America, was recently made on the tramway between Turin and Piossasio. It is stated that by its means two cars running at a speed af 35km. per hour were stopped in six seconds, and within a distance of 18m. The brake is being shown at the Turin Exhibition.

THE BRITISH ASSOCIATION MEETING.—Most of those who are going to attend the forthcoming meeting in Montreal have sailed. Among the last to go were Professor Dewar, General and Lady Lefroy, Mr. W. H. Preece, Lord and Lady Rayleigh, Professor W. Chandler Roberts, and the Earl of Rosse, who left Liverpool on Saturday last in the Allan liner "Parisian."

UNIVERSITY COLLEGE, BRISTOL.—The next session will open on the 7th October. The department of experimental physics will be, as heretofore, under the direction of Professor Silvanus P. Thompson, D.Sc. There is a physical and electrical laboratory attached to the college, which is open daily and on Wednesday evenings. Details of the course can be had of the registrar.

ELECTRIC LIGHTING IN SOUTH KENSINGTON.—It appears that the revocation by the Board of Trade of the provisional order for lighting certain streets in South Kensington has been a source of much regret to many of the inhabitants of the district; but it is hoped that next year a feasible scheme for the lighting of the streets by means of electricity will be matured and carried into practical operation.

UNDERGROUND WIRES IN CHICAGO.—The city of Chicago has brought five suits against the Baltimore and Ohio and Western Union Telegraph Companies, for contravening the bye laws by maintaining three overhead wires. It will be remembered that the city authorities some time since ordered all wires to be laid underground, under heavy penalties for disobedience. It is understood that the above will be test cases.

ELECTRIC RAILWAYS.—American electricians are just now taking up the question of electric railways with characteristic energy. The papers are full of projects for such railways here, there, and everywhere. New York is promised both underground and overhead railways, the cars on which are to be propelled by the aid of the electric current. Brush, Edison, Daft, Field, Hazard, and many others are engaged on experimental lines.

AN ATTEMPT TO REACH GENERAL GORDON.—It seems as if a man of poles and wire will reach General Gordon before any one else. A telegram has recently been received in London from Mr. E. Floyer, Inspector-General of Egyptian Telegraphs, and, by the way, an Englishman, dated from Debbas, stating that all was well, that he was six days only from Gordon, and endeavouring to pass on. We hope Mr. Floyer may succeed in accomplishing his task in safety.

THE ROYAL ENGINEERS.—Orders were received at Aldershot on Saturday for a portion of the 1st Division Telegraph Battalion, Royal Engineers, under the command of Captain Bennett and Lieutenant Tower, to at once hold themselves in readiness to embark for Egypt, to take part in the expedition up the Nile. They will take with them no less than a hundred miles of air line and about twenty-five miles of cable. These will be packed in parcels of about one hundred pounds each, so as to be easily carried by the men.

THUNDERSTORM IN ITALY.—A telegram from Rome, dated August 20, says :—"Last night a violent tempest broke over the region extending from Leghorn to Rome, including both cities. Rain and hail fell in great quantities; and the flashes of lightning, followed by deafening peals of thunder, were incessant. At Leghorn the cathedral was struck and set on fire, but the

Digitized by Google

flames were quickly got under. Here the electric motor at the railway station was struck, and the lightning also fell at the cemetery of San Lorenzo and near the Basilica of St. Paul *extra muros*."

News from Egypt.—The Government have given orders for the telegraph line to be carried from Wady Halfa to Surras. It appears that some coils of telegraph wire lying on the deck of a steamer which recently attempted the passage of the first cataract on the Nile were instrumental in saving it from destruction. Owing to the mismanagement of the Arabs engaged to haul her over both hawsers broke, the anchors proved of no use to stop her, and she was only brought to by throwing overboard some coils of telegraph wire, which caught in the rocks and fortunately held her.

Globe Lightning.—M. Gaston Planté has been making some very interesting and instructive researches into the probable cause of globe lightning, as it is called. With the aid of secondary batteries he obtained a current having an E.M.F. as high as 4,000 volts, and by this means he very successfully imitated globe lightning on a small scale. The results of his experiments were communicated a few days since to the French Academy of Sciences, and we had hoped to have given them in this week's issue, together with illustrations, but are compelled to postpone the article until next week.

Appointment.—Mr. W. C. Martin, of Dundee, has been appointed manager of the Electromotive Force Company (Limited), electrical engineers, Glasgow. Mr. Martin has long been connected with the telephone and electric light companies in Scotland, he having assisted in establishing the first telephone exchanges in Dundee, Aberdeen, and Edinburgh; and his late services with the Brush Electric Light Company of Scotland will have widened his connection throughout all the principal towns in Scotland. The electric lighting business recently started by him in Dundee will now be carried out by the company.

Electric Lighting in Brussels.—The Grand Place at Brussels is to be lighted by arc lamps. The machinery will be placed in a cellar in the Maison du Roi, and the current conducted thence to the lamps by underground cables. Two dynamos will be used at first, driven by a 12 horse-power Otto gas engine. The installation is being made by the Compagnie Générale d'Electricité, under the superintendence of M. Wybauw, the city engineer. Jaspar lamps will be used, and it is rumoured that the Hotel de Ville is to be lighted by incandescent lamps, the current being supplied from the same dynamo room.

The Philadelphia Exhibition.—The following gentlemen have been selected as members of the electrical commission to conduct experiments on the occasion of the exhibition at the Franklin Institute:—Professor H. A. Rowland, Baltimore; Professor John Trowbridge, Cambridge; Professor G. F. Barker, Philadelphia; Professor R. A. Fisk, San Francisco; Professor M. B. Snyder, Philadelphia; Professor J. Willard Gibbs, New Haven; Professor Simon Newcomb, Washington; Professor E. J. Houston, Philadelphia; Professor C. A. Young, Princeton; and Dr. W. H. Wahl, Philadelphia. Professor Rowland is chairman.

Electric Railway at Cleveland, U.S.—Later details of the application of electricity to the propulsion of tramcars on the East Cleveland-street Railroad Company's line at Cleveland, U.S., have come to hand, though they are not very explicit or satisfactory. Thus we learn that a car was propelled, "at first slowly, at length at a speed of probably five miles an hour, though the inventors (Messrs. Knight, Bentley, and Brush) claim that from eight to fifteen miles an hour can be obtained." We note, however, that the track on which the experiment was made "is probably the roughest to be found in the city of Cleveland."

Electric Lighting for Lighthouses.—The Trinity yacht "Argus" has been engaged during the week with the Trinity House authorities and a party of scientific gentlemen from Canada in making a series of very important observations from the Channel in connection with the experimental lighthouses at the South Foreland, and the full extent of the penetrating power of the lights is being tested under various conditions. Captain Sidney Webb, Master of Trinity House, and Mr. Price Edwards are conducting the observations, which are expected to last several weeks. An interesting article on this subject, which we reprint from *Nature*, will be found in another column.

The Prince of Wales's Visit to Newcastle.—Great preparations were made in Newcastle-on-Tyne for the visit of the Prince and Princess of Wales. Both gas and electricity contributed to the illuminations, which were carried out on a large scale. It was intended to have an arc lamp on the upper lantern of St. Nicholas Church, which would be visible for many miles round. Their Royal Highnesses stayed with Sir William Armstrong, at Cragside, Rothbury, which it will be remembered has for some time past been lighted by incandescent lamps. A large arc lamp was placed at the top of the house for the occasion, and was used to light up the surrounding country.

Electric Lighting in Church.—The Roman Catholic church of St. John, built by the Marquis of Bute, at Old Cumnock, Ayrshire, has recently been fitted throughout with the electric light, under the personal superintendence of Mr. William Massey, electrical engineer, of Twyford. There are in all about 70 incandescent lamps of 20 candle-power, and the effect is very good, the architectural features of the building having been carefully studied and the lamps arranged with due regard to the religious character of the place. The necessary current is supplied by means of a dynamo and steam engine placed in a small house hidden among the trees of the churchyard, where it is also intended to generate electricity for working the organ bellows.

The Greely Expedition.—According to telegrams from New York, Lieutenant Greely has published further details of his three years' enforced residence in the Arctic regions. During that time he made some observations which will no doubt prove useful to scientific men. He says "the extremes of temperature at the camp on Discovery Bay, which they had named Fort Conger, was from 52 deg. above freezing point to 66 below. In February, 1883, the mercury was frozen into a solid mass, and continued in that state for 15 days. The ordinary outdoor clothing of heavy flannels was found to be quite sufficient even on the coldest days. The extreme range of the barometer was from 29in. to 31in. The electrometer registered nothing. The aurora was noiseless, which is contrary to Sir George Nares's experience in 1876, but it was sufficiently bright to cast a shadow."

Lighthouses in France.—According to a recent communication published in the *Bulletin* of the Societé Internationale des Electriciens, the electric lamps in use in French lighthouses have proved far more satisfactory than the oil lamps. It is further found that the former cost for maintenance from four to six times less than gas or oil per unit of light emitted. Magneto electric machines which supply alternate currents are used together with Serrin arc lamps. The latter have been modified by M. Berjot to suit the particular

Digitized by Google

service for which they are required, and quite recently M. Berjot's lamp has been improved by M. Le Baron. Berjot's modification consisted in substituting for the iron core of the electro-magnet in Serrin's lamp, which became so heated by the alternate currents as to cause a dilation of the parts of the regulator, and consequently interfered with its proper working, four solenoids placed in a shunt from the main circuit.

Electricity and Colliery Explosions.—Mr. Edward Thompson, C.E., writes to the *Daily Chronicle* on this subject as follows:—"It is well known that when the atmosphere becomes too highly charged, the electric fluid passes from the clouds to the earth in the form of lightning, to distribute itself in the ground. But to what depth does it enter, and to what degree does it become distributed? Is it that it passes from one stratum to another, until certain strata become charged to the same extent as the clouds from which it originally came? If this be the case, is it not probable that a sudden fall in the temperature of the air may cause the electric fluid to again return to the atmosphere, or be drawn off by the cool air? But what has this to do with colliery explosions? The theory is this: the mine has been supplied for months with air charged with electricity, which in its passage has left behind a large amount in the coal strata. A sudden change in the temperature and composition of the atmosphere takes place; the cool air is forced into the mine, then a peal of thunder is heard beneath the ground, and the electric fluid finds a ready passage up the shaft to again distribute itself in the clouds. If this theory be correct, at the fall of the year we may expect to hear of several colliery explosions."

Printing by Electricity.—The *Lawrence American* of July 9th says:—"For more than ten days past the entire power for running not only the large Hoe press upon which this paper is printed, but for the cylinder and job presses of the entire printing establishment, has been from electricity coming over a single wire from the dynamos, four blocks away; the fires under our steam boiler have now slept nearly two weeks, while the little electrical machine, weighing only 800lb., quietly, steadily, unceasingly, without jarring or difficulty, keeps up its marvellously equal revolutions. There is no delay in waiting to get up steam, no loss of time from any of the ordinary uncertainty of boilers, but whenever the minute comes when the power is required, a single movement of the lever, and the wheel starts upon its swift unchanging revolutions. We believe the *American* is the first daily newspaper, if not the first regularly published journal of any description, to be printed in this country with electrical power. To what will not this yet but little understood power be turned?" It may be the first daily newspaper printed by this agency, but it is not the first journal so printed by many years. On January 18th, 1840, the *Electro-Magnet and Mechanic's Intelligencer* appeared in New York; it was printed by a press worked by an electro-magnetic machine made and invented by Mr. Devenport, an ingenious and go-a-head blacksmith of Philadelphia. A reference to his machine will be found at p. 399 of our 9th volume.

Another Electric Launch.—On Monday a trial of an electric launch was made on the canal from Bolton to Bury by Mr. Banks, electrician, 32, Corporation-street, Bolton. The launch is 21ft. by 4ft. 6in. beam, and has been built specially for this purpose. The current is supplied by twenty F.-S.-V. accumulators (½ h.-p. type), and actuates a Rekenzaun motor coupled to the propeller shaft direct. The E.M.F. during the trip varied from 45 to 35 volts, and the rate of discharge was 31 amperes. The propeller is 12in. diameter and 11in. pitch, and makes 450 revolutions per minute. This is being replaced with another only 7in. pitch, when it is expected that the maximum speed obtained on Monday will be increased from six to eight miles per hour. Great satisfaction was expressed at the performance of the little craft by J. R. Budson, Esq. (for whom the launch has been built) and party, the only drawback being the weeds, &c., in the canal getting entangled in the propeller. To persons on the banks of the canal it appeared somewhat strange, and various suggestions were made as to the cause of motion, as nothing can be seen standing above the sides of the boat. The departure and arrival of the boat was witnessed by a large number of people, including many gentlemen interested in the progress of electricity. The cells and motor were working for over three hours, and with the exception of a slight heating of the motor everything was satisfactory. The accumulators were charged at Mr. Banks's works in Lorne-street, and so far have given every satisfaction. The boat weighs 7cwt., cells (charged) 7cwt., and the motor 1cwt. A switch is placed convenient for the man in charge of the rudder, whereby he is enabled to have any number of cells at work. The motor is also fitted with reversing gear.

Balloons.—Particulars of the balloon experiments recently carried out by Captain Rénard, at Meudon, mention of which was made in our last issue, are beginning to leak out. The *Standard's* Paris correspondent says that on Tuesday "the voyage was described in detail at the Academy of Sciences. It took place on the 9th inst. The weather was calm. The balloon, of elliptical form, was fitted with an electric motor, a screw, and a rudder. It rose to a height of fifty metres. Captain Krebs handled the rudder, and Captain Rénard maintained the permanence of elevation. When the screw had acquired a rotary movement the balloon moved towards the point fixed upon, which was the Villebon Hermitage. At this moment there was a breeze from the east of the celerity of five metres a second, and the balloon sailed against the wind. On reaching the Villebon Hermitage the officer in charge of the rudder waved a flag, which was the signal of return. The balloon was then seen to tack, describing in so doing a semi-circle of three hundred metres radius, and sailed towards Meudon. On approaching the lawn from which the ascent had been made the balloon gradually descended in an oblique direction, and reached the spot aimed at. It is intended that further experiments shall be made in which a committee of the Academy are to take part. The Minister of War has been furnished with full details of the apparatus, but these are, of course, kept a close secret from the public. The motor is said to be composed (*sic*) of a series of accumulators supplying for some hours a power of ten horses. These accumulators set in motion the screw by which the apparatus is propelled. The balloon is of light silk, of a very resisting quality, and covered with a netting which bears the car and the propeller." We presume the *Standard's* correspondent means to say that these accumulators set in motion a motor which actuates a screw by which the apparatus is propelled.

The Post Office Protection Act.—This Bill, which was passed during the Session just concluded, is to come into force on the 1st September. Amongst other things it enacts that "every person who forges or wilfully and without due authority alters a telegram, knowing the same to be forged or wilfully and without due authority altered, and who transmits by telegraph as a telegram, or utters as a telegram, any message or communication which he knows to be not a telegram, shall, whether he had or had not an intent to defraud, be guilty of a misdemeanour, and shall be liable on summary conviction to a fine not exceeding £10, and on conviction on indictment to imprisonment with or without hard

Digitized by Google

labour for a period not exceeding twelve months. If any person, being in the employment of a telegraph company (that is, any company, corporation, or persons carrying on the business of sending telegrams for the public under whatever authority, or in whatever manner such company, corporation, or persons may act or be constituted), wilfully omits or delays to transmit or deliver any telegram, or by any wilful act or omission prevents or delays the transmission or delivery of any telegram, or improperly divulges to any person the purport of any telegram, such person shall be guilty of a misdemeanour, and be liable on summary conviction to a fine not exceeding £20 sterling, and on conviction on indictment to imprisonment with or without hard labour for a term not exceeding one year, alternatively to a fine of £200. If any person, being in the employment of a telegraph company, as already defined, negligently omits or delays to transmit or deliver any telegram, or by any negligent act or omission prevents or delays the delivery or transmission of any telegram, such person shall be liable on summary conviction to a fine not exceeding £20 sterling. Nothing in this Act shall extend to any act or omission on the part of a person employed by a telegraph company in relation to the transmission or delivery of a telegram where such act or omission is in accordance with the provisions of any international telegraph convention for the time being in force in the United Kingdom, or with any reasonable regulations with respect to the transmission and delivery of telegrams made by the telegraph company and approved by the Postmaster-General."

THE DAFT ELECTRIC RAILWAY.—The *Electrician* of New York says:—"The new railway at Coney Island is operated by the Daft system, and extends for 780ft. along the west side of the West Brighton Pier. The track is of 2ft. gauge, the rails being of the T pattern, 20ft. in length, 8lbs. to the foot. These are laid on strips of wood, and all firmly bolted to the pier planking. No attempt is made at insulation, none being needed, as on the wettest days the escape of current would be scarcely perceptible. The dynamo is shunt wound, and capable of furnishing a 6 horse-power current. Like all of Professor Daft's machines, the E.M.F. is extremely low. The intensity of the current varies with the external resistance, and upon this depends the speed of the generator. Its weight is about 650lbs. and its normal speed 1,100. It is driven by an 8 horse-power vertical engine, with boiler to correspond, manufactured by the New York Safety Steam Power Company. The speed of the engine being 250, direct belting was possible. The motor is of the same model as its predecessor, the Ampère, which made the successful trial test at Saratoga. Its name, Pacinotti, is equally appropriate. The body is built of 2in. ash, and is 6½ft. long by 3ft. wide. The superstructure is simply a dash-board 20in. high, to which the switches for controlling the motor are attached; a box on the rear, within which is placed the receiving dynamo. In front of this box and attached to it is the driver's seat. Upon his right is the lever for reversing the brushes on the commutator, and, consequently, the direction of its rotation. The running gear consists of four 12in. wheels with 4in. centres. To prevent short circuiting between the rails, the wheels on one side are insulated by the use of wooden centres. A wooden apron on the four sides, extending to within an inch of the rails, conceals the lower part of the motor. The motion is transmitted from the receiver in the box to a counter shaft beneath, and from there to each pair of wheels. The receiver is compound, having a capacity of from 3 to 4 horse-power. Numerous variations in its resistance may be made, thus controlling the speed of the motor. Its weight is about 450lbs., and the speed of the armature from which the best results are obtained, about 1,400. The speed is of course under control of the driver through his switches. The right-hand switch combines in an ingenious manner a make and break switch, with one for regulating the flow of the current to the receiver. The destructive results to an ordinary switch by the breaking of a heavy current have been avoided in this contrivance, as also in the brake switch, without the introduction of useless resistance. Although in use for some time they evince but the faintest traces of fusion. Two cars are provided for the transportation of passengers, each 12ft. 2in. long and 32in. wide, weighing about 400lb., and accommodating 20 persons, 10 on each side sitting back to back, making a normal load of 40. As many as 50 people have been carried at one time, a total weight of about 4 tons. The weight of the Pacinotti is about 1,200lb., and its maximum speed from 12 to 15 miles per hour, although this is obviously limited on so short a track."

ELECTRIC LIGHT PATENTS IN AMERICA.—With regard to the decision of Judge Shipman in the suit brought against the United States Company by the Brush Company, reported in our issue of the 2nd instant, p. 283, the Brush Company of Cleveland, U.S., have issued the following circular:—"It will, no doubt, surprise our agencies and lighting companies to learn that a suit of this company against the United States Electric Lighting Company, which has been before the court for a long time past, has been decided by Judge Shipman in favour of the defendants. In 1876, two years prior to the date of Mr. Brush's patent, a man named Hayes made a lamp containing a clamp somewhat resembling the clamp used in the Brush lamp, but used quite differently. The lamp was a failure, and after a number of attempts to make it work properly, the clamp was taken off, thrown into a scrap box, and the whole matter dropped. No other lamp was ever made with the clamp, and as this one had never been regarded as successful, either by the maker or any one else, until it was thought that it could be made use of to beat us, and was, as we believed, purely experimental, we treated it as an abandoned experiment, and therefore no anticipation of Mr. Brush's invention, which was entirely successful from the start. Judge Shipman decided, but apparently after serious doubt, that it was not strictly an abandoned experiment, and on this point alone decided the case against us. The case will be at once appealed to the United States Supreme Court, and followed up to the end. The only issue involved in the final hearing of this suit was the lifting and feeding clamp in the lamp. We have other suits still pending against the agents of the United States Company, or users of its apparatus, on other patents that are of much more importance than the one recently decided. We also have a number of other suits on various patents against other systems of lighting, as will be seen by the accompanying list, and infringers will do well to bear in mind that so far only a single one out of more than forty Brush patents has been judicially declared invalid, and we propose, as heretofore, to prosecute all infringers who disregard our rights. Suits are now in progress in various United States circuit courts against users of infringing apparatus covered by patents other than the one passed on by Judge Shipman. Among these are suits against users of the following systems:—The United States (Weston), the Fuller Electrical Company, the Excelsior Electric Light Company (Arnoux and Hochhausen), the Schuyler Company, the Van Depoele Company, the Boulton Carbon Company, the Pittsburgh Carbon Company. Suits are also in preparation against other infringers, including the Thomson-Houston system, which infringes some of our most important patents upon the

Digitized by Google

dynamo machine. The above suits include many different patents, all of which are controlled by us."

Electric Lighting.—An answer to the letter of "A. S.," which appeared in *The Times* of the 7th inst., and which we reprinted in our issue of the 9th inst., appeared in last Wednesday's issue of that journal over the signature "G." The writer says:—"I think the public generally will agree with him ('A. S.') in thinking that the experimental installations, both in public and private establishments, prove the excellence of the electric light and its immense advantage over gas. In reply to the question so commonly asked, 'Why does not electric lighting go ahead?' 'A. S.' furnishes an answer which practically throws the whole blame upon the Electric Lighting Act of 1882, and that because, under this Act, it is provided that only a 19 years' contract may be entered into. It does not seem to have been sound policy to limit the contracts to nineteen years, and it is probable that this limit has checked the application of electricity for lighting our streets and houses; but I think it will be found that fault lies also with the electric lighting companies. For instance, the Act provides, and very reasonably in the interest of the public, that undertakers shall not prescribe to householders and others to whom they supply current the use of any particular kind or form of lamp. This practically means that the undertakers shall supply to consumers an electrical current of varying properties, so that any kind of lamp may be used. I would ask, which of the electrical companies, or under what, if any, system this condition can be complied with? That it must be complied with before electricity can be generally applied is evident, whether the Act requires it or not. Then, again, is it possible to do more than establish isolated installations, when, in order to light any quantity of incandescent, or, as they are now called, glow lamps, it is necessary to have noisy machinery on or near the premises lighted, the cost of bringing a suitable current from a distance being prohibitive on account of the expense of the leads? Hence it follows that to enable the public generally to profit by the electric light the current must be brought from convenient stations at a distance (in some cases considerable) from the area of consumption. Again, I ask, what electric lighting company or system can do this economically? 'A.S.' speaks of accumulators as affording the means of storing electricity from the street wires for distribution in the houses; but accumulators involve a serious and unavoidable loss, and, though probably valuable if not indispensable as a reserve, can hardly furnish a solution of the problem. Although the unhealthy gambling of which electric lighting, as an honest industry, was the victim some 18 months ago, has retarded its legitimate development, now that the atmosphere has been cleared by the disappearance of many bogus and other unsound companies, it is hoped that the remaining companies will seriously apply themselves to the task, difficult, perhaps, but by no means impossible, of supplying electricity economically in the various forms required by different consumers; and if this result were really attained there can be little doubt that an appreciative public would gratefully accept the boon. There is no reason either to suppose that the enormous gas interests would suffer by a development of electrical enterprise; on the contrary, it would probably be found that, although less gas would be used for producing light, more would be employed for heating purposes, for which latter a less expensive manufacture would suffice. I think the exercise of a little public spirit, which would be found the soundest policy for private interests, too, leading to the united action of the principal companies interested, would bring about the happiest results for consumers and shareholders alike, both as regards gas and electricity."

What Will be Heard at Montreal?—*The Times* of the 19th inst. indulges in a little prophesy as to what will be heard at Montreal when the British Association meeting has been opened. The President of the Association, Lord Rayleigh, is, says the prophet, both a man of affairs, a Cambridge professor, and an original worker in some of the most abstruse departments of physics. He will be able, in his address, to refer to what he saw of Canada in his visit of 17 years ago, and is likely enough to gratify his audience by the admiring terms in which he will be able to speak of the past of the Dominion and the strong hopes which he has formed of its future. But Lord Rayleigh has too high an estimate of his responsibilities and position as president to occupy his hour in saying pleasant things of the Canadians. The branch of science with which he is more particularly connected has the widest and most varied field and the most far-reaching bearings in practice; and, therefore, an account of recent progress in the various departments of physical science, when given with Lord Rayleigh's well-known skill and clearness, would be sure to interest any intelligent audience. Such, therefore, we believe, is likely to be the subject of this year's presidential address. Lord Rayleigh cannot but refer to the serious loss which science has sustained since last meeting in the death of Sir William Siemens, and he may take advantage of the opportunity to say a good word on behalf of inventors. Electricity, especially in some of its practical applications, cannot fail to come under the notice of the president, and he may have some hopeful words to say on the future of electric lighting. Among the names he may have to mention of those who have done important service in the recent progress of electricity as well as other branches of physics, will probably be some whom the United States, at least, if not Canada, can claim as citizens. Of almost equal practical importance with electricity is thermodynamics, including as it does such curious problems as the dissipation of energy, and such inventions as the steam engine. Under the heads of motion of fluids, acoustics, and optics Lord Rayleigh may also have to record important advances in recent years, and in these connections he cannot but refer to his eminent predecessor at Cambridge, the late Clerk-Maxwell. It is possible also that the president may make some reference to the place of science in education, and if so his opinions are not likely to be very acceptable to the out-and-out adherents of the older leaning. It would be only in accordance with precedent that the relations of science to the intangible and the unseen should be touched upon in the presidential address; but if Lord Rayleigh does so we may be sure it will be in words of tenderness and hope. Such, so far as we can learn, are likely to be some of the topics touched on in the presidential address at Montreal; of one thing we may feel sure that in Lord Rayleigh's hands it will be worthy both of the Association and of the unprecedented occasion. From the presidents of sections we expect, of course, to have something more special than from the President of the Association. Sir William Thomson, as president of the physical section, will no doubt choose some special point in his wide domain for the subject of his discourse; but we may be sure that he will not let the opportunity pass without throwing out some ideas bearing on the very foundations of scientific knowledge. If rumour speaks correctly Sir William Thomson is likely to deal briefly with a subject bearing closely on the nature of matter itself, and some of the ideas he is likely to broach will probably prove suggestive of new lines of experiment as well as of speculation. Indeed, his address may turn out to be one of those flashes of speculative genius which occasionally burst forth and lighten up the dark places of science.

THE INDUCTION OF CURRENTS IN CORES.

BY OLIVER HEAVISIDE.

(CONTINUED FROM PAGE 201.)

Normal or Harmonic Distributions of Magnetic Force.

The problem of determining the manner in which the magnetic force and induced current in a core inserted within a long solenoidal coil vary, when the coil circuit containing a battery or other source of steady E.M.F. is suddenly closed, is somewhat more simply managed by reversing it, and finding the manner in which the magnetic force subsides when the E.M.F., after having set up the permanent state, is suddenly removed, without interrupting the circuit or altering its resistance. And this is a special case of the more general, but theoretically quite as easily managed, problem of starting at a given moment with *any* distribution of magnetic force in the core, subject only to the condition of being directed parallel to the axis, and only varying in strength with distance from the axis, and, leaving the system to itself, determining the subsequent state of things, the coil circuit being open or closed, but without other E.M.F. than that arising from the subsidence of the core's induction. The initial strength of magnetic force may vary from layer to layer in a perfectly arbitrary manner, either continuously or with abrupt changes of strength.

As regards the arbitrariness, we may obviously, by means of a previously acting arbitrarily variable E.M.F. in the coil circuit, set up an infinite number of different states of magnetic force. But they will not be arbitrary, because the magnetic force will, in all such cases, vary continuously in strength from layer to layer. That abrupt changes of strength are admissible in the initial state may be thus shown. Considering the core as made up of a great though finite number of thin concentric tubular shells, we have a set of linear electric circuits. From their coefficients of self and mutual induction, and their resistances, we have all the data required for determining what will happen when we start with given currents in these circuits, and leave the system to itself. The circuits being independent, the initial strengths of current in them may have any values we please; and since there is no breach of continuity in passing from a finite number of circuits to an infinite number making up a solid core, it follows that in the mathematical treatment of the subject the initial current, and therefore also the magnetic force, may vary abruptly in passing from the axis outward, although of course special means would be required to set up the discontinuities in strength.

We may also, from the theory of linear circuits, see at once what the form of our solutions must be in the case of a continuous core. For, if there are n circuits, there are n distinct rates of subsidence, and the currents at time t after the moment of leaving the system to itself are given by n equations of n terms each, of the form,

$$\left.\begin{aligned}\gamma_1 &= A_1e^{D_1t} + A_2e^{D_2t} + A_3e^{D_3t} + \dots\\ \gamma_2 &= B_1e^{D_1t} + B_2e^{D_2t} + B_3e^{D_3t} + \dots\\ \gamma_3 &= C_1e^{D_1t} + C_2e^{D_2t} + C_3e^{D_3t} + \dots\\ &\dots\dots\dots\dots\end{aligned}\right\} \quad . \quad . \quad . \quad (64)$$

$\gamma_1, \gamma_2, \dots$ being the currents at the time t in the first, second, &c., circuits. Here there are n constants $D_1, D_2, \dots$ which are the same for every current, and n^2 constants A, B, C, . . . but the *ratios* of the constants in any column are fixed by the electrical data (as are also D_1, D_2, &c.), leaving only one constant in each column arbitrary, making n altogether, whose values may be found from the given initial strengths of the n currents, thus completing the solution.

Now, these circuits being concentric shells to start with, in passing to the case of a continuous core, making the number of shells infinite, we see first that the form of the solution must remain unaltered. Next, that the number of constants D_1, D_2, &c., becomes infinite, whilst they are the same for all parts of the core. Thirdly, that, supposing $\gamma_1, \gamma_2, \dots$ are the currents in consecutive shells passing from the axis outward, the coefficients A, B, C, . . . in any one column of (64) become the successive values of a continuous function of r, whose magnitude alone is left arbitrary, so that we may write (66) in the form of a single equation

$$\gamma = A_1u_1e^{D_1t} + A_2u_2e^{D_2t} + A_3u_3e^{D_3t} + \dots \quad . \quad . \quad . \quad . \quad (65)$$

γ signifying the current at distance r from the axis, $u_1, u_2 \dots$ being functions of r determined solely by the electrical data, and $A_1\ A_2 \dots$ constants to settle the absolute magnitude of each term.

And lastly, we see that, since at the time $t=0$, we have

$$\gamma_0 = A_1u_1 + A_2u_2 + A_3u_3 + \dots,$$

and since the initial current γ_0 is arbitrary, it must be possible to expand any function of r in a series of u's, by properly determining the magnitude of the A's.

Special proofs of the possibility of the expansion of any function in series of a definite kind are usually of a singularly obscure and unsatisfactory nature, quite apart from their speciality or want of applicability to other forms of series. But if, as in the above, we pass from the solution of a set of linear differential equations with one variable, the time, to that of a partial differential equation, we see the absolute necessity of the possibility of the expansion. It would be a miracle were the expansion impossible. Have we got the right *form* of function in the first place, and next, have we got *all* of them, to satisfy the conditions of a physical problem? If so, the possibility of the expansion requires no proof.

By (65), and the relation $\gamma = -\frac{1}{4\pi}\frac{dH}{dr}$ between the current and magnetic force, the general solution for the magnetic force is of the same form, viz.:

$$H = A_1u_1e^{D_1t} + A_2u_2e^{D_2t} + \dots \quad . \quad . \quad . \quad . \quad (66)$$

where u_1, u_2, &c., are functions of r to be found by putting the elementary solution ue^{Dt} for H in the characteristic equation of H, viz.:—

$$\frac{1}{r}\frac{d}{dr}r\frac{dH}{dr} = \frac{4\pi\mu}{\rho}\frac{dH}{dt} \quad . \quad . \quad . \quad (14)\ bis$$

Since $\frac{d}{dt}e^{Dt} = De^{Dt}$, we obtain

$$\frac{1}{r}\frac{d}{dr}r\frac{du}{dr} = \frac{4\pi\mu}{\rho}Du \quad . \quad . \quad . \quad . \quad (67)$$

whose solution gives the function u. Being of the second order, it has two distinct solutions, say v and w, so that

$$u = av + bw \quad . \quad . \quad . \quad . \quad . \quad . \quad (68)$$

is the complete solution. One of v and w may be found at once by assuming $u = a_0 + a_1r + a_2r^2 + \dots$, inserting in (67), and making it true for every power of r. This gives

$$v = 1 + \frac{4\pi\mu}{\rho}\frac{r^2D}{2^2} + \left(\frac{4\pi\mu}{\rho}\right)^2\frac{r^4D^2}{2^24^2} + \left(\frac{4\pi\mu}{\rho}\right)^3\frac{r^6D^3}{2^24^26^2} + \dots \quad . \quad (69)$$

Put $\frac{4\pi\mu D}{\rho} = -n^2$, for subsequent convenience, and we hav

$$v = 1 - \frac{n^2r^2}{2^2} + \frac{n^4r^4}{2^24^2} - \frac{n^6r^6}{2^24^26^2} + \dots = J_0(nr) \quad . \quad (70)$$

for one solution of (67). This function is usually denoted by $J_0(nr)$, and was first employed by Fourier. Whether he invented it or discovered it is a doubtful point; the question is raised whether mathematical truths lie within the human mind alone, or whether the infinite body of known and unknown mathematics could exist in a dead universe. But this is metaphysics, which is all vanity and vexation of spirit, especially in this shirt-sleeve weather.

The other solution may be shown to be

$$w = \frac{2}{\pi}\left\{ v\log nr + \frac{n^2r^2}{2^2} - (1+\tfrac{1}{2})\frac{n^4r^4}{2^24^2} + (1+\tfrac{1}{2}+\tfrac{1}{3})\frac{n^6r^6}{2^24^26^2} - \dots\right\} \quad (71)$$

For proof it is sufficient to test that it satisfies (67) and is not the same as (70).

Digitized by Google

The general form of the *u*'s in (66) is thus completely known. But we do not want the second solution, *w*, at all at present in dealing with a core solid to its centre, because *w* becomes infinite when $r=0$, on account of the logarithm. Its coefficients, therefore, require to be zero to make the magnetic force finite at the axis of core, *i.e.*, *w* does not come in at all. It will occur later. At present we have

$$H = A_1 v_1 e^{D_1 t} + A_2 v_2 e^{D_2 t} + \dots \quad . \quad . \quad . \quad (72)$$

in which the *v*'s only differ from one another in having a different value of *n* or D.

The nature of the function *v* is shown in Fig. 1. Distance from the axis of the core is measured along the base line to the right, and the value of *v* upward. The curve *v* crosses the base line an infinite number of times. After a few fluctuations it becomes very nearly a sinusoidal curve, but with diminishing amplitude, varying inversely as the square root of the distance from the axis.

The magnetic interpretation is, if the strength of magnetic force in a core at different distances from its axis be represented by the curve *v* the magnetic force will subside everywhere at the same rate. When it has fallen to $1/m$ of its initial strength at any point, it has fallen to $1/m$ of its strength at every other point, so that the curve representing the force at any moment remains similar to itself.

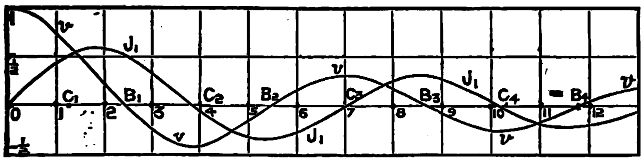

Fig. 1.

The other curve in Fig. 1, marked J_1, shows in a similar manner the strength of the current accompanying the magnetic force; its equation is

$$J_1(nr) = -\frac{d}{d(nr)} J_0(nr) \quad . \quad . \quad . \quad . \quad .(73)$$

or, by (70),

$$J_1(nr) = \frac{nr}{2}\left(1 - \tfrac{1}{2}\frac{n^2r^2}{2^2} + \tfrac{1}{3}\frac{n^4r^4}{2^24^2} - \dots\right) \quad . \quad . \quad (74)$$

The curve *v* may be drawn to any vertical scale, since this amounts merely to fixing the absolute strength of magnetic force. But as to the horizontal scale, this depends upon what the boundary conditions are. By means of a suitable boundary condition we may arrange to have the boundary at any distance along the base in Fig. 1, where of course the curve must stop.

Example I.—Coil Circuit Interrupted.

If the coil be absent, or its circuit broken, the boundary value of the magnetic force is compelled to be zero. Now in Fig. 1, $v=0$ at B_1, B_2, &c., and at any of these places we may imagine the core to terminate and the curve stop. This gives a definite series of values to *n*, of which the first four are

$$\left.\begin{array}{llll} an_1 = 2{\cdot}405, & an_2 = 5{\cdot}520, & an_3 = 8{\cdot}654, & an_4 = 11{\cdot}791; \\ a^2n_1^2 = 5{\cdot}783, & a^2n_2^2 = 30{\cdot}471, & a^2n_3^2 = 74{\cdot}888, & a^2n_4^2 = 139{\cdot}037. \end{array}\right\} \quad (75)$$

Now, in Fig. 2, the base line, OP, represents *a*, the radius of the core, and the four curves, the first four normal distributions of magnetic force, being the curve *v* in Fig. 1, drawn upon four different horizontal scales, so as to reach the boundary, P, at the first, second, third, and fourth roots of $v=0$. There are an infinite number of other normal systems, corresponding to the higher roots. The normal system v_m divides the core into a solid central cylinder, surrounded by $m-1$ concentric tubes, at whose boundaries the magnetic force vanishes, being oppositely directed in consecutive tubes. The corresponding current vanishes at the places of maximum magnetic force, and the magnetic force vanishes at about the middle of each current segment.

The time constant measuring the slowness of subsidence of a normal system is

$$-1/D = 4\pi\mu/\rho n^2,$$

thus being proportional to the magnetic permeability, to the conductivity, to the sectional area of the core, and inversely to the square of *na*. Of all metals except iron, copper is the one in which any normal system subsides most slowly; on the other hand, the great permeability of soft iron overbalances its comparatively low conductivity and makes it the metal of slowest subsidence.

Copper.—$\rho = 1{,}700$, $\mu = 1$. These make $4\pi\mu/\rho = {\cdot}0074$, and the time constants of the first four normal systems to be, by (75),

${\cdot}0013a^2$, ${\cdot}00024a^2$, ${\cdot}000099a^2$, $000054a^2$, seconds,

where *a* is the radius of the core in centimetres.

Iron.—$\rho = 10{,}000$, $\mu = 100$ say. These make $4\pi\mu/\rho = {\cdot}1256$, and the time constants

${\cdot}0217a^2$, ${\cdot}0041a^2$, ${\cdot}0017a^2$, ${\cdot}0009a^2$,

which are 17 times as large as for a copper core of the same radius. In an iron core of 10 cm. radius (5in. diameter), the time taken by the first and most important normal system of magnetic force, inducing a current only in the core itself, to fall in strength from 2·718 to 1 would be 2·17 seconds. If of 1 m. radius it would take 217 seconds.

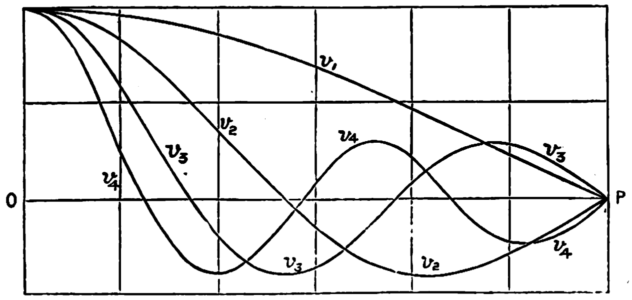

Fig. 2.

Note on Earth Currents.

The remarkable slowness of subsidence of currents in large masses of metal, or, equivalently, in proportionately larger masses of badly conducting material, is vaguely suggestive in regard to earth currents. Without intending any strict comparison, it may be remarked, first, that although the "earth' may be poorly conducting, yet there is a good deal of it. And next, that the "earth currents" observed on long lines of telegraph during magnetic storms are, neglecting the minor fluctuations, remarkably alike in their behaviour in some respects. Although a big "wave" may set in one way, and continue of great strength, for some considerable time, even minutes, to be followed by another wave reversing the current, yet the transition from one to the other never takes place suddenly; even the most rapid reversal of a big wave takes several seconds to accomplish. A similar sluggishness may be observed in all large changes of current strength; and it is suggested, without any hypothesis as to the cause of these earth currents, what keeps up such powerful currents for a long time in one direction at one place in at least the superficial portion of the earth (of course in closed circuits) of which portions find their way into telegraph lines, that the characteristic sluggishness is due to the electro-magnetic retardation as the currents in the earth change their strength and distribution.

(TO BE CONTINUED.)

Post Office Volunteers.—The 24th Middlesex (Post Office) Volunteers were encamped at Aldershot all last week, mustering between 400 and 500 strong, and took part in the manœuvres and drill, for which about 5,000 volunteers and as many regulars had been brought together. The signalling corps, made up exclusively of telegraphists, worked with the Royal Engineers, receiving instruction in the erection of wires and paying out of cable. On Friday, detachments of these men were assigned to the attacking and defending forces, maintaining telegraphic communication with their respective headquarters during the sham fight.

ON THE ELECTRO-DEPOSITION OF CARBON, &c.*

BY G. GORE, LL.D., F.R.S.

The following experiments were made as attempts to electro deposit carbon, boron, and silicon :—

Experiment 1. A fused mixture of 200 grains of pure sodic hydrate, 170 grains of pure precipitated silica, and 610 grains of the mixed anhydrous carbonates of potassium and sodium was electrolysed by means of a current from ten Smee's elements, with a sheet platinum anode, and a thick platinum wire cathode. The conduction was free, and much oxygen, which relighted a red hot splint, was liberated at the anode. Dark streams flowed from the cathode; sodium was also set free, and if the cathode was only slightly immersed, bubbles of sodium vapour were emitted and took fire at the surface of the liquid. After one hour's action, the platinum anode had lost ·37 grains in weight. The cathode had a feebly adherent rough deposit of a dull jet black colour upon it. This deposit was subsequently washed and dried; a portion of it burned with a glow when heated to redness on platinum and left a minute residue of grey platinum. It also deflagrated with fused nitre below a red heat, and vividly by heating with potassic chlorate. It did not dissolve nor evolve any gas in a mixture of strong nitric acid and pure concentrated hydro-fluoric acid. It was therefore not silicon, but carbon containing a minute quantity of platinum.

As carbon was not readily deposited from the fused carbonates of potassium and sodium (*see* Experiment 4), whilst silicon was deposited from fused silico-fluoride of potassium (*see* Experiment 3), and as an excess of silicon fused with potassic carbonate sets free carbon, but silicon with an excess of the carbonate liberates carbonic oxide, the carbon liberated in the present experiment may have been a secondary result, and an effect of previously deposited silicon reacting upon the fused mixture. It was with an expectation of this effect that I employed silica in the mixture.

Experiment 2. I also electrolysed in a platinum cup a fused mixture of 475·2 grains of 97·1 per cent. sodic carbonate†, and 217·4 grains of borofluoride of sodium, by means of the same current, a sheet platinum anode, and thick platinum wire cathode. Conduction was free. Gas arose from the anode. A small amount of black deposit formed on the wire. After having been well washed the deposit was dried, put on a platinum dish, and heated to redness. It burned with sudden incandescence until nearly the whole was consumed. It was therefore nearly wholly carbon.

Experiment 3. I electrolysed in a platinum cup a fused mixture of 300 grains of 97·1 per cent. pure potassic carbonate and 442 grains of silico-fluoride of potassium by a current from ten Smee's cells, a sheet platinum anode and a platinum wire cathode. Gas arose from the anode, and at first only gas arose from the cathode also. After that, streams of black matter poured down from the cathode, and the latter acquired a blackish film, but subsequently became alloyed and fused on its surface. The deposit was therefore partly or wholly silicon.

Experiment 4. A mixture of 10 parts of pure anhydrous sodic carbonate and 13 parts of pure anhydrous potassic carbonate was fused in a platinum cup, and electrolysed by a current from eight Smee's cells and platinum electrodes at a red heat. Very free conduction occurred. Gas was copiously evolved from the anode, an abundant liberation of sodium occurred at the cathode. No gas arose at the cathode, but dark streams issued from it beneath the surface of the liquid. The anode became brown, but had lost only ·9 grain during one hour and a half's action. The cathode did not alloy with the sodium, but became brown, and was corroded at the surface of the liquid. A thin cathode of pure gold soon alloyed with the sodium, and melted at its extremity, although the temperature was below that of melting silver (probably in consequence of alloying with sodium); a thick one also gave off sodium vapour, alloyed and fused. A thick cathode of pure silver gave off sodium freely, but was soon cut in two at the surface of the liquid; its end became arborescent, as if it had absorbed vapour of sodium and expelled it again as it does oxygen. No free carbon appeared.

Experiment 5. I also electrolysed a mixture of 274 grains of pure sodic carbonate, 375 grains of pure potassic carbonate, both anhydrous, and 206 grains of crystallised boracic acid, in a similar manner at a red heat. There was free conduction, much gas from the anode, and an instant jet black deposit formed upon the cathode, and could be burned off by a red heat. Metallic sodium was set free at the cathode, especially during deep immersion. The anode was soon much corroded, and acquired a very smooth surface, and platinum was deposited upon the cathode. No free carbon was ultimately found.

Experiment 6. Potassic cyanide fused in a porcelain crucible was electrolysed by means of a current from 25 Smee's cells with a coke anode and an iron cathode. Free action occurred, much gas was evolved from the carbon, and some from the iron. A blackish deposit formed upon the iron and sank to the bottom. A platinum cathode dissolved quickly.

Experiment 7. Melted potassic cyanide in a porcelain capsule was electrolysed by means of a gas carbon anode, a thin platinum wire cathode, and a current from two cells of zinc and platinum in dilute sulphuric acid. No deposit occurred on the cathode in a quarter of an hour.

Experiment 8. I electrolysed distilled water by means of a current from 30 Smee's cells and a gas carbon anode of fine quality and a platinum wire cathode, the two electrodes being very close together. Very faint conduction occurred. The water became brownish in one hour; the carbon of the anode produced this effect. The anode was slightly disintegrated on the side towards the cathode. No deposit of carbon occurred.

Experiment 9. By means of a current from the same battery and a plumbago anode, I electrolysed a solution of potassic hydrate (with and without addition of oxalic acid). Free action occurred, and plenty of gas came from both electrodes. Saturated solutions of oxalic acid in hydrochloric acid, and in nitric acid, were also electrolysed by means of platinum electrodes. No carbon was deposited in either case.

Experiment 10. I electrolysed a solution of pure formiate of sodium in the strongest formic acid by means of a current from four Smee's cells and electrodes of platinum. A black film deposit formed upon the cathode. It was not platinum nor carbon, but apparently oxide of iron.

Experiment 11. Some oxalic acid was melted in its water of crystallisation, and the liquid electrolysed by the current from two small Smee's cells with platinum electrodes. Conduction was very feeble. Gas was evolved, but no solid deposit occurred.

Experiment 12. I passed an electric current during one week from four Smee's cells, by means of platinum wires, through pure very dilute sulphuric acid in a large V glass tube, one leg of which was kept full of a mixture of carbonic oxide and carbonic anhydride gases. The anode acquired a thin reddish coating, which dissolved soon after the current was stopped. No carbon was deposited.

Experiment 13. A cold saturated solution of pyrogallic acid in water was electrolysed by means of a current from 25 Smee's cells, a large platinum anode and a platinum wire cathode. Gas came rather freely from the wire, but none from the anode, and the liquid became quite brown by oxidation. No carbon was deposited.

Experiment 14. Strong hydrochloric acid containing a large gas carbon anode and a very small platinum wire cathode was electrolysed by means of a current from thirty Smee's cells. Free action took place. Much gas came from both electrodes; apparently chlorine from the anode, and hydrogen from the cathode. The cathode soon became black, but not when it was deeply immersed.

Experiment 15. A carbon anode in pure nitric acid was rapidly disintegrated by a current from two Smee's cells. The conduction was free. A gas carbon anode was also much disintegrated in a solution of potassic chromate by a current from thirty Smee's cells. Gas came from both electrodes.

* Paper read before the Birmingham Philosophical Society, July, 1884.
† The impurity consisted wholly of water

Digitized by Google

Experiment 16. Hydrocyanic acid gas liquefied by cold, and containing a little water, was saturated with carbonic oxide gas, and a current from three to twelve cells of a Smee's battery passed through the liquid by means of two fine platinum wires. Gas was evolved from the cathode only. After three hours' action no carbon was deposited.

Experiment 17. Fuming Nordhausen sulphuric acid, also a syrupy solution of phosphoric acid, were saturated with dry carbonic anhydride, and then electrolysed by means of platinum wire electrodes, and currents from 112 Smee's cells in single series; carbon was not deposited.

Experiment 18. A saturated solution of oxalic acid in water was electrolysed by means of a current from ten Smee's cells, a charcoal anode and platinum wire cathode, in a hermetically closed glass tube. Gas was evolved, and the cathode became black. As the pressure increased, the conduction diminished and at a pressure of about 50 or 60 atmospheres the tube burst. By the electrolysis of a saturated solution of oxalic acid in alcohol with electrodes of platinum wire a thin black deposit was formed upon the cathode.

Experiment 19. The degrees of electric conduction resistance of distilled water and water saturated with carbonic anhydride at 60°F. were examined. No conspicuous difference was perceived.

Experiment 20. A current of coal gas was passed during fourteen days through a glass vessel over dilute sulphuric acid, the acid liquid being constantly electrolysed by means of four Smee's cells and platinum wire electrodes. A little gas was evolved from the wires all the time, but no signs of deposited carbon appeared.

Experiment 21. The electric current from a battery of three cells, composed of magnesium and palladium wires in water, conducted into water above a layer of CCl_4 by a purified gas carbon anode and palladium wire cathode did not set free carbon.

Experiment 22. The dry brown salt produced by exposing thin sheets of potassium to the vapour of carbonic bisulphide was dissolved in ether, and the solution electrolysed by a current from 25 Smee's cells and platinum wire electrodes. Much gas was evolved from the cathode, but no carbon set free.

Several of these experiments prove that carbon, boron, and silicon may be separated from their melted compounds by means of electrolysis; but although carbon was slowly deposited in several cases, in no instance was it obtained from an aqueous solution, or in a crystalline state.

ON THE ELECTROLYSIS OF FLUORIDE, CHLORATE, AND PERCHLORATE OF SILVER.*

BY G. GORE, LL.D., F.R.S.

By means of pure dilute hydrofluoric acid (prepared as described in *Phil. Trans.* Roy. Soc., 1869, p. 196) and pure oxide or carbonate of silver, a rather strong solution of pure argentic fluoride was obtained, and was then acidified by addition of pure hydrofluoric acid in order to fit it for electrolysis.

This liquid is a remarkably good conductor of electricity, and is decomposed with the greatest ease by employing electrodes of silver and an electric current derived from a single cell composed of zinc and platinum in dilute sulphuric acid.

I have elsewhere (*Phil. Trans.*, Roy. Soc., 1870, p. 235) described some of the phenomena attending the electrolysis of a strong aqueous solution of this salt not containing any free acid, such as the extremely rapid formation of a very thick coating of beautiful and bright crystals of silver upon the cathode, soon becoming half an inch in thickness and rapidly extending over the bottom of the vessel to the anode, and metallically uniting the electrodes unless the deposit is frequently removed. The increase of these crystals is so rapid with a strong solution and current that if the vessel is a small one it soon becomes half filled with them.

* Paper read before the Birmingham Philosophical Society, June, 1884.

There is, however, another phenomenon to which I now desire to call attention, viz., that whilst a thick and smooth anode of pure sheet silver in a suitable solution of potassic cyanide dissolves gradually away and retains its original whiteness, cohesive strength, and most of its original smoothness, until it has become extremely thin, a similar anode in the fluoride solution quickly becomes exceedingly rough, of a grey aspect, and very friable throughout its thickness, having lost its original degree of cohesive strength.

Imagining that this loss of cohesion might be due to some substance set free by electrolysis and absorbed by the silver, as in similar cases of absorption of hydrogen and other liberated ions at metallic cathodes, I took a tube of pure silver 2½in. deep, ⅝in diameter, and about 1 mm. thick, closed at the bottom by pure silver, and employed it as the anode, the upper end of the cup being tightly closed by cork, through which was fixed a slender platinum tube connected by an india rubber tube, with an open, slender, and bent glass tube containing mercury, in order to render manifest any diffusion of gas into the interior of the tube.

Under these conditions the liquid was electrolysed until a large hole was corroded in the tube; no signs of gas or odour, however, appeared, nor was the cork which closed the tube bleached or blackened. I conclude, therefore, that the loss of cohesion of the silver was not due to diffusion of liberated fluorine through the silver.

A solution of chlorate of silver was formed by adding to 1¼ oz. of aqueous chloric acid (containing as impurity traces only of hydrochloric acid or a chloride) 10 grains of argentic oxide; it nearly all dissolved. The liquid was filtered and then electrolysed by means of electrodes of pure sheet silver, and a current from two Smee's cells charged with a mixture of one volume of sulphuric acid and 50 of water. Conduction was very free for a short time; the anode, however, soon became coated with a black film, probably of peroxide of silver, which appeared to stop the current. Silver was freely deposited at first. The deposit was loose, and not very white. The anode corroded but slowly, and permanently continued nearly black. By employing one Smee's cell only, the deposit was more slow and more coherent, and remained attached to the cathode. The solution requires a feeble current, a large cathode, and much larger anode.

To form the solution of argentic perchlorate, fifteen grains of oxide of silver were added to one ounce by measure of aqueous perchloric acid; it nearly all dissolved. The liquid contained either hydrochloric acid or a chloride rather freely. The solution was then filtered and electrolysed by means of a current from two Smee's elements feebly charged and electrodes of pure sheet silver; copious conduction occurred. The anode quickly became black, as if peroxide of silver was formed, but the current did not much diminish. The cathode soon acquired a very bulky deposit of loosely adherent silky crystals of silver. The liquid was again filtered, and then diluted with half an ounce of water, and a current from only one Smee's cell now employed. The anode became less dark in colour, the conduction was still very free, and a smaller bulk of crystals was deposited. A wire of silver was now substituted as the anode, and the crystals removed. The anode rapidly corroded, and acquired a thick loose coating of black matter, which kept falling off; it then acquired a thick green coating, but evolved no gas. The solution is a remarkably good conductor. It requires a very large cathode, and a rather small anode.

NEW STEAMER.—The steamer "Saturno," which has just been completed by Messrs. A. and J. Inglis, of Pointhouse, in the Clyde, to the order of a River Plate company, for river service in South America, is lighted throughout by incandescent lamps, which have been fitted up by Messrs. William Harvie and Co., of Glasgow.

WEST INDIA AND PANAMA TELEGRAPH COMPANY.—The estimated traffic receipts of this company for the half month ended the 15th August are £2,345, as compared with £1,968 in the corresponding period of 1883. The May receipts, estimated at £6,164, realised £6,296.

THE ELEMENTS OF ELECTRIC LIGHT ENGINEERING.

BY E. C. RIMINGTON AND C. W. J. CRAWLEY.

(CONTINUED FROM PAGE 319.)

Having a characteristic curve drawn for a given speed to obtain one representing another speed,

Let the curve O P K M be the characteristic for speed of s revolutions per minute; we wish to obtain one of a speed of r revolutions.

From any point K in the curve drop the perpendicular K n, produce n K to p, making $n\,p : n\,K :: r : s$, or $n\,p = \frac{r}{s}\,n\mathrm{K}$; then p will be a point in the curve for the speed r. By taking various points along the curve O P K M and performing the same operation we obtain a curve O p L, which will be the curve required (*vide* Fig. 16, p. 139 *ante*).

The reason we make $\frac{np}{n\mathrm{K}} = \frac{r}{s}$ is that when the current is constant round the field-magnets, the magnetic field produced by the latter is also constant, and then E.M.F. varies approximately as the speed.

A given current is required through a given resistance to find at what speed the dynamo will require to be run.

Let R = given resistance in ohms, and C = given current = O C (Fig. 17.)

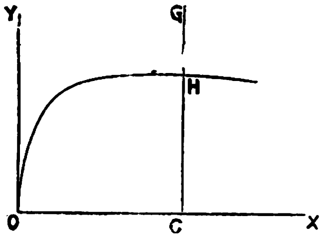

FIG. 17.

From C draw perpendicular cutting curve in H, on it mark off C G = C R volts, then

C H : C G :: speed for curve : required speed.

It often happens that we cannot keep the speed of a dynamo the same when we are varying the external resistance, particularly when it is driven from some engine that we cannot well regulate, such as a gas engine; in this case we need not trouble to keep the speed quite constant, but should keep it as much so as possible, and note it down against every observation of current and E.M.F. As we cannot well now obtain the total E.M.F's by setting off the terminal E.M.F.'s starting from the line of internal resistance as before, we must calculate the total E.M.F's from the formula

$$E = e + \rho\,C,$$

where E = total E.M.F., e = terminal E.M.F., C = current, and ρ = internal resistance of the machine.

Suppose we are drawing a curve for n revolutions per minute, and the number at which the machine was running when we took the observation was m, then the required total

$$\text{E.M.F.} = \text{total E.M.F. at } m \text{ revolutions} \times \frac{n}{m}$$

$$= \frac{n}{m}\left(e + \rho\,C\right).$$

If, for example, we are drawing a curve for 1,000 revolutions per minute, and when we took one of our observations we found the speed = 900, terminal E.M.F. = 70 volts, current = 20 amperes, $\rho = 1$ ohm. Then required E.M.F. $= \frac{1000}{900}\,(70 + 20) = 100$ volts.

So we set off along 0×20 divisions representing amperes, erect a perpendicular, mark off on it 100 divisions representing volts, and obtain a point in the curve.

To find the Electrical Efficiency of a Series Dynamo.

The electrical efficiency of a dynamo is the ratio of the electrical work done in the external circuit to the electrical work done in the total circuit.

Now, electrical work done in the external circuit = C^2 R, and the electrical work done in the total circuit = C^2 $(R + \rho)$. Therefore electrical efficiency $= \frac{C^2 R}{C^2 (R + \rho)} = \frac{R}{R + \rho}$, or is the ratio of the external resistance to the sum of the external and internal resistances, or total resistance. If in the circuit we have a secondary battery, we can represent it as an "ohmic" resistance, although the greater part of the opposition it offers to the currents is due to the back E.M.F. (*i.e.*, the E.M.F. tending to set up a current in the opposite direction to the charging current), and not a true ohmic resistance.

If there is a difference of E.M.F. between the battery terminals of ϵ volts, and a current of C amperes passing through it, it is equivalent to such a resistance as with ϵ volts at *its* terminals will also allow C amperes to pass, that is to a resistance of $\frac{\epsilon}{C}$ ohms.

But it must be remembered that this resistance varies with the current; it is, in fact, made up of two parts, the *true* internal resistance of the battery, and the resistance equivalent to the back E.M.F. divided by the current.

Suppose we have ten cells in series, each of two volts and ·01 ohm internal resistance, then the total *true* resistance = ·01 × 10 = ·1 ohm, and the back E.M.F. = 2 × 10 = 20 volts. When there is a current of eight amperes flowing, there is an E.M.F. at the terminals of 2 × 10 + 0·1 × 8 = 20·8 volts, and the ohmic resistance equivalent to this battery is then $\frac{20{\cdot}8}{8} = 2{\cdot}6$ ohms; but when there is a current of twelve amperes flowing there is an E.M.F. of 2 × 10 + ·1 × 12 = 21·2 volts at the terminals, and the ohmic resistance is now $\frac{21{\cdot}2}{12}$, or only about 1·8 ohm.

To formulate,—

$$R = \frac{\epsilon + \rho C}{C} = \frac{\epsilon}{C} + \rho \text{ ohms},$$

where ϵ = total back E.M.F.

ρ = total internal resistance of battery.

C = current passing through battery.

This also holds good in the case of a motor.

To Find the Electrical Work in the Circuit in Horse-power.

The work in the external circuit

$$= \frac{eC}{746} = \frac{e^2}{746R} = \frac{C^2R}{746}\,\text{h.p.},$$

e being the terminal E.M.F. in volts, C the current in amperes, and R the resistance of the external circuit (including all back E.M.F.'s, &c.) expressed in ohms.

Work expended in the coils of the dynamo $= \frac{C^2\rho}{746}$ h.p.

Total work in the circuit $= \frac{C^2 (R + \rho)}{746}$ h.p.

$$= \frac{E\,C}{746} = \frac{(e + \rho C)\,C}{746}\,\text{h.p.}$$

The mechanical efficiency of a dynamo is the ratio between the work in the external circuit and the work put into the dynamo as measured by a dynamometer on the pulley wheel, or

$$= \frac{e\,C}{746\,W}$$

where W = the power in horse-power applied to the dynamo as measured by the dynamometer.

It now remains to be seen how to arrange a small installation, employing a series dynamo as the generator. We will suppose that we are using incandescent lamps.

Incandescent lamps are usually arranged, as we have before stated, in multiple or parallel arc (Fig. 18), but if the E.M.F. given by the machine be double that required for each lamp, they must be put two in series, as in Fig. 19, the objection to this method being that we cannot extinguish a lamp without

Digitized by Google

also extinguishing the one in series with it. In Fig. 18, A and B are the two main leads, one coming from each terminal of the dynamo; as many lamps as desired are arranged between them, one terminal of each lamp being connected to A, the other to B. Smaller wires, such as *a* and *b*, can be lead off from A and B, one wire being connected to A, the other to B, and more lamps arranged between *a* and *b*; other smaller leads, *a b*, can be made to branch off from *a* and *b*, and so on.

Suppose, as a practical example, we wish to put up 30 incandescent lamps, each requiring an E.M.F. of 50 volts, and taking a current of 1·4 ampere. If we arrange the lamps

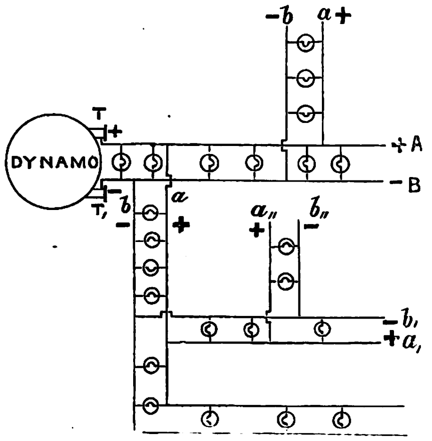

Fig. 18.

in single multiple arc, as Fig. 18, we shall require a machine giving an E.M.F. of 50 volts at the terminals when supplying a current of 42 amperes (1·4 × 30). If, however, as in Fig. 19, the lamps are arranged two in series, the dynamo must have an E.M.F. of 100 volts at the terminals while giving a current of 21 amperes (15 × 1·4).

We might again put the lamps three in series, in which case the dynamo would have to give an E.M.F. of 150 volts at the

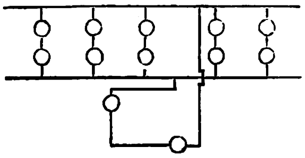

Fig. 19.

terminals when supplying a current of 14 amperes, but lamps are very seldom put more than two in series, and rarely that. We might, however, use lamps of higher resistance, *e.g.*, requiring an E.M.F. of 100 volts and a current of ·7 ampere.

When working incandescent lamps from a series dynamo it often happens that on turning on the switch and thus completing the external circuit the lamps do not light up, scarcely any current being generated by the dynamo. This phenome-

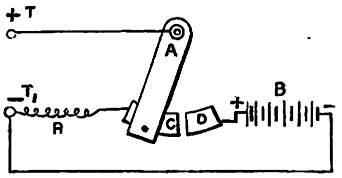

Fig. 20.

non arises from the fact that, as the resistance of incandescent lamps is about double cold what it is hot, the external resistance is above the critical resistance (as it is technically termed) for the speed at which the dynamo is being driven.

The critical resistance for a certain speed is the greatest resistance through which the machine when running at that speed will give any appreciable current; any very slight diminution in this resistance or increase in the speed will enormously increase the current.

In order, therefore, to produce sufficient current to light the lamps and thus lower their resistance, the dynamo must be momentarily circuited through a small resistance, or the speed must be increased for a short time, the best plan being the former, as it is not an easy matter to increase the speed with a well governed engine, and moreover the increase in speed will make the lamps burn beyond their proper candle-power.

When it is necessary to employ a series-dynamo for the purpose of charging secondary batteries the machine will have to be circuited through a resistance equivalent to the resistance of the batteries, as explained before, and then, when sufficient current is developed to allow the machine to get up a sufficiently high E.M.F. to overcome the opposing E.M.F. of the batteries, it should be switched on to them; this is best done by the employment of a two-way switch thus:—

T and T_1 being the terminals of the dynamo, R a convenient resistance, B the batteries. The arm of the switch A must be wide enough to touch the contact piece D before it breaks at C (Fig. 20).

LITERATURE.

Telegraphy. By W. H. Preece, F.R.S., and J. Sivewright, M.A. Third Edition. [Longmans, Green, and Co. 1884.]

When a book has reached a third edition it has proved its utility, for one can hardly imagine a book being bought merely for the sake of having it on one's shelves. The science of electricty is growing so rapidly that in a few years the young student will have to decide what branch he will study, for to study the whole will be the work of more than a lifetime, and as the science extends the arts based on the science will extend and diverge likewise. Indeed, the telegraphist cannot hope to be at the same time master of "electric light operations" and of "electro-chemical or electro-metallurgical operations." Each of these subjects, then, demands special manuals. The book before us deals with the principles and practice of telegraphy, restricting itself more directly to land telegraphy, the authors evidently and rightly thinking that submarine work deserves a special manual. Such a manual would be a useful adjunct to the one before us. The authors of this work have probably had far more experience, and are better able to judge what experience has found to be right than most people. Hence, with the exception of the use of the term "quantity" in the second paragraph—an exception we have taken before—we are not prepared to combat the views expressed. The principal additions to this edition will be found in the chapters on "The Telephone," "Fast Repeaters," and "Quadruplex Telegraphy," also a table on the "Imperial Standard Wire Gauge," at the end of the book. The chapter on "Commercial Telegraphy" is omitted, although at p. 281 the headline is still retained. The alterations up to p. 281 are not very important. The information given is just that required by every one commencing the study of telegraphy, and is absolutely essential if a real knowledge of the work is desired.

A Handbook of Electrical Testing. By H. R. Kempe. Third Edition. [E. and F. N. Spon. 1884.]

This is by far the best book on the subject of testing in English, or indeed in any other language. The work is almost perfect. Perhaps we might suggest the addition of descriptions of Saunders's key, and FitzGerald's method for measuring the internal resistance of batteries. Of the latter Mr. Sprague writes it "is by far the simplest." The information given is exceptionally clear and full, while too great praise cannot be given on account of the general arrangement, correct mathematics, and careful endeavour to always show the why and the wherefore of the operation, as well as its possible accuracy. It is needless to write further of this new edition, except that we may say the author has taken the opportunity to add several valuable tables and descriptions to those in the second edition, and to impress upon students the necessity of studying this work thoroughly, in order that they may not only carry out tests in a purely mechanical manner, making the connections as they have been told to make them or seen others make them, but that they may obtain a real intellectual insight into the operation.

ANSWERS TO CORRESPONDENTS.

J. CHAPMAN.—*If you refer to "The Electrician" of June 28th last, p. 150, you will find Dr. Gore's remarks upon aluminium. The information there given, and the references made, will no doubt be amply sufficient to indicate to you all that you require to know.*

LIGHTNING CONDUCTORS.

"The free and frequent use of the testing galvanometer is, indeed, the natural consummation of the beneficent work which was initiated by Franklin one hundred and thirty-five years ago." Such are the concluding words of the *Edinburgh Review* in its article on lightning conductors, to which we promised a short time ago to refer at greater length when an opportunity arose. And, indeed, although the writer has given us an interesting historical *resumé* of the subject, from the time of Hawksbee, Gray, and Franklin to the present day, and has gathered together a great deal of useful information from sources hitherto widely apart, we rise from the perusal of his article with our admiration of the electrical celebrities of the last century greatly enhanced, nothing material in the same direction having been discovered by their modern successors. A later study of the conditions necessary for protecting buildings from lightning by means of metallic conductors has perfected the system, at least theoretically, and the invention of apparatus for testing its efficiency has rendered the process simpler; but from the moment when Franklin, who had had his attention drawn to the identity of static and atmospheric electricity, observed that "electric discharge was attracted by points," and determined on "ascertaining whether lightning had not the same tendency," the whole range of subsequent inquiry was practically anticipated. To say this is no reflection on modern science, for the pointed lightning conductor attached to Franklin's house in 1752 fulfilled all the functions of a lightning conductor, nothing better being either practicable or necessary.

But between the discovery of a law with a useful application and its general adoption there is a wide gulf, and for reasons which reflect no discredit on anybody in particular the unquestionable utility of Franklin's device failed to meet with general acceptance until sixty or eighty years after his time. The suggestion was taken up both in England and in France, but apparently only by individual enthusiasts; whilst in America its more extended adoption led to some accidents which were natural under the circumstances, and which provoked equally the denunciations of pulpit and press. Small blame to either for this, seeing that even in England an engineer in the service of the British Government as recently as 1826 recommended the removal of lightning conductors from all public buildings as dangerous expedients; and later, in 1838, they were actually so removed from the arsenals and magazines in India by order of the Governor-General. The truth was, and it is the one truth which remains still to be enforced at this day, that unless the conductors were properly erected they were a source of positive danger. Several conditions were necessary for complete success, failure in respect to any one of which might result in disaster. The conditions were broadly understood, but they were not always complied with, nor was their relative importance at first fully appreciated. Accidents from lightning despite of conductors were not of unfrequent occurrence then, and they are not infrequent now; the difference is that after a long course of years we have acquired such confidence in the protector itself that nothing but imperfection in the method of applying it will account for its failure.

But the process by which this confidence is inspired was a long one; not only had unprotected buildings to be struck whilst protected ones escaped, but the cause of protected buildings not escaping had to be investigated and proved. A long series of observed facts had to be compared before sceptics were convinced. Some capital evidence on one or two highly important points was supplied by the navy. It was the practice on board ship to drag up a chain to the masthead, and let it hang several feet in the water. The captain who first ventured on this expedient must have been a bold man, with more faith in science than in the Providence which sailors are supposed exclusively to trust in. Whenever a ship so equipped was assailed by lightning she invariably escaped uninjured, but it generally happened that the chain was shivered to atoms. This was an expensive but instructive form of lightning conductor. Evidently a perfectly continuous conductor was needed, and this, coupled with the perfect outlet which the sea afforded, resulted in complete immunity from accidents of that kind. A perfect conductor from the highest point to a perfect conducting medium at its lowest were, then, the main conditions of efficiency. Applied to structures on land protection is as certainly and as easily obtainable. The great thing is to get these conditions enforced and maintained.

It is true there are some variations of method, and at least one that may be called rival and revolutionary. Professor Melsens' cage-like system for the protection of that precious architectural gem, the Hôtel de Ville, at Brussels, is one that errs, if it errs at all, on the right side, by connecting so many

Digitized by Google

points of the building with abundant outlets to earth—exceeding in these safeguards anything that has been thought or found to be necessary elsewhere. Again, there is some divergence of opinion as to the dimension of the wire; and some valuable reminders are given by the Edinburgh reviewer concerning the employment of galvanised iron, the coating of which, being thin and the better conductor, is apt to get fused, and in any case may mislead as to the conducting capacity of the wire in mass. But on the whole there is a general agreement among experts growing closer every day; and the heretical suggestion of Major Parnell to do away with tall rods, substituting for them earth-buried plates, with short earth points surrounding the building, may be dismissed as lacking any substantial evidence to support it.

Turning, however, to the reviewer's own observations where he leaves history for criticism we are not sure that we can always agree with him. He is, we think, unduly severe on the rules put forward by the Conference of the Meteorological Society in 1882. It is true that the rules added nothing to our previous knowledge, and might have added something if the committee had investigated instead of framing rules straight off. But for what they profess to be, however, the rules are of general utility, and not seriously open to misconstruction. There is no comparison between the resistance created by bad joints and that of lengthening the conductor. For lightning rods the differences in length are not great, and the variation of their resistance on this particular account is less appreciable than the reviewer seems to imagine. We cannot agree with him either in advising the utilisation of gas or water pipes for "earth" purposes; indeed, his paper is weak generally on the subject of earth, and in this recommendation is a dangerous adviser, as his own account of the fire at the Dolphin, Chichester, might have warned him. Some fuller statement of facts relating to the risks to buildings from lightning incurred, as he alleges, from the affixing of overhead wires, would have been very acceptable. But, as a whole, the current number of the *Edinburgh Review* will well repay a careful perusal by all who are interested in protecting life and property from the destructive effects of lightning.

CORRESPONDENCE.

CAPACITY OF A CONDENSER.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: [*See* p. 297.] So far as the possible objection to the method that the condenser may not become completely charged in the time allowed, that is removed by seeing in any experiment that the resistance external to the condenser is sufficiently small (when being charged) to allow of its becoming practically fully charged, barring the residual phenomenon of absorption or viscosity, in less than half the period of the fork. In Mr. Glazebrook's experiments the resistance external to the condenser was always under 1,000 ohms, which, with $\frac{1}{3}$ microfarad capacity, would make the time constant $\frac{1}{3000}$ second. This is about $\frac{1}{12}$ of the shortest semi-period (period $\frac{1}{128}$ second), so that there was ample margin throughout. But, other things being the same, the frequency could not be much raised without destroying the margin of safety.

The condenser being fully charged for, say, $\frac{1}{3}$ of the whole time, and the charge being always of the same kind, must cause viscosity to have some effect on the result, nearly the same at different speeds, presumably making the apparent capacity slightly lower than the true instantaneous capacity.—Yours, &c., OLIVER HEAVISIDE.

WHAT IS ELECTRICITY?

TO THE EDITOR OF THE ELECTRICIAN.

SIR: Mr. D. G. FitzGerald has often in your columns asserted, substantially, that electricity is a material substance. I have read so much of his vigorous writing that I am sure he feels he has good reasons for his assertions. Some years ago he began a series of articles in *The Electrician* on this subject, but did not finish it; it seemed to me that he got lost in mathematical puzzles. I cannot see how this problem can be solved by the twisting about of mathematical formulæ, or the enunciation of theories which lack experimental proof.

If Mr. FitzGerald will make it his convenience and pleasure to favour *The Electrician* and its readers with a series of articles on this subject, giving without reserve his ideas of the nature of electricity, arguing and explaining from a physical basis only, and citing experimental evidence in proof of the same, he will delight and instruct your readers, among whom is, yours, &c., SAMUEL PURNELL.

San Francisco, California, Aug., 1884.

SIEMENS' ELECTRO-DYNAMOMETER.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: In your publication of to-day, at page 318 a description is given of "the Siemens Electro-Dynamometer," in which, with the object of avoiding the variation due to loss of magnetism common to other galvanometers, a fixed coil of insulated wire is employed to actuate a suspended coil.

I shall be obliged by your pointing out that this principle of constructing standard galvanometers was patented by my brother, Mr. Edward Bright, and myself so long ago as 1852, as may be seen by reference to the specification and drawings of the patent No. 14,331 (Old Law).—Yours, &c.,

CHARLES T. BRIGHT.

31, Golden-square, London, Aug. 16, 1884.

THE RISE IN TEMPERATURE OF ELECTRIC LIGHT LEADS.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: In *The Electrician* for June 28th "Student" writes that he cannot understand the formula given at p. 213 in Munro and Jamieson's "Pocket Book of Electrical Rules and Tables," viz.:—

$$\tau^0 = \frac{4\rho}{Jh\,\pi^2} \cdot \frac{c^2}{d^3}.$$

Where τ^0 = the increase of temperature Centigrade of the wire aboveits surroundings.

ρ = the specific resistance, or the resistance of 1 cubic centimetre of the conductor, given as 1,700 *absolute* units of resistance for pure copper, or ·0000017 ohm at 10° C. or 50° F.

c = the current strength in *absolute* measure, *i.e.*, amperes $\times 10^{-1}$.

J = Joule's equivalent, or $4 \cdot 2 \times 10^7$ ergs, *i.e.*, the amount of energy equivalent to the raising of one gramme of water from 0° to 1° C., or one gramme-degree (*see* p. 16).

h = the heat emitted from the surface of the conductor per square centimetre per second by radiation and convection, given as 2×10^{-4} for bright copper.

$\pi^2 = 9 \cdot 8696$.

d = diameter of conductor in centimetres.

Using the above values for ρ, J, h, and π, he finds correctly that

$$\tau^0 = \frac{c^2}{d^3 \times 12 \cdot 192} \text{ in degrees centigrade;}$$

but here he stops, because he has failed to notice that, as ρ

Digitized by Google

was taken in absolute measure or C.-G.-S. units, so c must also be taken in absolute measure.

If ρ were in ohms, then c would be amperes.

An example or two will, however, make this clear to him. Suppose the case of a bright copper wire ·254 centimetre diameter (*i.e.*, $\frac{1}{10}$in., or very nearly No. 12 Board of Trade gauge), having a current of 10 amperes passing through it, by what temperature will the wire exceed that of the atmosphere which is at 10° C?

$$\text{Here } d = \cdot 254 \quad \therefore d^3 = \cdot 016387,$$

$$c = 10 \text{ amperes} = 10 \times 10^{-1} = 1 \text{ C.-G.-S. unit.}$$

$$\therefore \tau^0 = \frac{1^2}{\cdot 016387 \times 12\cdot 192} = 5^\circ \text{ C. or } 9^\circ \text{ F.}$$

If "Student" will look at the table given at p. 214, he will find 9° F. as the rise of temperature for this wire with a 10-ampere current flowing through it.

Again, taking the same wire, but passing a current of 20 amperes through it, we find

$$C = 20 \text{ amperes} = 20 \times 10^{-1} = 2 \text{ C.-G.-S. units;}$$

$$\therefore \tau^0 = \frac{2^2}{\cdot 016387 \times 12\cdot 192} = 20^\circ \text{ C., or } 36^\circ \text{ F.,}$$

which also corresponds with the figures in the table, page 214. The whole of the tables pp. 214 to 216 have been so calculated. Every factor in the formula is well known, except h, the heat emitted per square centimetre per second. We find Professor Forbes, who adopts this same formula in his well-known paper read before the Society of Telegraph Engineers last March (*see Journal* of the Society, No. 52, Vol. XIII., p. 238), uses for h, in the case of *polished* copper, the constant $1{\cdot}68 \times 10^{-4}$, or ·000168, and for *blackened* copper 3×10^{-4}, so that Sabine's value for *bright* copper, viz., 2×10^{-4}, is in tolerable agreement therewith. Perhaps Dr. Fleming, who answered "Student" in your issue for June 5th, may have by this time so extended his experiments as to be able to give us a more exact determination for h, or constructed a formula to agree with his experiments.

The value given by Professor Forbes in his paper already referred to for the specific resistance ρ is 0·000001642 ohm at 0°C., and the resistance for any temperature $t°$ above 0°C. of a cubic centimetre of pure copper is therefore

$$0{\cdot}000001642 \left(1 + \frac{\cdot 38t}{100}\right)$$

which gives the number we used, viz., ·0000017 ohm, or 1,700 C.-G.-S. units, at about 10°C. or 50°F.

You were rather severe, Mr. Editor, in your review* of the book upon the tables calculated from the formula referred to by "Student," but the fact of the matter is this, that Sabine's data was the only information we could find when compiling this part of the book, and we shall be glad to substitute anything better whenever it comes out. We have corrected all the mistakes brought to our notice for the second edition, and we hope you will keep your promise by again referring to the book, and, perhaps, kindly point out any errors or improvements not already noticed by other reviewers, as we wish to keep the book up with the times, and render it correct. We should have answered "Student" sooner, but we have been absent for some time.—Yours, &c.,

Aug. 20, 1884. MUNRO and JAMIESON.

* We have not yet reviewed the work. What we did was to notice it in order that readers should know of its existence, believing that such a work was wanted, and would be duly appreciated. We could not see the utility of certain tables, and said so, imagining that the useless ought to give place to the useful. Our intention was not to be, or appear, severe, merely to indicate the direction of our thoughts. The value and the failings of such a work can only be ascertained by the lapse of time and constant use, and we certainly intend referring to it again in due course. —ED. *E.*

ELECTRIC LIGHTING.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: I thank you for the insertion, in your last issue (this day's date), of the correspondence I sent you on the 13th inst. One or two errors, however, having crept into the letterpress, I beg to hand you herewith a corrected copy, and to request that you will be kind enough to make the necessary rectification in your next impression.—Yours, &c.

J. E. PICKERING, Secretary.

The National Company for the Distribution of Electricity by Secondary Generators, 18, Warwick-street, Regent-street, W., Aug. 16, 1884.

ERRATA.—Third paragraph from bottom of first column, page 321, for "118 wires (No. 21)," read "48 and No. 26." The equation at the bottom of this column should be

$$E_P = 100\frac{13{\cdot}000}{14{\cdot}500} = 89\%,$$

and not as given. In the third paragraph of second column, for "8 a.m." read "1 a.m." In the next paragraph, fifth line, for "cost of the plant" read "rest of the plant." In the concluding paragraph, ninth line, for "supply" read "employ."

[The copy, and not the printers, is to blame for the above mistakes.—ED. *E.*]

CITY AND GUILDS OF LONDON INSTITUTE EXAMINATION IN TELEGRAPHY.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: The results of the City and Guilds of London Institute examinations of last May have just been issued. Can any one explain to me the strangely erratic character of those in *telegraphy?* In this and in previous years I have found in this subject that it is utterly impossible to even approximately forecast the results from a knowledge of the aptitude of each student. Such a process I have always found possible in connection with Science and Art Department examinations. But in *telegraphy* everything is a surprise. The student who is poor both in theory and in practical work quite as frequently takes a good place as does he who has an aptitude for both; and, indeed, in my experience, it happens as often as not that the latter is ignominiously plucked, although there may be every reason to believe that he has worked a first rate paper. Can anyone offer a solution of these apparent inconsistencies?—Yours, &c.,

20th August, 1884. R.

SUPPLEMENT No. 5.—CORRECTION.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: The diameters of Nos. 32 and 33 are printed as ·108 and ·100 instead of ·0108 and ·0100 respectively.—Yours, &c.,

London, E.C., 18th August, 1884. A. DALGLEISH.

HEALTH EXHIBITION—VI.

Most visitors to the Exhibition cannot fail to be struck with the gorgeous lighting of the entrance hall. The grand electrolier of Verity's is as attractive now as it was at the Crystal Palace. Passing from the entrance into the South Gallery the style is completely altered—ornateness gives place to the utmost simplicity. From an æsthetic, and indeed from any point of view, the simplicity is too simple, and although one is struck with the long range of lamps—for rafter beyond rafter we have "those twinkling points of fire"—they certainly seem to require a little different arrangement. We have heard views expressed quite the opposite of these, maintaining that alteration would spoil the effect. At any rate, in this gallery there are about 1,100 Swan lamps exhibited by Messrs. Siemens Brothers and Co. Besides this part of the building, Messrs. Siemens light the Conservatory and the Prince of Wales's Pavilion. The lighting of the latter is almost perfect, and the visitor acknowledges the ingenuity displayed. Here, too, the

Digitized by Google

great value of the electric light is seen in the non-destruction of the delicately tinted ceiling and wall decoration. The lamps used in the Pavilion are Swan lamps, but some Siemens arc lamps will be found in the engine room and in the Conservatory.

The electric current for the lamps in the South Gallery is generated by Siemens's alternate current machine, using an exciter for the field-magnets. Two such machines of the type known as W_{11} are used, the exciter in each case being of the type known as D_7. The output of the W_{11} machine is about 30,000 volt-amperes, with 1,100 revolutions of the armature per minute, requiring a total of from 50 to 60 horse-power to drive the machines. The circuits of the two machines are independent, so that if anything goes wrong with one machine the lamps only on alternate ribs of the roof would be affected. The difference of potential between the mains is the same at the last lamp as the first, owing to the adjustment of resistances, so that all the lamps should be of the same brightness, that is providing the filaments are all homogeneous and similar. Fusible cut-outs are placed at all points where a branch wire is joined up to the main, so that should there be any accident and too great a current to the branch, the cut-out acts and saves the branch.

In the Conservatory there are four arc lamps, each of about 4,000 actual candle-power. The four lamps are arranged in parallel arc, and the current is generated by one SD_0 self-regulating machine.

The SD_2 machine is said to have an output of 3,600 volt-amperes, and to require some 7½ horse-power. All the machines will be found in the electric light engine room, and the necessary power is obtained from the main shafting, driven by the double cylinder engine of Messrs. Davey, Paxman, and Co. Besides these machines, there is another Siemens machine in the engine room, which has been christened by the men about the place as "Jumbo." This machine is used in the fountain illumination, and will be mentioned hereafter.

The HAMMOND ELECTRIC LIGHT AND POWER SUPPLY COMPANY exhibit excellent examples of their work and lighting system. The principal feature is a 43in. diameter helix Ferranti dynamo, in which are embodied many of their recent improvements. This is a beautiful machine, and as far as we know has done its work well. The frame is of the new service type, and of great strength as well as considerable elegance. The field is composed of two castings bolted together, each containing a crown of 24 electro-magnets, the poles of which are only 9-16ths of an inch apart, being coupled in two parallels within an exciting current of 33 amperes; the field is therefore very intense. The armature is built of $1{\cdot}5 \times 9{\cdot}5$ mm. bare copper strip, insulated only between the layers, and firmly based on a wide flanged phosphor bronze hub. The armature is in three parallels, giving an internal resistance of ·02 ohm, and at a speed of 590 revolutions per minute generates an electromotive force of 400 volts. The current, which is sufficient for some 1,500 lamps, is collected by centrifugal mercury collectors, consisting of copper discs, revolving on annular troughs of mercury. These are simply perfect in their action, and give no trouble whatever. The lubrication is effected throughout from one oil vessel, from which the lubricant is fed at pressure through a series of nickelled copper tubes, fitted with transparent dropping cups, regulated by separated taps. The supply of oil is thus capable of being regulated to any part at will. The machine, together with its exciter, is bolted on a massive bed-plate, the motion being communicated from the former to the exciter by one of the company's new flexible shaft couplings. This coupling is very neat and effective, and seems to deserve the good opinions it has obtained. As a whole this company's exhibit shows a very promising appreciation of the practical exigencies of electric lighting, and is carried out in a thoroughly substantial engineering manner.

The company is also exhibiting a 40-light Brush machine and lamps, the steadiness with which the latter burn proving that the old complaint of flickering can be perfectly cured. This company is also exhibiting their Swinburne incandescent lamp, having it is stated an efficiency of 60 watts per 20 candle-power.

INCANDESCENT LIGHTING.

BY T. H. SEYMOUR HAWKER.

(CONTINUED FROM PAGE 247.)

Having considered the rudimentary principles on which a circuit is planned, we can turn our attention for a time to the dynamos, lamps, and other apparatus which are employed. The actual theory of construction and description of mechanical details I will leave for the present, as there has been so much reference to these matters in the columns of *The Electrician* lately, and I may simply be reiterating or anticipating the writings of others.

In all cases of electro-magnetic induction an electromotive force, or difference of potential, is generated between two points (which in the dynamo are practically at the armature terminals) by the variation of the magnetic potential of the conductive part between them.

"Potential" is defined as the ability to perform work. Hence the unit magnetic potential is the energy necessary to bring a magnetic pole of unit strength from an infinite distance up to unit distance from a similar pole.

At unit distance from a pole of strength n the potential will therefore be $= n$, as that pole will be capable of performing n units of work in repelling a unit pole to an infinite distance. The potential will vary along the lines of force of the field maximum to zero.

Any conductor placed in a magnetic field will at each point of its length assume the potential of the field at that point which it occupies. Variation of position will vary the potential of the parts of the conductor, necessitating the transformation of a quantity of energy or performance of work equal to $V_1 - V$. If the circuit is open the equivalent will appear in the form of an E.M.F., which is probably merely a molecular tension, having difference of values at the two extremities of the conductor; and if closed as the product of the electric current which will be produced into the active E.M.F. driving it.

This is the general dynamic principle evolved in induction, and from this point of view we can describe a dynamo as a machine arranged so as to nearly continuously vary the potential of the parts of its inductor or armature, and give a high value of energy evolution in a given time; or $\frac{V_1 - V}{t}$.

Adding to the length of the conductor, which is varying its position in the field, will increase the E.M.F. produced by increasing the linear dimensions of the active portion, but the accompanying increase of resistance will diminish the current factor of the energy flow—C E.

Great lengths of armature conductor are therefore employed to produce high E.M.F.'s, and lesser lengths and wider sectional areas for large currents.

The E.M.F. produced is also inversely proportionate to the time t during which the energy $V_1 - V$ is evolved, and hence for large E.M.F.'s high speeds are necessary, while lower speeds will do for lower E.M.F.'s, even if by reason of the lowness of internal resistance the current produced be large.

For incandescent lighting low tension machines giving large current are now universally employed, except where the exigencies of circumstances are more regarded than a consideration of the relative merits of the series and parallel circuit system. When, however, single high resistance lamps of, say, 200 volts can be obtained of good quality, there will be doubtless a general adoption of this E.M.F. as the maximum allowable by the Board of Trade, in order to obtain the advantages of smaller cables and reduced heat waste attending the corresponding reduction of current.

By increase of speed, machines even of very low resistance, *i.e.*, short length of armature conductor, may be caused to give high E.M.F., and the energy output of dynamos of this type is very great as compared with their mass of inducing metal or weight of copper in armature.

They have, however, the disadvantage of great wear and tear to plant, unless carefully driven, and are often objected to on this account.

Digitized by Google

The practical difficulties attending the multiplication of speed by machine banding also militate against the success of the high speed dynamo, but the attention at present being paid to the development of high speed engines promises soon to reduce this objection, by substituting direct coupling to engines.

It is necessary that the speed of a dynamo should be a determinate function of the current flowing in the external circuit, or the E.M.F. at its terminals.

With a constant rate of energy supply a steady unvarying speed should be maintained, which should be automatically reduced or accelerated as the work diminishes or increases.

This is the function of an electrical governor, and has for its principal reason that the E.M.F. is varied by the speed, and it is required to keep the E.M.F., which varies with the resistance of the external circuit, constant throughout any possible variations of current by alteration of the number of lamps lighted.

In commutator or continuous current machines, however, another reason prevails. The brushes or collectors are adjusted to a diameter of the commutator relative to the field poles known as the diameter of commutation. This most advantageous angle for the contact of the brushes is the angle whose tangent is the ratio of the strength of the field polarity to that of the polarity induced by the passage of the current. When, therefore, the masses of iron of the field and armature cores are of unequal saturation, any cause tending to alter the current will also vary the angular lead and throw the brushes relatively out of position, causing sparkling and loss of efficiency.

In self-exciting machines this is still more marked. Constant, or rather regularly varying speed is a necessity, therefore, for both reasons, though the variation of lead can be much reduced by separate excitation, and is entirely absent with alternating current machines, owing to the nature of their collectors.

The effect of the enormous change of lamp resistance with different temperatures of the filament of course tends to increase and exaggerate any variation of lead when possible.

The question of the relative merits of continuous and alternating currents for electric lighting has been largely discussed of late years, but as each system has its special advantages and disadvantages, circumstances can alone decide which is most generally preferable. As a general rule alternating currents are more easily handled than continuous, being less liable to strike destructive arcs at switches, &c., and the use of block or mercury collectors making contact with revolving continuous bosses much simplifies the generator while necessitating less attention when running. Notwithstanding the extra cost of separate exciter which is necessary with the majority of alternating machines, the simplified construction enables them to be made much cheaper than commutator machines. Again, instead of the very cumbersome and wasteful resistances which are necessary with continuous currents, when it is required to turn down or graduate the lights, advantage can be taken of the opposing E.M.F. which is induced when a continually varying current is brought closely parallel to another portion of itself. This device is so effectual that, by the aid of a small apparatus and switch combined, in use by the Hammond Electric Light and Power Company, consisting of a volute of copper tape, greater or less lengths of which can be thrown into circuit, several hundred lamps can be regulated to any brilliancy from full power to dead out, and this by simple counter E.M.F.—without waste.

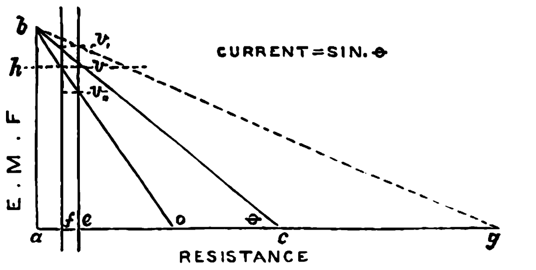
On the other hand, the rapid variations of the alternating current, although so useful in some cases, almost entirely unfit it for electro-magnetic or electrolytic work. The self-induction of the alternating current is often so great that a coil of a few ohms resistance can induce a reversed E.M.F. of such magnitude as to so nearly neutralise the direct E.M.F. that, with 100 volts at the terminals, only a fraction of an ampere will pass. Moreover, the alternating current is very active in inducing Foucault or "eddy" currents in neighbouring conductors, and thus wasting energy. The choice of a machine to suit the conditions prevailing at any special installation depends a great deal on the method of excitation.

With a separate exciter is is only necessary to choose a resistance of armature equal to or not exceeding that value which will give the previously determined circuit efficiency by its ratio to the aggregate resistance of the hot lamps. Separate excitation, by avoiding the reactive effects of derived exciting currents, imparts considerable steadiness to a plant, making the light less sensitive to variation of driving speed and external resistance.

The exciter should be chosen to drive the maximum safe current through the field coils, and this should give as nearly as possible saturation of the iron on the field magnets. When the exciting current is derived from the generator itself very opposite attributes prevail, according as the field is connected in series with or as a shunt to the external circuit. With the series machine the field is fed with the entire current generated, and anything which affects this current, such as variations of E.M.F., or external resistance, must also react on the E.M.F.-generating-power of the machine. Thus an increase of resistance decreases the current, and unless the iron be supersaturated reduces the intensity of the field, which again reduces the E.M.F., and so on, until equilibrium is established.

With incandescent lighting on the parallel system of connection, on decreasing the number of lamps the resistance is increased, and the E.M.F. at the lamp terminals increased, and *vice versâ*. Therefore, within certain limits the attributes of the series dynamo in decreasing its E.M.F. with increased external resistance are advantageous, as the tendency is to keep the E.M.F. at the lamps constant irrespective of number.

The usual characteristic diagram of a circuit will illustrate this. Let $a\,b$ represent to any scale the E.M.F. of a generator at a certain speed, and let $a\,f$, $f\,e$, and $e\,c$ similarly represent the resistances of dynamo, leads, and lamps respectively. Then the line $b\,c$ will represent the fall of E.M.F. along the resistances.



Circuit Characteristic Diagram.

If the number of lamps be halved, the resistance of the latter portion will be doubled, and the fall of potentials represented by the line $b\,g$. This cuts the ordinate at the lamp terminals at a point, v, much higher than previously, as the same E.M.F. is running down through a higher resistance. The E.M.F. at the lamps will thus be excessive, as the normal circuit will necessarily have been arranged so that with a total E.M.F. of machine $= a\,b$, the E.M.F. $f\,v$ at the lamps will be just sufficient, the surplus E.M.F. $b\,h$ being allowed in order to drive the current through the leads and machine.

Similarly, on doubling the number of lamps the resistance through which the E.M.F. runs down is less, and the internal and fixed resistances absorb a greater proportion of it, leaving a less and insufficient E.M.F. at lamps. It must be evident that the ratio in which the lamp E.M.F. will be effected depends greatly on the nature of the circuit—particularly the ratio of fixed to lamp resistances—and therefore in order that the fault may be corrected by the use of a series generator we must be able to control definitely the individuality of the machine.

Now, in the first case, it is required, by using a sufficient length of conductor wrapped round the field-magnets carrying the total current, to excite these magnets to, or nearly to, saturation. The E.M.F. at the lamps varies with the ratio of the fixed and lamp resistances, and in order to correct this the current must vary similarly. In the series machine, however, the variation is in a much greater ratio, and requires to be modified by "compounding" with an additional shunt-

Digitized by Google

wound coil in order to attain perfect self-regulation. I hope in a future article to consider fully the proportioning of the compound and other machines.

In using a plain shunt machine the tendency is to exaggerate the effect produced by varying the number of lamps running. Reducing the number, for instance, increases the external resistance, and by driving more current through the field coils increases the magnetisation, unless saturation is already attained, and thereby enables a *higher* E.M.F. to be generated when a reduced is alone wanted. Many so called "automatic" devices have been proposed and tried for the purpose of compensating for these defects, by the insertion of resistances or shunting of the field, but all I have met with have been unsatisfactory and clumsy, and as even the best self-compensating or compound wound machines have a considerable range of defect I advocate in all cases a regulation by *speed of driving* depending on a good electrical governor for acceleration when E.M.F. is too low at the lamps, and retardation when too high. The strength of an electro-magnet depends directly on the length of conductor in its coil and the strength of current carried thereby. The effect in producing a magnetic pole is varied also by a constant depending on the nature and mass of the iron constituting the core, and is inversely as the square of the mean radius of the convolutions of the conductor from the axial centre of mass of the core.

Or $M = \frac{a\,C\,L}{r^2} \ldots$ and $\therefore L = \frac{M\,r^2}{a\,C}$,—which gives the length of a conductor carrying a current, C, necessary to magnetise a bar of magnetic constant a and radius r to a polar strength M.

The constant a is determinable experimentally, and is for a cylindrical core of the form $a = k . \frac{2\,C\,r}{Z\,r^2}$, Z being length of core, r radius, and k coefficient of magnetic induction.

A knowledge of the minimum size of wire which can safely carry a normal current C will give a clue to the resistance per length L of the winding of a field-magnet. The aggregate resistance of shunt dynamo for a circuit efficiency ratio of n % must with a lead resistance i and hot lamp resistance λ be equal to

$$\frac{\lambda}{100-n} - l = \frac{F\,A}{F+A},$$

or the multiple arc resistance of field and armature. As F, the field resistance, can be calculated as above, and λ is known, the necessary armature resistance A can be obtained. The construction of machines does not come within the scope of the present article, or we might trace this further.

(TO BE CONTINUED.)

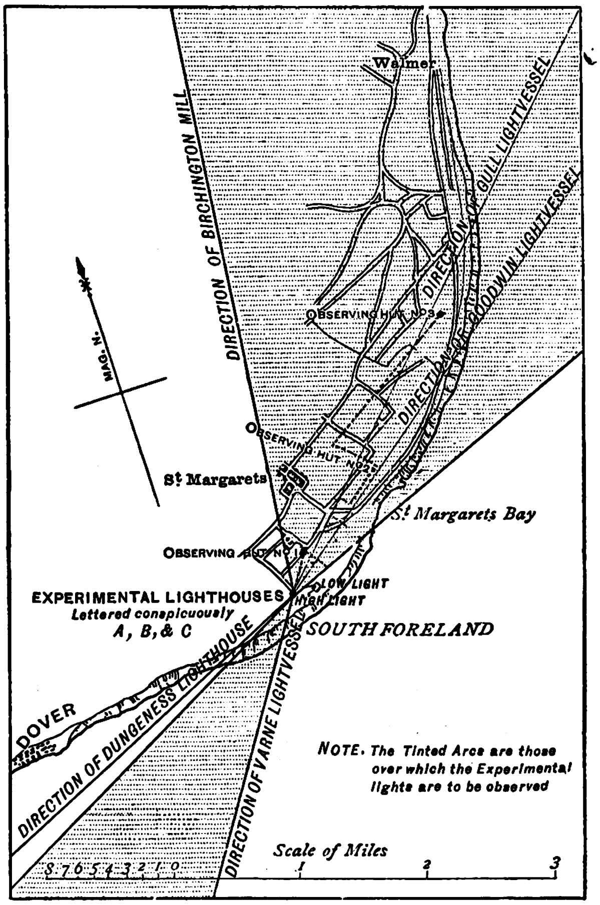
THE TRINITY HOUSE EXPERIMENTS ON LIGHTHOUSE ILLUMINANTS.*

The great advances made during the past few years in the science of illumination have rendered it desirable, or rather absolutely necessary, that experiments should be undertaken with a view to the determination of the advantages and disadvantages attending the use of different illuminants in lighthouses. With this view the Corporation of Trinity House have commenced a series of experiments at the South Foreland.

There are at present on the South Foreland two lighthouses, known as the high light and low light, and both of these are illuminated by electricity. Near these, three experimental lighthouses have been erected for use with the electric light, with gas, and with oil respectively. The electric apparatus consists of three arc lamps and three magneto-electric machines made by Baron de Meritens. The lamps are placed one above the other in the tower. The carbons being used are "compound carbons," made up of many small rods of carbon of square section, coated with copper, and Siemens's "core-carbons," made of gas carbon, with a central rod of graphite. When worked up to their full power, each lamp is estimated to be capable of giving a light equal to 30,000 candles.

The second tower is fitted up with Mr. Wigham's gas burners. To supply the burners a small gasworks, fitted with retorts, purifiers, and a gasholder capable of holding about 5,000 cubic feet, have been erected near by. The tower contains four burners, one above the other, each burner consisting of concentric rings of jets. The total number of jets on each burner is 108, making a total on the four burners of 432 jets; but the outer rings may be removed when less light is required, so that each burner may be used with 28, 48, 68, 88, or 108 jets. A talc chimney above the flame produces the necessary draught; no glass or talc is placed over the most luminous portion of the flame.

The intensity of the light when all the jets on all four burners are used is stated by the inventor to be equal to 12,000 candles. The third tower is for the present devoted to the oil and gas burners invented by Sir James Douglass. The oil is supplied from a tank to the burners under a slight pressure. One oil burner has six concentric wicks, and has a power of 720 candles; a second has seven wicks and a power of 1,000 candles. There are three burners in the tower, placed one above the other. Each tower is provided with lenses both for revolving and for fixed lights. The highest power of the gas tower is a quadriform light, of the other towers a triform light. Besides the illuminants already mentioned, there are gas burners from the Sugg and from the Siemens Companies, which will be tested in the lighthouse towers.



Plan showing points of observation for testing the power of the various lights being tried at the South Foreland.

For observing the lights and testing them, a line of observation has been measured out in the direction of Deal, and three huts have been erected at a distance of half a mile, a mile and a quarter, and two miles and a half respectively from the towers. These huts are fitted up as photometric observatories. The lights are focussed on one of the huts, and they are then measured in all conditions of weather by means of the pentane unit of light devised by Mr. Vernon Harcourt.

* Reprinted from *Nature*, for Aug. 14.

Digitized by Google

When the weather is too thick to allow of direct comparison with the unit, the lights are compared one with another by means of a polariscope-photometer, in which the ordinary image of one light is brought to equality by means of a Nicol prism with the extraordinary image of another light. In ordinary weather a ray from the lighthouse tower enters a hole in a shutter and falls on a portion of a paper disc. A contiguous portion of the disc is illuminated by the pentane candle fixed on one side of the opening in the shutter. The disc can be moved on a trolley to and fro until equality of illumination is reached, when its distance from the candle is measured. This measure and the known distance of the observatory from the lighthouse give the necessary data for determining the illuminating power of the light. By these measurements, taken at different distances in various states of the atmosphere, the penetrative power of the several illuminants will be determined. For instance, in very clear weather the electric light may give twenty times the light of the oil light; a slight haze comes on and the electric light is found to be only ten times as bright. It has suffered in a greater ratio than the other. A mist blows by the towers, and the superiority of the electric light becomes less and less marked; before the lights are finally obscured the superiority has vanished. It need hardly be stated that this question of penetration is the most important point the Trinity House are called on to settle.

The principle of superposition of lights also raises an interesting point. When two lights are placed close together they can be seen at a greater distance than one light. Up to what point will this increase of range continue on multiplying the lights without altering the intrinsic brightness of each? It may be that in thick weather the eye can detect a large area of low illumination better than a smaller area of higher illumination; and it may be that the electric light with its smaller lenses suffers from this reason in comparison with the oil and gas lights with their larger lenses.

We hope that the experiments will not be discontinued before these points have been thoroughly sifted, as they only can be satisfactorily, on the actual working scale.

We may add that the electric machines and cables are being tested by Professor Grylls Adams, and the photometric observations taken by Mr. Harold Dixon. Mr. Vernon Harcourt is appointed to watch the experiments generally and report to the Board of Trade.

We give a plan of the district showing the point of observation, which includes the Coast Guard stations and light-ships in the vicinity.

LIGHTNING FLASHES.

We think the following letter and illustrations, taken from last week's *Colliery Guardian*, may be interesting to our readers. The writer is Mr. Ralph Loudon, of Framwellgate Colliery, Durham:—

"With your permission I should like to call the attention of the readers of your journal to, not a curious form of lightning, but a form seldom witnessed by persons in our latitudes.

"The accompanying diagrams, Nos. 1, 2, 3, represent fairly the appearance of three discharges of electricity which occurred on Sunday, the 13th ult. Fig. 1 appeared of a brilliant yellow colour, and hung for from three to five seconds like a ribbon dangling in the heavens. The discharge was direct, from cloud to earth, as may be seen from the appearance of the lightning presented.

"After an elapse of about a quarter of an hour a second discharge took place, and had the appearance as given in Fig. 2. The colour in this case was of a bluish yellow, and remained visible for about two seconds. The atmospheric resistance was probably stronger in the latter than that of the former; hence the path taken up by the lightning.

"Still later on in the evening another phenomenon was presented to vision. Fig. 3 is as near the leading features of the discharge as I remember. It was momentary flashes of pale lightnings, and seemed to emanate from a nucleus, but to give anything like an accurate outline of this discharge is quite beyond my power.

"Suffice it to say, the representation given shows how strangely Fig. 3 contrasts with Fig. 1. Rain was falling heavily during this thunderstorm. Similar appearances of lightning followed, but the clouds had drifted too far from my

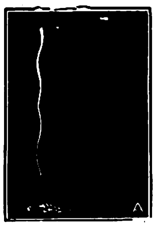


Fig. 1.

Fig. 2.

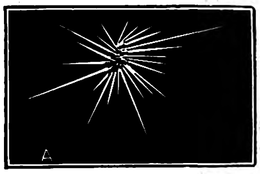

Fig. 3.

locality for me to map anything like good pictures. The reason I have troubled you thus is because these are the first phenomena of the kind I have seen, although some hundreds of times I have seen similar discharges from electrical machines. Books on electricity speak of discharges of electricity from the clouds like those given you as a common occurrence, but I wonder how many of your readers can compare these book illustrations to the discharges in nature. Hoping these illustrations may prove of service to many thoughtful minds, more especially those who take a lively interest in electrical matters, yours, &c."

EXPERIMENTS ON THE EFFICIENCY OF INCANDESCENT ELECTRIC LAMPS.*

BY HORACE B. GALE.

(CONCLUDED FROM PAGE 307.)

We have then to express the relations of three pairs of quantities. This might be done by three separate diagrams, but as the current is always equal to the electro motive force divided by the resistance, it may be represented, for any point on the curve, by the tangent of the angle included between the vertical axis of co-ordinates, and a line from the origin to the given point. Therefore, by drawing radial lines through the origin (which is in this case outside the limits of the diagram), we are enabled to lay off amperes of current on a scale of equal parts at the bottom, thus making the same curve express the relation between three variables.

To find the current for any point on either of the curves, it is necessary only to follow a radial line from the given point down to the scale at the base of the diagram; or, starting with a certain current, follow the radial lines up to the corresponding point on the proper curve; then to find the resistance of the lamp with the given current, follow a horizontal line from that point to the scale at the right; or to find the electromotive force follow a vertical line through the same point to the scale at the top. In short, given any one of the three quantities—electromotive force, current, or resistance—the other two may be found at once from a single curve. This device for expressing graphically the triple relation between the principal electrical quantities the writer believes to be new, and it is presented as one that will be frequently found convenient.

In other diagrams electromotive force is again represented on the horizontal scales at the top and bottom, and the height of any point on either curve shows on the vertical scales at

* Reprinted from *Van Nostrand's Engineering Magazine.*

Digitized by Google

each side the number of candle-powers of light which the lamp will give with the indicated electromotive force. The resistance of a lamp is found to fall quite rapidly as the electromotive force is increased, until the carbon becomes incandescent, when the change goes on more slowly, the resistance of a lamp when giving its light being rather more than half its resistance when cold. The candle-power increases slowly at first, but afterwards with increasing rapidity, until, if the electromotive force is carried above a certain point, the carbon filament is broken. Other curves show clearly what has before been stated, *i.e.*, that a certain amount of power must be expended in a lamp before we begin to get any light; and that the brilliancy of the light expressed in candle-powers then rises more and more rapidly as the energy expended is increased; also how rapidly the efficiency of the lamps increases as the candle-power is raised.

It is noticeable that all the curves have the same characteristics, viz., that the efficiency at first rises very rapidly with increase of candle-power, and that afterwards, while the change goes on more and more slowly, the rate of increase in efficiency becomes at the same time more nearly uniform, or in other words, the curve approaches to a straight line. This would indicate that, however high the temperature of a carbon filament may be raised, raising it higher will still increase its efficiency as a light giver.

It must not be inferred, because the curve of any lamp is above the rest, that this lamp is absolutely more efficient than the others; for, as already pointed out, when a lamp designed to give 10 candle-power is run at, for example, 16 candle-power, its efficiency becomes higher than its normal value; whereas, if a 24-candle lamp is run at 16 candle-power, its efficiency falls below its normal value. Consequently, when lamps rated at different candle-powers are compared at the same candle-power, the lamp with the lower rating has an advantage. The only way to arrive at a fair comparison is to take the efficiency of each lamp at a point on its curve which corresponds to the rated candle-power. Comparing the lamps in this way, we find that the Maxim 16-candle lamp stands highest, and the Edison 10-candle lamp next.

It should be noticed that the Edison 16-candle lamps furnished for this test were not of the same grade as those in general use for isolated lighting. The latter may be run in parallel circuit with the 10-candle lamps, each giving its own proper candle-power; whereas the Edison 16-candle lamps on which these tests were made would give only about six candle-power on the same circuit with the 10-candle lamps, when the latter were at their normal brightness. The diagram shows that at the same electromotive force the 16-candle lamps gave only about two thirds as much light as the 10-candle lamps. This peculiarity was due to the high resistance of the 16 candle lamps, which, as will be seen from the table of resistances previously given, averaged about 291 ohms when cold. Measurements afterwards made by the writer upon ten 16-candle lamps, collected from various plants of the Edison Company throughout New England, showed the following results:—

RESISTANCE COLD.

Lamp No. 1	162	Ohms.
" " 2	176	"
" " 3	163	"
" " 4	186	"
" " 5	177	"
" " 6	175	"
" " 7	189	"
" " 8	186	"
" " 9	212	"
" " 10	197	"
Average resistance	182·3	ohms.

These lamps averaged 16 candle-power at 95 volts, the same electromotive force required to bring the 10-candle lamps to their normal brightness, and were therefore evidently the grade of lamps intended to run on the same circuit with the latter. They were not obtained in time to make a complete test at all candle-powers, but measurements were made at the rated candle-power, which gave the following average results.

EDISON LAMPS AT 16 CANDLE-POWER.

Electromotive force	95·	volts.
Current strength	0·92	ampere.
Resistance	103·3	ohms.
Volt-amperes	87·4	
Candle lights per horse-power	136·6	
Lamps per horse-power	8·54	

The following are the figures for the Maxim 16-candle lamps:—

MAXIM LAMPS AT 16 CANDLE-POWER.

Electromotive force	68·9	volts.
Current strength	0·9	ampere.
Resistance	76·5	ohms.
Volt-amperes	62·2	
Candle lights per horse-power	192·	
Lamps per horse-power	12·	

The results of these experiments indicate that the essential factor in the efficiency of an incandescent lamp is not high resistance, but high incandescence. The Maxim lamps, which displayed the highest efficiency, gave a slightly whiter light than the others, showing that the carbons were heated to a higher temperature, though their resistance was lower than that of the Edison lamps. The fact that a low resistance filament is usually coarser than one of high resistance would tend to make it endure equally well at a higher temperature.

DYNAMO-ELECTRIC GENERATORS.

(CONTINUED FROM PAGE 324.)

Arago Disc.

We now come to a machine of more recent invention than the others or most of them, and one which presents some novel and interesting features. Instead of using two field poles, widely removed, and with a mass of iron between them to concentrate the field, there is a large number of magnets of much smaller size, they are brought very nearly together, and no iron whatever is used in the armature. To accomplish this the field-magnets are arranged in two sets, with their axes parallel to the spindle of the armature, and distributed in a circle at equal distances apart. These two sets, say with ten magnets in each, are placed opposite each other, the inner ends with expanded pole-pieces being free, and the outer ends bolted to, and held in position by, two upright ring-standards. The coils are connected so as to form alternate poles in each set, unlike poles in each set facing each other. On passage of a current there are formed twenty alternating electro-magnets, with strong fields between opposite poles, and, because of the proximity of these poles, the concentration is effected without introducing any iron mass between. If any radial wire be rotated between these poles, it will, in one revolution, pass through ten strong fields, cutting the lines of force at right angles, and having induced currents generated which will change direction ten times. To obtain this radial direction of the moving wire, the coils are wound on a block in a triangular fashion, small curved blocks of insulating material being introduced for clamping screws. The centre block is then removed, leaving a firm, hollow, triangular coil, the making of which, being on a form and in a lathe, has occupied little time and labour. A number of these coils are now built up into a disc armature, and are held in position by a hub plate and a ring of composition, and screws passing through the insulating blocks. If to be an alternating machine separately excited, then there are as many coils as there are pairs of field-magnets; but if for continuous currents two more are used, that is twelve when there are ten pairs of field-magnets. In the alternating machine the coils are connected, so that whatever the current it has the same circuit direction for all coils, and the two free ends of the range of coils are taken to two rings, from which the current is taken by brushes or springs. With ten coils there are ten reversals of the current in a revolution. When, however, the current is to be continuous the connections to the commutator are much more complicated than is ordinarily the case.

The coils are connected in reverse order in a continuous circuit, and the bights of the connections connected to the

Digitized by Google

rings by wires, &c. Considering a single coil, in one-half a revolution it must have the current reversed in it five times, because it passes through five alternating fields. Since there is not the same number of armature coils as there are poles, the reversal of current in the different poles will not be simultaneous, but will occur in two coils, and opposite ones only at the same time; but the total number of reversals in a half revolution must be thirty—that is, the number of pairs of coils in the armature multiplied by the number of pairs of field-magnets passed in that half revolution. In other words, the successive reversals follow each other six times as fast as the reversal in a single pair, the armature advancing one-sixtieth part of a full revolution between two successive reversals. But the commutator advances no faster than the armature, and if there were only twelve blocks, the potential of a single block would change five times while in contact with one brush. Hence, it becomes necessary to multiply the number of commutator strips, so that strips of like potential may be continually presented to the proper brushes.

A little consideration will show that if the number of armature coils is m and the number of pairs of field coils is l, the number of sections in the commutator must be $\frac{ml}{2}$ in the case taken, 60—and that each bight or ring must be connected with $\frac{l}{2}$ section of the commutator, at regular intervals, and in sequence. In the machine exhibited at the Crystal Palace flat contacts were used, causing a great deal of sparking, but the machine is a new one, and some practice is necessary in developing its unquestionably valuable principles. If, as is probable, the sparking of the machine can be stopped, it will prove a highly effective dynamo, because there is no waste of energy in heating iron, and the machine can be cheaply made. The brushes are mounted on a swinging frame. Several forms are made; among others being one with a double armature and commutator, the one supplying the field with a continuous current, and the other the external circuits with an alternating current. Another form has only two pairs of field-magnets, and with radially wound armature coil.

Siemens Alternating.

This machine, like the one just described, has a large number of field-magnets. From a base-plate two circular frames rise, which are steadied by tie-bars extending from one side to the other. On the inner faces project a range of circular magnets with extended pole-pieces, the cores being turned down at the outer end so as to fit into holes in the circular frames, where they are firmly held by nuts. They are so wound that each magnet has opposite to, and on each side of it, poles of the opposite character. The armature coils are arranged in disc form, and there are as many as there are field-magnets. The coils are wound on an oval or elliptical piece of wood, the longest diameter being radial. They are mounted in a German silver frame, which is thickly pierced with holes to cut off the induced currents which would be formed. The coils are connected in any desired arrangement of series or multiple circuit, or in independent circuits, the ends being taken to rings on the spindle of the armature, whence the currents are taken off by contact springs. The field is excited by a separate circuit from another machine. A common arrangement is to have a high speed engine, a continuous current dynamo, and an alternating current machine mounted on one common bed-plate.

Lontin.

I will briefly describe two forms only, both of which depend for the production of currents upon the magnetisation and demagnetisation of circular or conical cores which are surrounded by wire. In one of these the field-magnets are short and vertical. On a central boss are arranged forty soft iron spokes, in four circles, each set being one-fortieth of a revolution in advance of the next on one side, thus constituting a helical construction. The object of this is to equalise the effort on the armature, and produce a more equable current. Since a magnet coil has the same current induced in it when leaving a pole of given character as when approaching the opposite pole, it follows that all the wire above the horizontal line joining the poles of the field-magnet has a current induced in one direction, and the wire below it a current in the opposite direction. By connecting all the coils in a series, and bringing the several bights to a range of commutator strips, a continuous current is obtained.

This current is generally used to excite another machine, one used for distributing currents over several circuits. In this the inducing or field-magnets are ranged around the periphery of a drum, which is rotated, the current being supplied through contact springs to maintain the spokes at a constant alternate magnetic state. Around this ring, enclosing the periphery, is a fixed iron shell, from the inner surface of which radiate a large number of short soft iron cores, wound with wire. These are coupled in independent sets, and the ends are taken to a switchboard. When the drum rotates the shell poles are alternately magnetised and demagnetised very rapidly, and alternate currents are formed which are distributed over the different circuits. This total reversal of the polarity of the cores is an objection of considerable weight, and is one reason why these machines are not as efficient as those of the Gramme and Siemens type.

Gramme Auto-Exciting.

This is a small machine designed to furnish an alternating current, and, at the same time, to be self-exciting. On a cast-iron bed-plate are bolted two upright and nearly circular standards, connected together by six tie-rods. One of these has a circular rib or lip, on the inside of which are fastened four magnets, joined two by two, so as to form two poles only. On this end of the shaft is carried a small Gramme ring and commutator, and the current formed supplies both fields. On the other end of the spindle are carried the inducing magnets, a range of six, radially mounted, and with extended pole-faces. These faces are curved, so as to present an equal magnetic action for some distance. The coils in which the currents are induced are arranged in the form of a cylinder, and enclose the inducing magnets, the inner turns being in close proximity to the polar extensions. The ends are taken to a switchboard, where they may be coupled for tension or quantity. The machine is compact, but, save the fact that it is much used with the Jablochkoff lights, I know nothing of its efficiency.

SHIPS' LIGHTS.

We give below the latest regulations regarding ships' lights which have been drawn up by the Board of Trade and the Admiralty jointly, and have received royal sanction. We think they will prove interesting to those of our readers engaged in cable-laying operations, and although they refer in part only to a cable ship, still those on board the latter should be acquainted with the whole of them. The preface to the regulations tells us that on and after September 1st, 1884, the new regulations shall, so far as regards British ships and boats, be substituted for the regulations dated the 14th August, 1879.

Regulations for Preventing Collisions at Sea.

Art. 1. In the following rules every steam ship which is under sail and not under steam is to be considered a sailing ship; and every steam ship which is under steam, whether under sail or not, is to be considered a ship under steam.

Rules concerning Lights.

Art. 2. The lights mentioned in the following articles, numbered 3, 4, 5, 6, 7, 8, 9, 10, and 11, and no others, shall be carried in all weathers, from sunset to sunrise.

Art. 3. A seagoing steamship when under way shall carry—

(*a*) On or in front of the foremast, at a height above the hull of not less than 20ft., and if the breadth of the ship exceeds 20ft., then at a height above the hull not less than such breadth, a bright white light, so constructed as to show an uniform and unbroken light over an arc of the horizon of 20 points of the compass, so fixed as to throw the light 10 points on each side of the ship, viz., from right ahead to two points abaft the beam on either side, and of such a character as to be

Digitized by Google

visible on a dark night, with a clear atmosphere, at a distance of at least five miles.

(b) On the starboard side a green light, so constructed as to show an uniform and unbroken light over an arc of the horizon of 10 points of the compass, so fixed as to throw the light from right ahead to two points abaft the beam on the starboard side, and of such a character as to be visible on a dark night, with a clear atmosphere, at a distance of at least two miles.

(c) On the port side a red light, so constructed as to show an uniform and unbroken light over an arc of the horizon of 10 points of the compass, so fixed as to throw the light from right ahead to two points abaft the beam on the port side, and of such a character as to be visible on a dark night, with a clear atmosphere, at a distance of at least two miles.

(d) The said green and red side lights shall be fitted with inboard screens projecting at least 3ft. forward from the light, so as to prevent these lights from being seen across the bow.

Art. 4. A steam ship, when towing another ship, shall, in addition to her side lights, carry two bright white lights in a vertical line one over the other, not less than 3ft. apart, so as to distinguish her from other steam ships. Each of these lights shall be of the same construction and character, and shall be carried in the same position as the white light which other steam ships are required to carry.

Art. 5 (a) A ship, whether a steam ship or a sailing ship, which from any accident is not under command, shall at night carry, in the same position as the white light which steam ships are required to carry, and, if a steam ship, in place of that light, three red lights in globular lanterns, each not less than 10in. in diameter, in a vertical line one over the other, not less than 3ft. apart, and of such a character as to be visible on a dark night with a clear atmosphere at a distance of at least two miles; and shall by day carry in a vertical line one over the other, not less than 3ft. apart, in front of, but not lower than her foremast head, three black balls or shapes, each 2ft. in diameter.

(b) A ship, whether a steam ship or a sailing ship employed in laying or in picking up a telegraph cable, shall at night carry in the same position as the white light which steam ships are required to carry, and, if a steam ship, in place of that light, three lights in globular lanterns each not less than 10in. in diameter, in a vertical line over one another, not less than 6ft. apart; the highest and lowest of these lights shall be red, and the middle light shall be white, and they shall be of such a character that the red lights shall be visible at the same distance as the white light. By day she shall carry in a vertical line one over the other not less than 6ft. apart, in front of but not lower than her foremast head, three shapes not less than 2ft. in diameter, of which the top and bottom shall be globular in shape and red in colour, and the middle one diamond in shape and white.

(c) The ships referred to in this Article, when not making any way through the water, shall not carry the side lights, but when making way shall carry them.

(d) The lights and shapes required to be shown by this Article are to be taken by other ships as signals that the ship showing them is not under command, and cannot therefore get out of the way. The signals to be made by ships in distress and requiring assistance are contained in Article 27.

Art. 6. A sailing ship under way, or being towed, shall carry the same lights as are provided by Article 3 for a steam ship under way, with the exception of the white light, which she shall never carry.

Art. 7. Whenever, as in the case of small vessels during bad weather, the green and red side lights cannot be fixed, these lights shall be kept on deck, on their respective sides of the vessel, ready for use; and shall, on the approach of or to other vessels, be exhibited on their respective sides in sufficient time to prevent collision, in such manner as to make them most visible, and so that the green light shall not be seen on the port side nor the red light on the starboard side.

To make the use of these portable lights more certain and easy, the lanterns containing them shall each be painted outside with the colour of the light they respectively contain, and shall be provided with proper screens.

Art. 8. A ship, whether a steam ship or a sailing ship, when at anchor, shall carry, where it can best be seen, but at a height not exceeding 20ft. above the hull, a white light, in a globular lantern of not less than 8in. in diameter, and so constructed as to show a clear, uniform and unbroken light visible all round the horizon, at a distance of at least one mile.

Art. 9. A pilot vessel, when engaged on her station on pilotage duty, shall not carry the lights required for other vessels, but shall carry a white light at the masthead, visible all round the horizon, and shall also exhibit a flare-up light or flare-up lights at short intervals, which shall never exceed fifteen minutes.

A pilot vessel, when not engaged on her station on pilotage duty, shall carry lights similar to those of other ships.

Art. 10. Open boats and fishing vessels of less than 20 tons net registered tonnage, when under way and when not having their nets, trawls, dredges, or lines in the water, shall not be obliged to carry the coloured side lights; but every such boat and vessel shall in lieu thereof have ready at hand a lantern with a green glass on the one side, and a red glass on the other side, and on approaching to or being approached by another vessel such lantern shall be exhibited in sufficient time to prevent collision, so that the green light shall not be seen on the port side nor the red light on the starboard side.

Art. 11. A ship which is being overtaken by another shall show from her stern to such last-mentioned ship a white light or a flare-up light.

[We omit articles 12 to 26.]

Art. 27. When a ship is in distress and requires assistance from other ships or from the shore, the following shall be the signals to be used or displayed by her, either together or separately, that is to say:

In the daytime—

1. A gun fired at intervals of about a minute;
2. The International Code signal of distress indicated by N C;
3. The distant signal, consisting of a square flag, having either above or below it a ball, or anything resembling a ball.

At night—

1. A gun fired at intervals of about a minute;
2. Flames on the ship (as from a burning tar barrel, oil barrel, &c.);
3. Rockets or shells, throwing stars of any colour or description, fired one at a time, at short intervals.

ELECTRIC LIGHTING AT GREENOCK.

It will be remembered that some time since the Greenock Police Board authorised the expenditure of £1,000 in electric lighting experiments, the motive power to be supplied by turbines. At the last meeting of the Board, held a few days ago, the following report by Mr. Stewart, gas manager to the Board, was read:—

"I have to report that seven offers for the supply of electric lighting plant have been received, as follow:—R. E. Crompton and Co., £1,050; E. Beckingsale, £1,040; Maxim-Weston Company (per H. Watt), £1,065 10s.; Muir and Mavor, £943; Anglo-American Brush Electric Light Company, £1,186 11s. 8d.; Henry Bennett and Co., £1,000; J. D. Andrews and Co., £900. With respect to offer No. 1, no details of estimate are given or any explanations. Offerer No. 2 gives long explanatory letter containing a good deal of information, and detailed offer, and also alternative tender for apparatus without the wire. Offerer No. 3—This is for arc lamps only, and two dynamos only, and offer is otherwise not consistent with specification. Letter giving explanation is with offer. Offerer No. 4 is in terms of specification. Offerer No. 5 includes wood trough and other apparatus not in the specification, amounting in all to £275, which deducted from amount of offer £1,186, leaves £911 11s. 8d. as nett amount of offer for comparison. This offer also includes the using of Callenders' bitumen coated wire, which is preferred, I am told, to the Kinetic Company's double lead coated wire. Offer No. 6 is a lump sum without details except a general statement in letter. Offer No. 7 is also a lump sum, and includes cost of laying wires in wooden trough of their own pattern. Messrs. Siemens and Co. declined to offer, and Messrs. the Callenders' Bitumen Telegraph Company have included their offer with the Anglo-American Brush Company, and send letter explaining why their wire is preferred over the Kinetic Company's wire." The Electric Lighting Committee agreed that Mr. Stewart and Mr. Wilson, C.E.,

Digitized by Google

should be authorised to consult Professor Jamieson, Glasgow, regarding the sufficiency of the specification and offers, and report to a future meeting, and the Board agreed to leave the matter in the committee's hands." The clerk was authorised to give the statutory notice to the Postmaster-General prescribed by the Electric Lighting Provisional Order.

THUNDERSTORMS.

A very ably-written account of the thunderstorms which broke over Scotland between Saturday and Tuesday, the 9th and 12th instant, appeared in *The Scotsman* of Wednesday week, for which we could not find room in our last issue. We reproduce a portion of it this week. Our contemporary says :—

"A thunderstorm of almost unsurpassed severity broke over the south-east of Scotland yesterday (Tuesday, the 12th instant). Alike in point of duration and intensity, there has been nothing experienced in Scotland to compare with it since, at all events, the great storm of July, 1873 ; and in some respects the storm of yesterday proved more violent and destructive than any within the recollection of old people. It broke over Edinburgh at about half-past nine in the morning, it attained its greatest violence about noon, and it continued to rage till almost 4 o'clock in the afternoon. The area of the disturbance seems to have been as extensive as its effect was alarming and disastrous. As regards the City of Edinburgh, the storm of eleven years ago may have been as fierce. But on few former occasions within memory has the flooding been more extensive, and if on former occasions the effect of lightning may have been productive of more actual damage, seldom has it been more alarming or threatening. The singular brightness and frequency of the lightning flashes, the terrific roar of the thunder which raged for hours immediately over the city, the remarkable spell of darkness into which the city for a considerable time was plunged, the great showers of rain and hail, the wonderful phenomena which almost everywhere were witnessed, particularly in localities where buildings were struck with the lightning, the narrow escape of properties from fire, and the numerous casualties render the storm perhaps the most memorable during recent years.

"Thunderstorms of more or less severity may be said to have prevailed throughout the greater part of Scotland since Saturday morning. A sharp outbreak was experienced on the shores of the Firth of Forth early on Saturday. About three on Monday morning a storm of short duration broke over Edinburgh, and in the afternoon again there were frequent flashes of lightning and peals of thunder. Monday was also characterised by a remarkably high temperature ; at eight in the evening the reading of the thermometer ranged from 85deg. in London to 58deg. in the Shetlands.

"As already indicated, Edinburgh has witnessed nothing to compare in intensity with the storm of yesterday (Tuesday, the 12th) since a day which is well within the recollection of observers—the 22nd of July, 1873. Like that of yesterday, the storm of 1873 was preceded by an unusually high temperature, the thermometer having on that occasion risen to 90deg. in several places in the Lothians. Three well-defined periods of intensity were noted during the storm of yesterday. The first continued from the outbreak till 11:30 ; there was then a lull, during which occurred some remarkable phenomena, notably the darkness in which the city was plunged ; the second period of intensity continued from noon till after one ; and the third from half-past one. The storm had passed to the north and north west by three o'clock ; but up till four there were now and again very loud peals of thunder. While the storm was at its height the frequency of the lightning flashes was such as to fairly dazzle the eyes of the spectator, and to create much alarm in many quarters of the city. During the storm of 1873 one of the observers of the Scottish Meteorological Society counted in one hour 680 flashes, with their accompanying thunder claps. This gives a rate of fully eleven per minute. The results of such exact observation yesterday may indicate an equally if not a more severe disturbance. On several occasions, particularly between twelve and one o'clock, the lightning was so persistent, flash succeeding flash in such quick succession, that it was almost impossible to determine numbers, or the thunder report which accompanied a particular flash. One observer says that during a considerable period flash must have followed flash at the rate of nine or ten a minute, and from ten to twenty minutes past twelve there were brief periods of continuity of light which were frequent as remarkable. The effect of the lightning flashes amid the strange gloom that prevailed was singularly impressive. Just about noon the lightning conductor at St. Giles's was three times struck. The lightning on each occasion appeared, after coming into contact with the conductor at the top, to quiver round the rod, to rush down and to burst out into a beautiful sheet of light just above the roof. It ascended, and again descending, burst out afresh and disappeared. In other quarters of the city the effect of the lightning was watched with much interest. Correspondents send notes of phenomena witnessed while the storm was at its height. 'A gentleman,' writes one, 'was proceeding along Easter-road about eleven o'clock, when suddenly he observed dropping from the clouds an immense ball of fire. On nearing the ground it burst with a terrific crash, leaving behind it a cloud of smoke, which hung for some time in the air, and gradually dispersed. The sight was a most impressive one, and likely to be remembered by all who may have have seen it.' Equally striking sights are described by another :—'While watching to-day's thunderstorm, I was much interested in seeing, a little north of the zenith, a complete ring of broken clouds wheeling round and round as if in a whirlwind, while the rest of the expanse of cloud remained still and unbroken. Another curious phenomenon I noticed. At the height of the storm a fiery "pair of scales" seemed for an instant suspended between the heavens and earth.' The wind had been—the little there was of it—from the north-north-west. Afterwards it changed to east-north-east. At nine in the morning the barometer, reduced to 32deg. and sea level, read 29·890 inches. At 11:50 it had risen to 29·900—the higher reading thus occurring at the termination of the period of the greatest darkness. Immediately thereafter the barometer began to fall steadily till four in the afternoon. This apparently slight rise in the barometer from nine till noon, and the more rapid, though still slight fall from noon till four in the afternoon, are, it has been observed, features peculiarly characteristic of thunderstorms, and deserve observation and examination. About ten the rain was exceedingly heavy, and it continued so during more than an hour. During the period of darkness, and twenty minutes thereafter, there was little or no rain ; but from about noon till almost two, the rainpour and hail showers were singularly severe. The hail may be said to have been little pieces of clear ice, measuring as much as half an inch in diameter. An observer near the Calton Hill says that pieces of this size were not falling here and there ; there were showers of them. The hail fell with, or immediately after, the heaviest downpour of rain.

"The weather moderated immediately after four, and there was a long period of calm. But about nine o'clock last night there was a renewed disturbance. Lightning flashed at intervals across the sky, and about half-past ten there were several peals of thunder. The following readings of the barometer, corrected and reduced to 32 degrees and sea level were taken at Leith by Messrs. Bolam and Redpath, of the Government Navigation School :—5:45 a.m., 29·899 ; 7:0 a.m., 29·890 ; 8:15 a.m., 29·896 ; 6:45 p.m., 29·888 ; 7:45 p.m., 29·888 ; 8:45 p.m., 29·884 ; 10:30 p.m., 29·861. During the day the barometer was very unsteady, but at half-past ten last night was falling steadily. At half-past one this morning there was a good deal of lightning, but no thunder. The temperature was high, and a heavy haze hung over the city.

"The rainfall at Leith between ten and four o'clock yesterday was 1·62 inch, which is equal to 162 tons per acre."

We cannot find room for the long record of accidents from lightning strokes given by the *Scotsman*, but we may mention that two of a group of four telephone wires supported on the roof of a farmhouse at Quarryholes, Easter-road, were destroyed by the lightning. A correspondent who witnessed the occurrence writes :—"There is a stretch of 150 yards from the telegraph pole on the south to the roof of the farm buildings, and the two wires between these points were totally demolished, the electric fluid escaping at joinings in the wires (covered with copper wire and strong cord) near the supports on the roof, with a loud report, amid a shower of sparks, flame, and sulphurous smoke. Several of us were standing near, and it appeared as if one of the "Sultan's" 10in. shells had burst over our heads. The wires were reduced into sparks, which fell about us in a molten state. I have picked up a handful of these, varying in length from 1-16th of an inch to 1½in., the metal being fused and the substance burned out of it. The fluid luckily confined itself to the wires." Another case in which the lightning is supposed to have entered a building by way of a telephone wire is recorded from Broughty Ferry. Our contemporary says :—"A young man, Mr. John Bremner, residing in West Brook-street, was struck by the electric fluid, and has never regained consciousness. Being an invalid, he had a private telephone connected with the church, and the electricity is supposed to have travelled along the wires and entered the room where he was sitting." He is since reported to be recovering, though complaining of acute pains in his back and chest. A peculiar case is reported from Port Glasgow where several men engaged on a steel ship, being built in the yard of Messrs. Russell and Co., Ardgowan-street, were struck by lightning. One of them, John Bolton, foreman carpenter, "had the skin of his mouth completely peeled off down to his throat." Another, M'Millan, a labourer, "was struck on the back, the lightning leaving a mark the size of a man's hand in the form of a tree."

Messrs. John Davis and Sons, of All Saints' Works, Derby, write that, during the thunderstorm on the 9th inst., a housemaid named Emma Harveson, whilst in the act of cutting bread for tea, at "The Limes," Mickleover, and when in the act of putting the knife into the butter (the window being open), had the knife violently struck out of her hand by a flash of lightning and dashed on the ground, the blade being broken in two pieces. It is presumed that the ivory handle, being a non-conductor, saved her from injury. There were two other knives on the table, but they were not influenced. About 45in. from the window were *two newly painted* iron rain down spouts. These show no signs of influence. The knife was broken whilst in her hand and the butter thrown about in all directions. Messrs. Davis and Sons state that the knife is in their possession, but bears no evidence of fusion by lightning.

LEGAL.

Re the Gulcher Electric Light and Power Company.

MR. CROSSKEY applied on the 20th inst. before the vacation judge, Mr. Justice Wills, for the sanction of the Court to the reduction of the capital of the above Company from £300,000 in £5 shares to £150,000 in like shares. The matter had in the usual manner been referred to the chief clerk, who had found that some creditors, but not all, consented, to the proposed reduction of capital. It now appeared that all the creditors who had not consented before the chief clerk had since either consented or been paid, with the exception of one creditor for £15 8s. 2d., whose debt it was now proposed to pay into court.

His LORDSHIP sanctioned the proposed reduction, and dispensed with the title "and reduced" from the expiration of fourteen days after the date of the order.

COMPANIES' MEETINGS.

The River Plate Telephone and Electric Light Company (Limited).

The second ordinary general meeting of this Company was held on Monday at the Cannon-street Hotel, Colonel Gouraud in the chair.

The report of the directors having been taken as read,

The CHAIRMAN said: I should first, perhaps, make one remark with regard to this meeting. The meeting was originally called almost immediately after the annual accounts of the Company were made up to the end of the Company's year—the 31st January last—when, as you were informed by a subsequent notice, a question had been raised as to the powers of the directors acting for the Consolidated Company with respect to the settlement of the debt to that company by this Company. The consequence of that was that the settlement in question had to receive the consideration of the shareholders of the Consolidated Company. That involved all the delay that has since occurred. The meeting of the Consolidated Company was in due course held, and the settlement unanimously approved by the shareholders of that Company. Immediately thereupon you were notified that your general meeting would be held with reference to the report, and with reference also to the ratification by yourselves of that settlement. But for the necessity of delaying this meeting you would have received your dividend some months ago, the money being at the time ready for distribution. So much with reference to the delay which you have experienced in receiving your dividend, and in meeting together for the purpose of receiving the report. With reference to the report I have really very little to volunteer to you. I think that you cannot but unanimously feel that it presents a very admirable position of the Company, more especially taking in connection with it the special resolution, and assuming that it will receive your support. The report tells you that the debt due to the Consolidated Company has since its date been settled, and it now remains with you to approve the correctness of the report, and if there are any questions I shall be pleased to answer them. You have a very handsome balance to carry forward, after paying the 9 per cent. dividend, which with the dividend paid last year will make a 9 per cent. cumulative dividend upon your investment from the date you made it. It is only in the power of the directors to recommend the dividend, but as soon as you approve it it will be paid.

Mr. CLARK: Is the dividend up to Christmas last?

The CHAIRMAN: Up to the end of January—up to the end of the Company's fiscal year. The Company's year terminates on the 31st January.

Mr. CLARK: Because the next year's termination will shortly take place.

The CHAIRMAN: That will be dealt with in next year's accounts.

Mr. CLARK: It is very late in the season for a Christmas dividend.

The CHAIRMAN: Well, I thought I had made a complete explanation for the reasons of the delay. It was impossible to have the meeting earlier.

Mr. CLARK: I think the matter ought to have been seen into before the notice was issued stating that everything was in readiness, and then it turned out that there was something amiss. I think the directors ought to have known all about that before they sent out the first notice.

The CHAIRMAN: I quite see your point, and can make it perfectly clear in a few words. You misunderstood one important point evidently. There was no question in this Company whatever. There was no doubt as to the powers of the directors of this Company to do all that they have done. They made up the report as soon as they got the accounts. The business is 6,000 miles from London. In due course the accounts came in and were audited, and the meeting was called. The doubt to which you refer, and which I thought I had explained, arose in the minds of some of the shareholders of the Consolidated Company as to the power of their Board to accept the settlement which the directors of that company and of this Company had agreed to; therefore it was proposed naturally to shield the directors from taking undue responsibility, although they believed—and believe now—that it was fully within their powers, and consequently a meeting of the Consolidated shareholders was called to consider the question. I presume that makes it clear to you.

Mr. CLARK: I think the directors should have made themselves thoroughly acquainted with that before they issued the first notice. I do not think that you have answered my question. I ask for information.

The CHAIRMAN: I have no doubt it is my own fault, I will not say it is yours.

Mr. CLARK: The directors knew there was a debt.

The CHAIRMAN: At the date of this report this Company had a creditor to a very large amount, and this creditor had been a creditor for a very long time, and it was considered desirable by the Boards of the respective companies—the debtor company and the creditor company—that the debt should be liquidated. Had no question arisen on the part of the other company to whom we owed this money we would have had our meeting at once and declared the dividend, but the question did arise in the other company as to the powers of the directors of that company to make the settlement. It was thought to be a settlement too much in favour of this Company, that was the reason given, and it is not unreasonable to expect that that might have been the case. The Directors of the Company were notified by a formal protest on the part of a number of their shareholders that they were not to carry out the settlement. Well, that raised the question of the powers of the directors, and in such cases it it invariably the custom that directors do not choose to go utterly regardless of consequences, but submit the matter to their shareholders for approval. That was done, and it has taken all this time. I will now move "That the report of the Company's working for the year ended the 31st of January last, with the balance-sheet, be adopted."

Mr. PATRICK CARNEGY: I beg to second that.

Mr. ATKINSON said that he bought some shares in what he considered to be the River Plate Telephone and Electric Light Company (Limited), and he was not aware that there were any debts owing. He knew nothing of any other company.

The CHAIRMAN replied that it was quite possible in buying shares in any company the hon. shareholder might not know at the moment what the debts were or what debts were owing to the Company. They had a progressive business, and it was not unusual for companies with that kind of business to borrow money. In the previous report, which was printed and circulated amongst all the shareholders, it was printed and published that there was a large debt owing by the Company, and that had proved to have been a debt very wisely incurred by the Board. It had been the means by which this Company had attained what he thought he was justified in saying was a most extraordinary position of success. The necessity of the Company to receive this credit, or to receive this assistance in the form of goods of one sort and other, arose from the fact that the shares were not taken up to an amount sufficient to meet the natural development of the business of the Company; therefore their being able to borrow was a fortunate circumstance, and it had worked to their advantage. The debt had now been settled on very satisfactory terms to the Company, and the assent of the shareholders would be asked to the arrangement.

The motion for the adoption of the report was then put, and carried unanimously.

The CHAIRMAN: In the report you have just adopted you have given your sanction to the payment of a further dividend, and I am going to ask you also, on the suggestion of the solicitor, to sanction the interim dividend which we paid you, which interim dividend was 9 per cent. per annum upon your entire investment up to the 30th April, 1883. The resolution is "That a dividend at the rate of 9 per cent. from the respective dates of payment to the end of January, 1884, including the interim dividend paid on the 1st August, 1883, be declared."

Mr. FITZGERALD: Excuse me, I should like to make a remark. It appears to me, with a debt of £20,000 owing to the Consolidated Company, which it was at that date, that that dividend should never have been paid. Of course, it has been paid to the shareholders, but, as a matter of policy, it should not have been declared as long as that debt was unsettled with the Consolidated Company. It seems to me—I do not know whether I am correct—that if the Company owes a large sum of money to another company, and that company could claim the money, the dividend should never have been declared by the company owing the money. I do not question that it was fairly earned, but it should have been explained to the shareholders that they owed the Consolidated Company at that date something like £20,000. I should like to make one or two further remarks in regard to this. I see that Colonel Gouraud states that when he accepted the chairmanship of the Company that the returns of the subscribers in Buenos Ayres and Monte Video showed a number of 1,160, and an annual value of £19,558. The increase up to the latest return shows 1,709 subscribers and an annual value of £26,985. Surely Colonel Gouraud does not take credit for having got those subscribers. The credit is due to the Board in Buenos Ayres. I think they are the gentlemen who are working there for us. I am merely making these remarks because I think it is not quite fair that the Chairman of the Company should take credit for things that have been done by other people. That is my way of looking at it. You know, gentlemen, all about the indebtedness of the Company. The Consolidated Company, of which I am at present the chairman, gave, or rather sold you instruments for the erection of installations in Buenos Ayres, but this Company could not pay the money, and that is the reason that this settlement has come about, and we, the present Board of the Consolidated Company, accept these debentures and shares in payment instead of cash for the instruments we have supplied. Of course we had to go into the books of the Company to see that everything was correct, and that is one of the reasons why your dividend was delayed. I merely mention that in case you should think I have in any way delayed the dividend. I assure you I should have paid the dividend myself if I could have done so on the date in May last, but until we saw everything was correct, as a matter of course we could not. I must endorse all Colonel Gouraud has said as to the position of the Company and the report as far as I can judge. The Company is doing extraordinarily well, and the dividend has certainly been earned. Of course some of you, gentlemen, are possibly aware of the reasons why the gentlemen do not offer themselves for re-election. It is hardly worth while that I should go into that, because the people who have been put in power in the Consolidated Company have determined to make this alteration on the Board.

The CHAIRMAN said that the remarks of Mr. Fitzgerald were premature, because the resolution had not been seconded, but he did not wish to interrupt that gentleman, but wanted to show him the patience which he (the Chairman) had displayed on many previous occasions.

Sir ALEXANDER ARMSTRONG then seconded the motion.

The CHAIRMAN: Gentlemen, with regard to Mr. Fitzgerald's remarks, I think I should be paying a very poor compliment to your intelligence if I were to point out to you that he rose to criticise the payment of the dividend in the same breath he told you we ought not to have paid it, and we had no right to do so in the face of the fact that we owed all this money, which the shareholders when they received this interim dividend did not know of. In the same breath he told you, by way of showing his importance as the Chairman of the Consolidated Company, and your supporter here, that if he had been able to do so he would have paid this dividend, which you are only receiving now, in May last. I think any further comment upon that is unnecessary, except in regard to the interim dividend being paid when the shareholders did not know that we owed the money. The interim dividend was paid almost immediately

after the report which was in the hands of all of you. I might mention to you, what perhaps you ought to know as something that took place at the meeting, that as the Directors then showed a large balance and handsome dividend in the report at the last annual meeting, a shareholder took very strong grounds that the Directors ought to pay a dividend, and he pointed out it was a most usual thing for Boards earning large dividends to pay the dividends, even if they borrowed the money, a fact to which we all assented, but which we did not think desirable to do at that time. So much then with regard to the dividend. I am glad to hear that Mr. Fitzgerald recommends the payment of the dividend, because if he took a contrary view in regard to that, I am sorry to be obliged to tell you you would not be able to have your dividend, as it would be in the power of an individual to keep you out of it. This leads me to make a reference to the portion of his remarks which applied to myself. It must be evident to you that Mr. Fitzgerald went a long way out of his way to make an insinuation; but that did not surprise me, because Mr. Fitzgerald has an unhappy weakness of doing that sort of thing. Mr. Fitzgerald, in another place, where he had certainly the advantage of me from the fact that he took the chair, claimed the credit—he evidently thought it a credit—for a production which I will venture to say is without any parallel in the history of companies in London—one full of insinuations unconnected with a single direct charge against any gentleman concerning whom the insinuations were made. It may be that that is Mr. Fitzgerald's idea of what is the duty of a gentleman, and what is due from one claiming to be a gentleman to other gentlemen. If so, no one can deny him the privilege. He is welcome so far as I am concerned to all the credit and to all the satisfaction that he may derive from such a course. I left the meeting, as I shall leave this, better satisfied with my own position—far better satisfied with my own position than with his. Now, I will tell you the facts in a word, in order that Mr. Fitzgerald may be saved the ignominy of leaving this room after having made another insinuation against gentlemen of the position of my colleagues. I say nothing worse than that, of having again made an insinuation. Of course, it must be a matter of surprise to any one who does not know all the circumstances that gentlemen who have gone through difficulties that I can give you no idea of, and brought the Company to a successful issue—that they should voluntarily throw up their positions as Chairman and Directors. That requires some explanation, but I had intended to spare you the trouble of receiving any in your own interests as shareholders. I am a shareholder, like yourselves. I and my colleagues have been anxious to hand this splendid property over to you without a blemish, without doing anything to prevent you from getting for your shares all that they are worth if you want to sell them, which is a great deal more, I am afraid, than you will get now. Therefore, after very careful consideration, on Saturday I wrote this circular, which I hope you have all received, in which I referred to the fact of our resigning, and endeavoured to do so with the least risk of doing you harm. I have received a number of letters from perfect strangers, who have asked me why we are resigning, from one who has protested against it, saying he took his shares in the Company on the faith of the present directors, and he desired to know why we were leaving. He told me that it was anomalous coupled with the report, and demanded to know the reasons, and finished his letter by telling me that under the circumstances he would hold me personally responsible for the return of his money in the Company. Well, gentlemen, I wrote in my circular:—"In reply to the several inquiries as to the reasons which have led me to resign, and Mr. Carnegy and Mr. Spensley not to offer themselves for re-election, I have to say that they are purely personal, and have obviously nothing to do with the present financial position of the Company, which is highly satisfactory, or with its prospects." I would have been glad to leave the thing there, but Mr. Fitzgerald, in the exercise of his greater wisdom, has chosen to make insinuations, or rather more than insinuations, and I propose to tell you what he meant to say. He meant to tell you that there is in the Board of the Consolidated Company a personal bitterness of feeling towards myself and certain of my colleagues that surpasses his powers of description, and that is saying a great deal. He has not attempted to tell you how bitterly he feels; he would have liked to have done so, but he has left that to me. Suffice it to say for your purposes that there is that feeling. Now, the Consolidated Company is your principal shareholder—rightly so because if the Consolidated Company had not supported you by this very credit which is involved in this debt you would not have been able to meet the demands—the enormous demands—for the extension of your system in Buenos Ayres and Monte Video. You could not have got the capital for the purpose. The Board before I joined it had several times tried to get it and had failed. Numerous efforts of ours had equally failed on account of this large debt. The Consolidated Company holds such a large controlling interest in the shares of this Company, that they could eject the Directors if they chose to do so, and at the time they could have ejected us if we had not resigned. Now, gentlemen, this is a statement of fact borne out by figures. Of course, Mr. Fitzgerald can do nothing without his colleagues. But they would probably take any course he recommended, and I think he would not stop short of any course to show his personal feeling towards ourselves. He would undoubtedly have tried to call an extraordinary general meeting of this Company for the purpose of putting us out. Well, it would depend upon whether he could control three-fourths of the shares of this Company; I do not think that he could do it—I have too much confidence in the common sense and the sense of fair play of the majority of Englishmen. We have over 100 shareholders, and the usual thing would have taken place—an extraordinary meeting, a committee of investigation—perhaps not even that, but formal resolutions to put us out—the result being that you would not be able to sell your shares at any price whatever. Now, that is what animated us in taking the course we have adopted. We have made this splendid property, and we are entitled to the credit of it—not entirely, perhaps, but, at any rate, to some of the credit. I am sorry that any one has misunderstood me in my personal circular, in which I pointed out how we found the Company when we came into it, and how admirably we leave it; but we have not taken all the credit to ourselves. I take it that you have all read the report which you have unanimously approved, and in that report we say "It will be observed that the net revenue for the year is £7,067 10s. 8d., as compared with £4,475 12s. 6d. for the previous year, showing the large increase of £2,591 18s. 2d., or, say, 58 per cent., a result which cannot but be extremely satisfactory to the proprietors, as it is to the Board, and for which the Board feel they are in no small degree indebted to the able and energetic management of their managing director in the River Plate, Mr. E. F. Powers, who has been ably supported by the local Board." It stands to reason that the local Board are entitled to more credit than ourselves if you like, but we are the Directors, and they are not.

In reply to Mr. CLARK,

The CHAIRMAN said that he had no doubt that the Telephone Construction Company would offer its shares in this Company to their shareholders as a means of raising fresh capital to carry on its various undertakings, and if the shareholders consulted their own interests they would take up the shares as a very good thing. Perhaps Mr. Fitzgerald would offer the shares to the shareholders of this Company; and it would only be fair if he did so, in which case he—the Chairman—only hoped that they would all increase their holdings.

Mr. FITZGERALD said that he should be only too glad to offer the shares to the shareholders of this Company if they liked to take them. So far as his Board was concerned, they were anxious to have the money. They had made this settlement by which they got shares because they could not get the money.

The CHAIRMAN having stated that he was very glad to hear that statement, the motion was put to the meeting and carried.

Mr. John Taylor and Major Henry Thomas George Fitzgerald were elected directors, and Colonel Gouraud, the Hon. Howard Spensley, and Mr. Patrick Carnegy resigned.

Messrs. Deloitte, Dever, Griffiths, and Co., the retiring auditors, having been re-elected,

Mr. FITZGERALD proposed that Sir Julius Vogel, who was entitled to a salary of £200 a year as a director, in consequence of his continued absence from England, and its probable duration, should be called upon to resign.

The CHAIRMAN ruled that the resolution was out of order, and said that the only way in which the matter could be dealt with was by calling an extraordinary general meeting.

The meeting was then made special, and a resolution was passed approving the terms of the settlement with the Telephone Construction and Maintenance Company.

A vote of thanks to the Chairman and Directors then terminated the proceedings.

NOTES.

AMOY.—The Great Northern Telegraph Company inform us that telegraphic communication with Amoy is restored.

EARTHQUAKE IN JERSEY.—A strong shock of earthquake was felt at Jersey on Tuesday morning, lasting about thirty seconds.

NAPLES.—A project is on foot for providing Naples with an underground railway, the tunnels of which it is proposed to light throughout by means of electricity.

BOOK RECEIVED.—"Dynamo-Electric Machinery," a manual for students of electro-technics. By Silvanus P. Thompson, B.A., D.Sc. Published by Messrs. E. and F. N. Spon.

ELECTRIC LIGHT FOR LOCOMOTIVES.—M. Sedlacyck's electric light for locomotives has been used on the engine "l'Erfurt," on the 3rd of this month, at the Steyr Exhibition, with great success.

ELECTRIC LIGHT IN PRESTON.—The contract for the electric lighting of the Park-lane Mills, Preston, has been given to Mr. F. D.'A. Goold, electrical engineer and contractor, 29, Arcade-chambers, St. Mary's-gate, Manchester.

MUNRO AND JAMIESON'S "POCKET BOOK."—We are informed that the first edition of this book has been sold, and that the second edition, with corrections and additions, is in hand and will be pushed forward as rapidly as possible.

TELEPHONY.—Mr. W. E. Irish, of Sunderland, has been trying his hand at an invention to automatically record the telephonic sounds as ordinarily transmitted by these instruments. It is doubtful if such a record is of much value.

WESTERN AND BRAZILIAN TELEGRAPH COMPANY.—The traffic receipts of this company for the week ending 22nd August were £2,609, after deducting the "fifth" of the gross receipts payable to the London Platino-Brazilian Telegraph Company.

THE BENNETT-MACKAY CABLE.—The "Faraday" finished paying the deep-sea portion of the second Bennett-Mackay cable on Tuesday morning, and she returns immediately to Woolwich to receive the remaining deep-sea portion and the American shore end.

WHITWORTH SCHOLARSHIPS.—Four of the successful candidates at the last examination were students of the College of Science and Arts at Glasgow. We believe this is the first time so many successes have been gained at one institution in any single examination.

BRISTOL.—At the fire on the premises of Messrs. Platnauer, Victoria-street, the telephone was called into service both at the Talbot Hotel and at the cab stand, Bristol Bridge, and was found to be of great value in rapidly calling the attention of the fire brigade to the outbreak.

UNIVERSITY COLLEGE, LONDON.—The examination for the Gilchrist Engineering Scholarships will be held on the 25th September and following days. The Entrance Scholarship is of the value of £25; the value of the Senior Scholarship is £80. Full particulars can be obtained from the College.

CHINA.—The Eastern Telegraph Company and the Great Northern Telegraph Company notify that the telegraph system in China has now been extended to Pekin. Telegrams are therefore now accepted direct for that city, and need not be addressed "Post, Tungchow," as formerly, the rate being 10s. per word.

FRENCH ELECTRICAL POWER STORAGE COMPANY.—Notice has been given that the vacation judge has fixed the 3rd September, at twelve o'clock at noon, at the chambers of Mr. Justice Pearson, Royal Courts of Justice, Strand, London, as the time and place for the appointment of an official liquidator of this company.

EGYPT.—The mounted portion of the air line section of the Telegraph Battalion Royal Engineers has been ordered to proceed to Egypt to join the Expedition up the Nile, in addition to the dismounted portion already under orders. This portion will be under the command of Lieutenant Stewart and Lieutenant Bagnal.

TELEGRAPHISTS AND ATHLETICS.—The annual meeting of the London Electric Athletic and Cyclist Club will be held at Stamford Bridge, Fulham, S.W., on Saturday, 6th September. There is a good programme, including foot races, and bicycle and tricycle contests, for which, we understand, a liberal sum in the shape of prizes has been subscribed by the metropolitan telegraph officials.

CHINA.—The Great Northern Telegraph Company announces that the courier service from the landing point of the Shanghai-Foochow cable up to the latter town having been stopped by the Chinese authorities, telegrams for Foochow, as sent hitherto, will only be accepted at sender's risk. Telegrams for Foochow may, however, be forwarded *viâ* Shanghai by means of the Chinese land lines.

GLASGOW.—Mr. D. Prentice Munzies, of 106, Elliot-street, Glasgow, has received instructions from Messrs. James Pullar and Sons, dyers, Perth, to make a large addition to the electric lighting of their city works, Perth. It will at present comprise 150 incandescent 20 candle-power and 14 arc lights, also the general re-arrangement of their present electric light plant, which comprises no less than 20 dynamos.

LIGHTING BARRACKS.—The Government have decided to commence the system of lighting barracks by electric light by a trial at the Royal Engineers' barracks at Chatham, where favourable circumstances are found, during next year. The estimated cost is £5,000 for installation and £500 per annum for maintenance, and will give an annual saving of £400. Should the trial prove successful, the system will be extended.

AUTOMATIC ELECTRICAL BARRIERS FOR LEVEL CROSSINGS.—It is reported that the French railway companies are trying the American electrical barriers for level crossings. They are in a normal condition set across the lines, thus allowing the street traffic to be carried on; but, on the approach of a train, the locomotive wheels pass over a contact, and close a circuit, which causes the barriers to shut off the street traffic and give passage to the trains, at the same time warning the public by the continuous ringing of a bell.

THE BRITISH ASSOCIATION.—The Montreal meeting of this Association was opened on Wednesday evening, when the President, Lord Rayleigh, read his address, which will be found in another column. On Thursday evening there was to be a soiree, and on Friday evening Professor Oliver Lodge was to lecture on "Dust," a subject which he would no doubt render both interesting and instructive. The meetings of the various sections began on Thursday, and we shall hope to give the various papers of interest to our readers in an early issue.

FREEDOM OF WICK PRESENTED TO MR. PENDER, M.P.—A meeting of the Wick Town Council was held on Saturday last, when the freedom of the burgh was conferred on Mr.

Digitized by Google

John Pender, member of Parliament for the northern burghs, on account of his assistance to the harbour authorities in the matter of the harbour loan. Mr. Pender briefly thanked the council for the honour done him, and assured them of his unabated zeal in harbour matters. Afterwards a public banquet took place in the Station Hotel, when the usual loyal and local toasts were given.

ELECTRIC WINCH.—The Northern Railway Company of France has adopted an electric winch for its goods depôt at La Chapelle, Paris. It consists of a four-wheeled truck, carrying the lifting apparatus and four small Siemens dynamos, two to act on the winch proper and two to propel the truck, the motion in both cases being transmitted by endless chains. Six men, including the engineer in charge of the dynamos and the fireman, can charge a hundred sacks, weighing together 10 tons, in a space of 48 minutes; and 38 minutes suffice when the winch has not to be displaced.

ELECTRIC LIGHT AT STEYR.—The current employed for lighting the palace of the Steyr Exhibition is supplied by sixteen dynamos, which supply as many arc lights. The manufactory of arms is lighted by eleven arc lamps. A great part of the town is lighted in the same manner. Another manufactory is lighted by three dynamos feeding 125 incandescent lamps, and another machine feeding seventy-five lamps. All these dynamos are worked by water or steam. The 203 arc lamps are nearly all of the Krucyi system, and the 450 incandescent lamps are of the Puluj system.

THE ELECTRICAL RESISTANCE OF ICE.—The resistance of ice has been measured by M. G. Foussereau. He says he determined the resistances of ice made from distilled water by taking for electrodes two thin cylindrical and concentric plates of platinum. He found the resistance became 15,000 times greater at the moment of congelation. The specific resistances varied from 4,865 megs. at – 1deg. C. to 53,540 megs. at – 17deg. C. "I found also," he says, "that the resistance of ice varies with the nature of the water from which it is made. A sample of town water 65 times better conductor than the distilled water previously mentioned gave ice conducting 30 or 40 times better."

TELEPHONING EXTRAORDINARY. — Experiments in telephoning to long distances have been made by the engineers of the International Bell Telephone Company between St. Petersburg and Bologœ (about 3,700 kilometres = 2,465 miles). Blake transmitting and Bell receiving instruments were used; and conversation could be kept up notwithstanding a rather high induction. It is but right to add that the experiments were made during the night, when the telegraph lines were not at work. The Russian engineers hope to succeed in speaking to a distance of 7,000 kilometres (4,665 miles), but to do this they must have combined all the conditions favourable to transmission.—*Bulletin de la Compagnie Internationale des Téléphones.*

SIXPENNY TELEGRAMS.—A writer in the *Daily News* of Wednesday happening to be in a post office in the City on the previous day, saw a gentleman hand in a telegram for Brussels, for which he paid sixpence. The clerk at the counter also informed him that messages were frequently sent to Bordeaux, Marseilles, and other places in France, at a cost of sevenpence halfpenny. Our contemporary's correspondent compares these rates with the costly shilling that must be paid if he wished to telegraph to a friend "only a few doors off in London." He opines that that this state of things should not be allowed to continue, and hopes the Post Office "will not be allowed to quietly drop their long advertised project of a reduction of the inland telegram rate to sixpence."

BOATING ON WINDERMERE BY ELECTRICITY.—A boat, driven by electricity, owned by Mr. J. R. Bridson, of Belle Isle, Windermere, and which is intended to be used by him to keep up communication between his island residence and the mainland, has just been tried. She is 21ft. long by 4ft. 6in. wide, and has ample accommodation for nine or ten persons. The electromotor is the invention of Reckenzaun, of London; and the power which supplies the motor is derived from twenty secondary batteries or accumulators, charged primarily by the dynamo machine used at a Bolton bleachworks for lighting purposes. The whole of the machinery is so disposed in the boat that it is not visible to the passengers. The ordinary pace will be ten miles per hour, which can, however, be easily increased. The screw is 12in. in diameter, with 11in. pitch, and makes 450 revolutions per minute.—*Northern Echo.*

ELECTRICITY AND CHOLERA.—"Amongst the means of fighting cholera," says the *Annales de l'Electricité*, "ozone is considered one of the most successful. It is supposed that this gas destroys the germs suspended in the air, and it is to its production that turpentine, lavender, and thyme owe their disinfectant qualities. Dr. Vigoroux has proposed a means for obtaining ozone in times of epidemics. He would electrify patients on an insulated stool by a simple static electric machine. The well-known smell of ozone becomes more marked if without causing a spark a conductor is approached to the patient. By this means ozone is not only given up to the air, it is produced at the very surface of the body—that is to say, at the very limit that the poisonous agent must itself pass to become dangerous. It is a kind of atmospheric breastplate against the invasion of microbes. We may add that many years ago we have heard of induction coils being used in hospitals to give off ozone."

WHAT AMERICANS THINK OF OUR CABLE MANAGEMENT.—The *Morning Journal* of New York says that:—"Efficient and able management is the key to success in all business enterprises, and in none more so than in cable service. The Direct United States Cable Company is an example of this. Splendidly equipped and with ample means behind it, nevertheless to the lynx eyed and skilled direction of Mr. John W. Fuller, its secretary and traffic manager, it owes that perfection of organisation which has meant profit for its owners as well as satisfaction to its patrons. That Mr. Fuller has brought his fine executive abilities and notable electrical knowledge to bear, under the still higher leadership of Mr. John Pender, the great cable king, is perhaps the ultimate reason of its success. At its six-monthly meeting on the 25th ult. it showed that over 250,000dols. went to the account of profit for the half year—a splendid result of great energies unremittingly devoted to the care and prosperity of a great property."

A WATERSPOUT.—During a thunderstorm a few days ago a singular phenomenon, which is more often observed at sea than on land, was witnessed at Simmondley, a village about one mile from Glossop. Behind the village rise precipitous hills, which girt part of the hamlet in something like the shape of a horseshoe, and in the centre of this runs a deep clough. When the storm was at its height the villagers became affrighted by a terrible thunderclap, which seemed to rend the heavens. In a moment or two an immense volume of water, carrying with it large quantities of earth and stones, rushed down the clough and flooded some of the cottages five feet deep with water.

Digitized by Google

The phenomenon was described by the natives as "the bursting of a cloud" (literally a waterspout), and its tremendous force may be gathered from the fact that where the water rushed to the earth it made a great indentation in the hill side sufficiently large in width and length to enclose a house. The cavity is about 12 yards long and nearly 8ft. deep.

A Cataract Lighted by the Electric Light.—Our contemporary *L'Electricité* has a full-page woodcut showing one of the cataracts on the Rhine, near Schaffouse, lighted by the electric light. It appears that the Steam Navigation Company on the Rhine and Lake Constance have inaugurated a night service with steamers having Bürgin lamps, for lighting the picturesque banks of the river. The boat started at nightfall from Schaffouse and made the passage as far as Biesengen. During the passage the passengers were enabled to admire the river and its banks lighted as if by daylight; the pilot could pick out at a distance the various beacons placed close to the water level, and could even bring the steamer alongside at Biesengen without the slightest danger. But not contented with merely lighting the steamers along their road, and to show off the cataracts or falls in a more imposing manner a powerful electric arc was placed on the right bank of the river, throwing its beam on the well-known falls of Schaffouse.

Signalling between London and Portsmouth.—Arrangements have been made by Major Thrupp, Inspector of Army Signalling, to place London and Wimbledon in communication with the Spithead forts by day and night for three days this week, the general idea on which the experiments are being carried out being that an enemy having landed on the South Coast and intercepted telegraphic communication between Portsmouth, London, and Aldershot, communication has to be maintained by signalling by means of flags and the heliograph by day, and by night with the flashing lamp and a system of rockets. The stations are Wimbledon to Epsom Downs, eight miles; Epsom Downs to Merrow Downs, near Guildford, thirteen miles; Merrow Downs to Hungry Hill, twelve miles; Hungry Hill to Hind Head, ten miles; Hind Head to Butser Hill, near Petersfield, fourteen miles; and Butser Hill to the Spithead forts, fourteen miles. To enable practice at longer distances, Merrow Downs and Hind Head were cut out for a time, so that the messages went from Wimbledon to Epsom, Epsom to Hungry Hill, Hungry Hill to Butser Hill, and Butser Hill to the Spithead forts, thus giving two distances of over twenty miles. At the time of writing we do not know the amount of success obtained in this experiment.

The Electric Light at the Law Courts.—The installation of machines and engines has hitherto been only temporary, being in an iron shed on the waste ground to the west of the building. The permanent plant will be placed in the crypt under the great hall. This change involves a considerable amount of labour, as the existing steam boilers, which were only designed for the ventilation of the building, will have to be removed, as also will nearly all the existing steam and exhaust pipes as well as several large tanks. When completed there will be two 100 horse-power Galloway patent boilers, two single cylinder horizontal engines, each indicating 105 H.P., at 60 revolutions, either one being capable of doing the whole of the lighting. The requisite speed for the dynamos, about 1,100 revolutions, will be obtained by two sets of shafting, with friction clutches on the first, so as to allow either or both the engines to be worked as necessary. Six Crompton-Burgin compound wound 10-unit machines, all coupled parallel, will produce the current for the general illumination, lighting about 650 twenty candle-power Swan lamps. A small Willans high speed engine, with electric governors, will drive a 6-unit machine for lighting an all day circuit of about 45 lamps. There will also be two Burgin series machines, each lighting a series of three 4,000 candle-power Crompton-Crabb arc lamps, in the central hall. The engines, boilers, &c., are being fitted by Messrs. Galloway and Sons, and the dynamos, cables, switch boards, &c., by Messrs. R. E. Crompton and Co., who fitted and wired the building, and under whose supervision the lighting was carried on until May last, when it was taken over by the Government, under the control of Her Majesty's Office of Works.

E.M.F.—Mr. G. Chaperon writes in the *Comptes Rendus* on a probable cause of the difference between the observed electromotive force of galvanic couples and that calculated from thermo-chemical data:—"Amongst galvanic couples which have an actual electromotive force considerably different from that calculated from thermo-chemical data, there are several which seem to exhibit phenomena due to the polarisation of the dissolved metal, and although these couples have a positive electrode which cannot polarise, they yield a current, the electromotive force of which falls very rapidly to zero. The author has determined the E.M.F. of several couples of this kind, and finds that they constitute systems which are polarisable up to the point of decomposition of the electrolyte into its elements, the difference of potential between the two electrodes increasing between zero and the point of electrolysis, and even beyond the latter, in accordance with an uninterrupted law. If $T\,m\,R$ and $T\,m\,H$ represent the work or electric energy corresponding, at a given temperature and pressure, with the absorption or restitution of the elements R and H of an electrolyte, by an electrode of the polarisable metal *m*, then $T\,m\,R$ and $T\,m\,H$ are not constant, but vary between very wide limits, diminishing as the proportion of R and H absorbed increases. It follows that the chemical work corresponding with the electric energy given back by the two polarised electrodes will generally be $T\,R\,H - T\,m\,R - T\,m\,H$, where $T\,R\,H$ is the energy of formation of the electrolyte. When polarisation follows an uninterrupted law, this value of the chemical energy will vary from $T\,R\,H$ to zero, between the point of electrolysis and the state of neutrality of the electrodes which is represented by the equation $T\,R\,H - T\,m\,R - T\,m\,H = 0$. Between the same limits, $T\,m\,R$ and $T\,m\,H$ will vary from zero to two positive values, each of which will, at the limit, be smaller than $T\,R\,H$, and it is the value of $T\,m\,R$ satisfying equation (1) which ought to be used instead of the heat of combination in calculating the theoretical E.M.F."—*Chem. Soc. Journal.*

The French Balloon Experiments.—Further light is thrown on the recent balloon experiments at Meudon by the following telegram from the Paris correspondent of the *Standard*, which is dated Tuesday night. He says:—"Messrs. Renard and Krebs' reported discovery of a steerable balloon occupied the Paris Academy of Sciences again yesterday. A letter was read from M. Dupuy de Lome, a member of the Academy, well known as a zealous labourer in the science of aeronautics. It is, in fact, by the principles laid down by M. Dupuy de Lome that Messrs. Renard and Krebs have been guided in the construction of their balloon. In the letter referred to M. Dupuy de Lome affirms that his own experiments in 1875 conclusively proved the practicability of guiding balloons in a horizontal direction. His machinery, however, did not permit a greater speed than 10 kilometres an hour, and this was not sufficient in face of a wind of

Digitized by Google

any superior degree of velocity. Messrs. Renard and Krebs will, however, says M. de Lome, employ, in an experiment to be made at an early date, a motor of a double power to that which he had used, and attain a speed of twenty-five kilometres per hour. The great progress made is, he adds, the invention of a machine which, including batteries and accessories, weighs only five hundred and sixty kilogrammes. M. Dupuy de Lome expresses himself altogether very sanguine upon the achievements of his fellow labourers, but it will seem to most people that light as the new electric machinery may be in comparison with that hitherto experimented with, a weight of five hundred and sixty kilogrammes is a dangerously large proportion of the total weight, namely, two thousand kilogrammes, of Messrs. Renard and Krebs' balloon. Various explanations are given of the reasons preventing the aerial voyage from Meudon to Paris last Saturday, which thousands of persons had assembled to witness. The truth is, that in the previous experiment the machinery had been damaged, and some modifications of detail had been judged desirable before further experiments were undertaken."

SIMULTANEOUS TELEGRAPH AND TELEPHONE MESSAGES.—M Van Rysselberghe and the telegraphic engineers of the Belgian Government are now engaged in completing the arrangements and modifications necessary for the simultaneous transmission of telegraphic messages and telephonic conversations. The Bell Telephone Company is also carrying out some important works in its central offices, as well as laying down junction lines, so as to permit of its subscribers using their instruments for distant speaking. At Brussels alone the length of the lines laid down for this purpose is nearly 70 kilometres = 45 miles. This brings up the length of wires in Brussels and its neighbourhood to over 1,100 kilometres = 730 miles, serving more than 600 stations. The total length of this company's wires in Brussels, Antwerp, Ghent, Verviers, and Charleroi is about 1,500 kilometres = 1,000 miles, serving more than 2,500 stations. Independently of the conceded lines, there are a number of private lines in Belgium established on the property of their owners. By the connecting of certain stations already in communication with the central offices, telephone lines of 15 and 20 kilometres, or 10 and 15 miles, have been worked. In the Antwerp concession, with which is connected the military system of that city, there is a combination of lines having a length of 33 kilometres or 22 miles. This combination is complicated by the intercalation in the circuit of five calling signals, which by their additional resistance, still further increase the total resistance. Notwithstanding this fact, the calls by the magneto-electric bells, imported into Belgium by the International Bell and Telephone Company, of New York, as also the telephonic communications by means of Blake microphones and Bell receiving instruments, are made without difficulty. Moreover, experiments have been made in Belgium, even on the longest line in the kingdom, with Blake and Bell instruments; and between Ostend and Arlon, a distance, as the crow flies, of 270 kilometres or 180 miles, telephonic messages have been exchanged by these means.—*Bulletin de la Compagnie Internationale des Téléphones.*

ELECTRIC RAILWAY IN CLEVELAND, U.S.—With reference to the trial trip of the new electrical street car invented by Messrs. Knight and Bentley, late of the U.S. Patent Office, and constructed by the Brush Electric Company, which took place on the Garden-street line of the East Cleveland Street Railroad Company, referred to in our last issue, the Cleveland *Iron Trade Review* of August 2nd adds the following particulars:—About a mile of the track on the former line, running out of New and Quincy streets, had been prepared for the test by the construction of a boxed trench, running between the rails, receiving the two small channel irons, which served as conductors of the electricity. Beneath the centre of the car was boxed the motor, a 15 horse-power Brush dynamo, connected with which were four coil wires, passing over large pulleys located beneath the seats, thence transmitting the motion to the axle. The action of this lever at the front of the car caused a copper brush, running in the channel, to come in contact with the electrical conductors; the armature began to revolve rapidly, and the axles and wheels of the car were propelled forward, at first slowly, at length at a speed of probably five miles an hour, though the inventors claim that from 8 to 15 miles an hour can be obtained. The electricity was generated by a 30 horse-power dynamo (*sic*) located some four miles away, and conducted to the street car barns on a No. 6 wire. Ultimately, it is the intention, we understand, to locate a full electric power plant at the main stables of the street car company on Euclid-avenue. The results of Saturday's experiments were satisfactory, though, of course, by no means complete. The car, loaded with passengers, made two short trips, running smoothly, rounding curves, and obeying the lever quickly. On Monday much more desirable results were reached, the car being run to Woodland Avenue Cemetery, a distance of about three-quarters of a mile; but by reason of the breaking of some portion of the apparatus it had to be taken back to the barns for repairs. It may be remarked that this piece of track is probably the roughest to be found in the city of Cleveland.

AN ELECTRIC TORPEDO BOAT.—Professor Tuck's electric submarine torpedo boat looks at a little distance very much as if it had been constructed by laying a large row boat upside down, on top of another large row boat, fastening it there, and painting them both sea green. The shell is of iron, however. The boat is 30ft. long. It is ballasted with lead, so as to sink to the water's edge, and its displacement is 20 tons. In the centre of what may be called the deck is sunk a well hole. By a simple air lock arrangement it affords a passage between the interior and the exterior of the vessel, even when the vessel is wholly under water. It is also the captain's look-out station, and is capped with a dome of heavy glass, so that if he chooses he can exclude the water and stand in the pit with his head and shoulders above the top of the boat, or he can leave the glass off and stand there in a diving suit. Close to his hand is a signalling steering apparatus, which transmits his orders to the helmsman down below. The boat has three rudders, one an ordinary vertical rudder at the stern, and the other two horizontal blades on the port and starboard quarters. These last help to govern the boat's movements up and down. To sink her, water is pumped into her compartments; to raise her, air is pumped in, and the water is forced out. Compressed air is stored aboard in six inch pipes. There is also an apparatus for reoxygenating air that has already been breathed. Moreover, there is a simple arrangement by which the ends of two rubber tubes can be floated up to the surface of the water and opened to the supply of fresh air up there. An electric motor, driven by force from storage batteries, runs the propeller. The interior, which is arranged for a crew of four or five men, is lighted by incandescent lamps. An indicator shows the distance of the boat beneath the surface. The estimated speed of the boat under water is eight knots. The torpedoes are to be carried outside the vessel, one at the prow and one at the stern. They are to be held there in

Digitized by Google

iron cylindrical sheaths by electro-magnets, which will release them when the current is cut off. They are ballasted with cork, and after placing one of them the torpedo boat retires to a distance, unreeling as it goes two wires, by which, at a proper distance, the torpedo is fired. The lead ballast proved insufficient to sink the boat below the water. On a recent trial near the Delamater Iron Works, New York, a crew of three men went aboard her, and, with Mr. John Rice as captain, a test was made of the electric engine. It drove the boat several miles up and down the river at a speed of ten knots, says the New York *Sun*. She answered her rudder well. She will soon be tried under water.

Electric Lighting.—The Board of Trade report that four applications for provisional orders were received on or before December 21st, 1883. One of these applications was made by a local authority, and the remainder by companies. The names of the applicants and the districts proposed to be lighted were:—1. The Edison and Swan United Electric Lighting Company; the object of this order was to transfer to the Edison and Swan United Electric Lighting Company certain rights, powers, and obligations conferred upon the Edison Electric Lighting Company by the provisional orders granted to those companies last Session in respect of various districts in the metropolis. 2. The Mayor, Aldermen, and Burgesses of the borough of Bury St. Edmunds. 3. The Telegraph Construction and Maintenance Company and the West London Electric Lighting Company, or one of them. 4. West Middlesex Electric Lighting Company. All these applications were granted by the Board of Trade. These have now received the Royal assent. All the sixty-nine provisional orders granted by the Board of Trade last Session were subsequently confirmed by Parliament. The orders granted to companies contained provisions either that the undertakers were to satisfy the Board of Trade that they were in a position to carry out the compulsory works or to appropriate a certain sum as a separate capital for the purposes of the undertaking, and to deposit or secure a specified sum of money to the satisfaction of the Board of Trade. In the event of these requirements not being complied with within a period of six months from the commencement of the order, or such extended period as might be approved by the Board, the Board of Trade were empowered to revoke the order on such terms as they might think just. The above period of six months expired on the 25th February, and before that time applications were received from the undertakers of all the orders (except one where the promoters had already gone into liquidation) for approval of an extension of time. After consulting the various local authorities concerned, the Board of Trade approved of an extension of time in 24 cases, and declined to approve of the others, in some cases in consequence of the opposition of the local authority, and in the case of the Metropolitan Brush Electric Light and Power Company, because that company had decided to liquidate its affairs. Applications were later made for a further extension of time as regards the orders of the Incandescent, the Provincial Brush, and the South-Eastern Brush Companies; in some cases the further extension was granted, and in other cases they are still under consideration. The Board of Trade are advised and propose to revoke those orders in respect of which no extension of time has been approved. Thus electric lighting, says the *Mechanical World*, in public is making little or no progress, and the field is left open to the gas companies.

Electricity Among the Ancients.—In Dr. Falconer's "Observations on the Knowledge of the Ancients Respecting Electricity," we have an account of amber, whether from Liguria or the north, and of Lapis Lyncurius "which attracts straws and leaves, copper and iron," and of electric fishes, subjects now better known to the ordinary reader; we have, however, less known speculations suggested to Dr. Falconer by "an ingenious and learned gentleman," on the knowledge of the Etruscans, familiar also to Numa Pompilius, who is said to have drawn fire down from heaven. This statement is corroborated by the manner of his successor's death. Tullus Hostilius was killed, the ingenious gentleman supposes, by mismanaging the process of bringing down the lightning. This is a fair explanation of the matter, and in the words of Livy, 'tradunt ira Jovis sollicitati prava religione, fulmine ictum cum domo conflagrasse." Livy says of him "that after examining the commentaries of Numa and finding there a description of certain occult and solemn sacrifices performed to Jupiter Elicius, he set himself to execute these in private; but from some impropriety in the commencement and conduct of these operations, he not only failed of being favoured with any intercourse with any celestial beings, but was, through the wrath of Jove, excited by his being importuned with such irregular rites and ceremonials, struck with lightning, and consumed together with his palace." We throw aside all these things in our new histories, and Numa Pompilius becomes an idea, like the frogs of Marcus Marci. Dr. Falconer's extract from Lucan is also very interesting, saying that the Etruscan Aruns collected the fires of heaven, and buried them in the earth with sad murmur. "What is this," he says, although the words have inverted commas as if they were a quotation, "What is this but the description of the use of a conductor to secure buildings from being struck by lightning?" The words are:—

> "Dumque illi effusam longis anfractibus urbem
> Circumeunt, Aruns dispersos fulminis ignes
> Colligit, et terræ mæsto cum murmure condit."

It certainly reads as if the fire itself were collected, but we fear the critics and dictionaries are against Dr. Falconer, and consider that it was the place struck by lightning or the objects struck. *Fulgur*, we are told, is an object struck by lightning, and the *Bidental* a place struck by lightning; both, however, have a sacredness, or at least awe, attached to them. In "Lucan's Pharsalia," translated by H. D. Riley, B.A., B. I., 585—599, we have—"Of whom, Aruns, the one most stricken in years inhabited the walls of deserted Luca, well skilled in the movements of lightnings, and the throbbing veins of the entrails, and the warnings of the wing hovering in the air." B. I., 503—610, "And while in prolonged circuit they go round about the emptied city, Aruns collects the *dispersed objects struck* by flames of lightning, and with a lamenting murmur buries them in the earth, and bestows a name upon the consecrated spots. Then does he urge onward to the altar a male with selected neck." Still, without pretending to a critical knowledge of Latin, we must seek some evidence that *ignes* meant the things struck by fire. If we look at Smith's Dictionary, we find that the priests "Bidentales" collected the earth and buried it in the ground with a sorrowful murmur, but the proof of this painful expression is the very passage in question, and we may yet ask if *condere fulgur* means the same as *colligere dispersos fulminis ignes*. Dr. Falconer seems to have found the truth hidden from the scholars unskilled in physics. He then endeavours to trace the use of spears as conductors, and quotes Livy's account of a spear which burnt for two hours and was not consumed. He gives Plutarch's account of balls of fire that were seen on the points of the soldiers' spears, and refers to the lightning on ships' masts, and the fires of St. Elmo. This connects the worship of spears with fire worship.—From "A Centenary of Science in Manchester," by R. Angus Smith, F.R.S., Ph.D., LL.D.

THE INDUCTION OF CURRENTS IN CORES.

BY OLIVER HEAVISIDE.

(CONTINUED FROM PAGE 339.)

Determination of Constants—Conjugate Property.

Referring to Fig. 2, by superimposing any number of normal systems, of which the first four only are shown, taken of any absolute magnitudes, we may produce an immense variety of distributions of magnetic force. They will all, by the manner of their conduction, be decomposable into the normal systems from which they arose. Now, by the reasoning previously stated, when the whole series of normal systems is taken, we may, by properly choosing the values of the A's in the series $A_1v_1+A_2v_2+\ldots$, make it represent *any* chosen function of r; of course single valued. The decomposition of the given function into normal systems is most easily effected by making use of the conjugate property $\int v_1v_2rdr=0$, possessed by every pair of different normal functions, the limits of integration being 0 and a, the axis and the boundary of the core.

The proof is easy. For u_1 and u_2, by (67), satisfy

$$\frac{1}{r}\frac{d}{dr}r\frac{dv_1}{dr}+n_1^2v_1=0, \text{ and } \frac{1}{r}\frac{d}{dr}r\frac{dv_2}{dr}+n_2^2v_2=0.$$

Multiply the first of these by v_2r, the second by v_1r, subtract the second result from the first, and then integrate with respect to r from $r=0$ to $r=a$. We find immediately,

$$(n_1^2-n_2^2)\int v_1v_2rdr=\Big[r(v_1v'_2-v_2v'_1)\Big]_0^a \quad . \quad . \quad (76)$$

the accents denoting differentiation to r. The right hand number vanishes at both limits, because v_1 and v_2 vanish at $r=a$, v'_1 and v'_2 being then finite; whilst both factors of rv'_1 and rv'_2 vanish with r, v_1 and v_2 being then finite. Hence, if n_1 and n_2 are different, we have

$$\int v_1v_2rdr=0; \quad . \quad . \quad . \quad . \quad . \quad (77)$$

the conjugate property to suit the present case. Now, given H_0 as a function of r, the initial distribution, to expand it in v's, thus

$$H_0=A_1v_1+A_2v_2+A_3v_3+\ldots,$$

multiply both sides by rv_1dr and integrate between limits 0 and a. We get

$$\int H_0rv_1dr=A_1\int v_1^2rdr;$$

since, by (77), all the rest vanishes. This gives the value of A_1, and similarly for the other coefficients, any one being given by

$$A=\frac{\int H_0vrdr}{\int v^2rdr} \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (78)$$

Using the particular u concerned. The denominator may be evaluated by (76). For, if in (76) we make $n_1=n_2$, making $v_1=v_2$ and $v'_1=v'_2$, it assumes the form $0\times\int v^2rdr=0-0$, and the integral, being the sum of squares, and therefore not vanishing, is to be found by the ordinary process. Differentiate (76) with respect to n_1^2, and then make $n_1^2=n_2^2=n^2$; this gives

$$\int v^2rdr=\Big[r\Big(\frac{dv}{dn^2}v'-v\frac{dv'}{dn^2}\Big)\Big]_0^a \text{ generally,} \quad . \quad . \quad . \quad (79)$$

$$\text{and } =av'\frac{dv}{dn^2}, \ (r=a), \text{ in present case.}$$

Now $\dfrac{dv}{dn^2}=\dfrac{1}{2n}\dfrac{dv}{dn}$, and, by (70), $\dfrac{dv}{dr}=n\dfrac{dv}{dn}$; therefore,

$$\int v^2rdr=\frac{a^2}{2n^2}\Big(\frac{dv}{da}\Big)^2=\frac{a^2}{2}\Big\{J_1(na)\Big\}^2 \quad . \quad . \quad . \quad (80)$$

$\dfrac{dv}{da}$ being the value of $\dfrac{dv}{dr}$ at $r=a$. Hence, by (78) and (80)

$$A=\frac{2n^2}{a^2}\frac{\int H_0vrdr}{\Big(\frac{dv}{da}\Big)^2}=\frac{2}{a^2}\frac{\int H_0vrdr}{\{J_1(na)\}^2} \quad . \quad . \quad . \quad (81)$$

Thus, when H_0 is given, the expansion is effected, and the magnetic force is known at any subsequent time.

$H_0=$ *constant.*

Put a battery on the coil circuit. It sets up ultimately $H_0=$ constant in the core. Break the circuit, or make its resistance very high, removing the E.M.F. Never mind the slight loss of energy in sparking, as, the core being free for induced currents, nearly all the energy will be dissipated therein. We can now evaluate the numerator in (81).

$$\int H_0rvdr=H_0\int rvdr=-\frac{a}{n^2}\frac{dv}{da}=+\frac{a}{n}J_1(na)$$

by (70) first, integrating, and then comparing with (74). This makes (81) become

$$A=2H_0/naJ_0(na),$$

and the complete solution is therefore

$$H=2H_0\Sigma.\frac{J_0(nr)}{J_1(na)}.\frac{e^{Dt}}{na} \quad . \quad . \quad . \quad . \quad (82)$$

the numeration to include all values of n.

The current density is got from this by differentiation; thus

$$\gamma=-\frac{1}{4\pi}H'=+\frac{H_0}{2\pi}\Sigma\frac{J_1(nr)}{J_1(na)}\frac{e^{Dt}}{a} \quad . \quad . \quad . \quad (83)$$

In establishing the solution (82) of the most simple case that presents itself (curve to be given in Fig. 3), we have entered more into detail than at first intended; as a refresher to the memory of readers who are acquainted with the methods employed, for the education of readers who may be only learning them, and because in the more complex cases to follow much of the reasoning will be exactly similar, so that the investigations may be given more briefly without loss of intelligibility. At the same time, there are numerous details and side matters of interest that must be omitted. Otherwise, we should "go on for ever," like the brook in lordly Alfred's charming poem, that came from haunts of cocks and hens, and made a sudden sally, and rumbled in and out the fern, and tumbled down a valley, with a number of other pranks, proclaiming at equidistant intervals its superiority to man in the constancy of its circulation.

Magnetic Energy and Dissipation.

The magnetic energy per unit volume being $\mu H^2/8\pi$, the amount T in unit length of core, by (82) and the conjugate property (77) making products vanish, is

$$T=H_0^2\frac{4\mu}{8\pi}\int_0^a 2\pi rdr\Sigma\frac{J_0^2(nr)}{J_1^2(na)}.\frac{e^{2Dt}}{n^2a^2}=\frac{\mu}{2}H_0^2.\Sigma\frac{e^{2Dt}}{n^2}. \quad (84)$$

by integrating, and using (80). (In these series it is of course only necessary to operate on one term, since they are all alike in their properties.)

This, of course, vanishes ultimately, the D's being negative. At starting, $t=0$, we know, from H being constant, that $T=\pi a^2\mu H_0^2/8\pi=\mu a^2H_0^2/8$; hence we must have, by (84),

$$\tfrac{1}{8}\mu a^2H_0^2=\tfrac{1}{2}\mu H_0^2\Sigma n^{-2}; \text{ or, } \tfrac{1}{4}=\Sigma(na)^{-2},$$

the values of na being those in (75), and their companions. This is true, for, examining the form of the expansion (70) of $J_0(nr)$, the sum of the squares of the reciprocals of the roots of $J_0(nr)=0=$ coefficient of the second term with the sign changed, *i.e.*, $\frac{1}{4}$.

To test that, the formulæ make all the energy be dissipated in the core according to Joule's law; the heat per second per

unit volume being $\rho\gamma^2$, the total per unit length of core, from the beginning to the end of the discharge, by (83), is

$$\frac{\rho H_0^2}{2\pi a^2}\int_0^\infty dt \int_0^a rdr \Sigma \frac{J_1^2(nr)}{J_1^2(na)} e^{2Dt} ; \quad . \quad . \quad . \quad (85)$$

where again we omit products, on account of the conjugate property of the normal systems of current, thus proved.

$$J_1(n_1r)\, J_1(n_2r) rdr = \frac{1}{n_1 n_2}\int \frac{dv_1}{dr}\frac{dv_2}{dr} rdr = \frac{r}{n_1 n_2}. \frac{n_1^2 v_1 v_2' - n_2^2 v_2 v_1'}{n_1^2 - n_2^2} \qquad (86)$$

by integrating and using (79). This vanishes when the limits are 0 and a.

Evaluating by differentiation for the case $n_1 = n_2 = n$, we get

$$\int_0^a J_1^2(nr) rdr = \frac{a^2}{2} J_1^2(na) \quad . \quad . \quad . \quad . \quad (87)$$

and using this in (85), we obtain, after integrating to t as well,

$$-\Sigma \frac{\rho H_0^2}{8\pi D}, \text{ or } \frac{\mu H_0^2 a^2}{2} \Sigma \frac{1}{(na)^2} = T, \ (t = 0),$$

as before found.

(TO BE CONTINUED.)

THE ELEMENTS OF ELECTRIC LIGHT ENGINEERING.

BY C. W. S. CRAWLEY.*

(CONTINUED FROM PAGE 343.)

Before starting a dynamo machine the collector or commutator should be well examined to see that it is properly clean; if not, it should be cleaned by rubbing it with a piece of linen rag, and then it should be just touched with oil (preferably lard oil) by holding an oily pad of clean wash-leather lightly against it when rotating. This ought to be done several times in the course of the day if the machine be running continuously. In the case of the Brush dynamo it should be done every half hour or hour. The brushes must be looked to; they should press evenly and firmly against the collector, but ought not to be screwed against it too tightly, or they will wear out very fast. When this happens, and they become ragged and uneven, they should be taken off, trimmed with a pair of shears, and then replaced. In putting the slit metal brushes on the Brush machine they should be clamped in the brush holders, so that when the machine is turned against the brushes the edges of the air insulation spaces on the commutator just do not catch the forward edges of the brushes.

See that the lubricators for the bearings are well supplied with oil before starting, and are in good working order, and that there is nothing† lying about that may catch in the armature when revolving. If on starting the machine and turning on the current there is much sparking at the brushes, it shows that their lead is wrong, and they must either be advanced slightly in the direction of rotation, or *vice versâ*, until the sparking is reduced to a minimum. In some machines the brush holders are mounted on a rocking arrangement, and so can be easily shifted when the machine is running; in the others the shifting must be done by putting the brushes further in or out of their holders.

When the current that a machine is generating is increased or diminished, increased sparking will probably be seen at the brushes, necessitating an alteration of the lead; as a general rule, if the current be increased the lead must be also increased, *i.e.*, the brushes must be slightly advanced in the direction of rotation, and *vice versâ*.

In altering the lead on a Brush machine where there are two or three pairs of brushes, each pair on a separate rocking arrangement, the first pair should be shifted very slightly forward or backward, as the case may be, then the next pair in the same manner, and, if there are three pairs, the third; then the first again, and so on, until all the pairs have the proper lead.

As we have several times mentioned the Brush machine without having described it, we shall now do so. The armature of this dynamo consists of a ring with projecting teeth, between which the coils are wound. There are eight of these coils, the inner end of four of which is joined to the inner end of the one diametrically opposite to it, while the outer ends are brought to the various segments of the commutators, of which there are two or three. When the machine is working, one pair of coils—that in the least useful part of the field (*i.e.*, when the rate of change of the lines of force passing through them is a minimum)—is cut out of action. The pair of coils at right angles to these, which is in the most useful part of the field, is in contact with one pair of brushes, while the other two pairs of coils, which are neither in their best nor worst positions, are joined together in parallel arc between the other pair of brushes. The two pairs of brushes and the coils between them, the field magnets, and the external circuit are all in series, as shown symbolically in Fig. 21, where the pair of coils between the brushes A A′ is in the best position in the field, and the two pairs in parallel between B B′ are in fairly good positions, each of these latter pairs having the same E.M.F. developed in it.

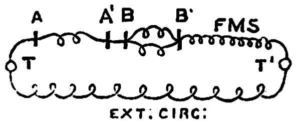

FIG. 21.

A A′ are one pair of brushes touching one commutator, and B B′ the other. For one eighth of a revolution there is one pair of coils in the best position between A A′, and two pairs in parallel between B B′; for the next eighth one pair in the best position between B B′, and two pairs in parallel between A A′; then, as before, for the next eighth, and so on, each pair of coils being cut out of circuit twice every revolution. The resistance, therefore, of a Brush machine consists of the resistance of one pair of coils plus half the resistance of one pair plus the resistance of the field magnets. If the resistance of the field magnets equals three ohms, and that of one pair of coils equals 1·215 ohm, the internal resistance of the machine is 1·215 + ·607 + 3 = 4·822 ohms, which is the resistance of a six-light machine.

In some machines the field magnets are connected up between the two pairs of brushes, *i.e.*, between A′ and B. The field magnets consist of two north poles, with large flat pole pieces placed opposite one another, and also two south poles placed in the same manner.

The Shunt Dynamo.

The next dynamo we shall consider is the shunt. In this machine the field magnets are wound with a great length of fine wire so as to have a high resistance, and are arranged in multiple arc with, or (as its name implies) as a shunt on, the external circuit.

As will be seen from Figs. 22 and 23, each brush is connected to one of the terminals and also to one of the ends of the fine wire with which the field magnets are wound. When the armature is rotated and a current generated in it, this current goes out by the + brush B to the terminal T, where it divides, part flowing round the field magnets F M, and part through the external circuit P (the proportion flowing through each being inversely as their resistances), and through these two branches it comes back to the − brush B and into the armature.

To find the Internal Resistance of a Shunt Dynamo.

In finding the resistance of a series dynamo it is not necessary to know the resistance of the armature and field magnets separately, as the internal resistance consists of the resistance of the two in series. In the case of the shunt machine, however, we *do* require to know the resistance of the armature and

---

* Mr. Rimington is unable to continue his assistance with these articles, which will therefore be completed by Mr. Crawley.—ED. *E.*

† Particularly iron "tools"; also bringing an iron or sheet tin oil can too near the armature should be avoided.

field magnets separately, as the total resistance of a circuit worked by a shunt dynamo is the resistance of the armature plus the joint resistance of the external circuit and the field magnets. Fig. 24 will perhaps show this better than the former one did.

Here the resistance of the circuit is $A+\frac{BP}{B+P}$, B being the resistance of the field magnets.

To measure A, connect the wires from the bridge box to the terminals T and $T_{\prime}$, having previously disconnected one end of the field magnet wire from one of the terminals or brushes to which it is attached.

To measure the field magnet resistance, join the field magnet wire again to the terminal or brush from which it was discon-

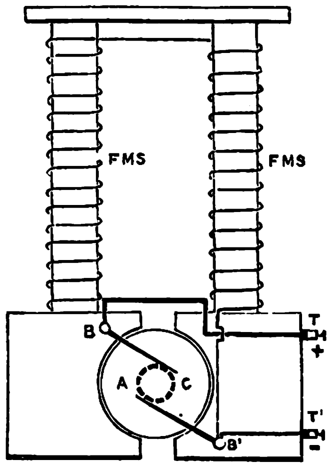

Fig. 22.—Shunt Dynamo.

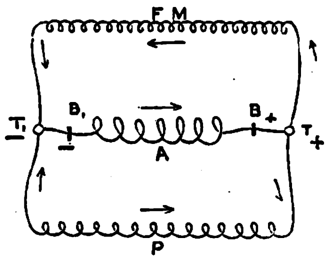

Fig. 23.—Extended Shunt Dynamo Circuit.

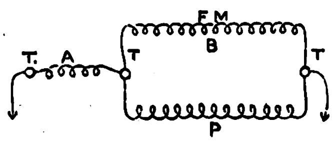

Fig. 24.

nected, and take one or both brushes off the collector or commutator; this will give the resistance of the field magnets.

Another method of finding these resistances without having to disconnect the field magnet wire is as follows:—

Firstly. Take the resistance of the machine through the terminals, with the brushes touching the collector; this will give us the joint resistance of the armature and field magnets, or $\frac{AB}{A+B}=m.$

Secondly. Take the brushes off the collector, and find the resistance as before; this will be the resistance of the field magnets, or B.

Then $$A=\frac{Bm}{B-m}$$

These resistances should be found in the same manner as was described for the series dynamo.

Suppose we are taking the measurements of a shunt dynamo, and we find the resistance of our lead wires from the bridge = ·004 ohms.

m + resistance of lead wires = ·3709 ohm.
B + „ „ „ = 4·464 ohms,
therefore m = ·3708 − ·004 = ·3668 ohm,
and B = 4·464 − ·004 = 4·46 ohms

then $$A=\frac{4{\cdot}46\times{\cdot}3668}{4{\cdot}46-{\cdot}3668}={\cdot}3996 \text{ ohm.}$$

Suppose, now, we run this machine through an external resistance of 1 ohm.

Then the total resistance in the circuit

$$={\cdot}3996+\frac{4{\cdot}46\times 1}{4{\cdot}46+1}=1{\cdot}2168 \text{ ohm.}$$

And if the total E.M.F. produced by the machine were 50 volts, the current flowing in the armature would be

$$\frac{50}{1{\cdot}2164}=41{\cdot}1 \text{ amperes,}$$

that in the external circuit

$$=41{\cdot}1\times\frac{4{\cdot}46}{4{\cdot}46+1}=33{\cdot}55 \text{ amperes,}$$

that round the field magnets

$$=41{\cdot}1\times\frac{1}{4{\cdot}46+1}=7{\cdot}55 \text{ amperes.}$$

Let in a shunt dynamo

A = resistance of the armature,	a = current in same.
B = „ „ field magnets,	b = „ „
P = „ „ external circuit,	p = „ „
E = total E.M.F.	e = terminal E.M.F.

As the current is generated in the armature, and when it leaves the brushes divides, part going round the field magnets and part through the external circuit, the current flowing through the armature is equal to the sum of the currents in the field magnets and external circuit, or $a=b+p$.

As it would be inconvenient to have to measure a or b we must find a and b in terms of p.

We have by Ohm's law

$$b=\frac{e}{B} \quad \text{and} \quad p=\frac{e}{P};$$

therefore $$a=\frac{e}{B}+\frac{e}{P}=\frac{e\,(P+B)}{BP}=\frac{p\,(P+B)}{B}.$$

This last equation gives us the current through the armature in terms of the current in the external circuit and the external and field magnet resistances.

A more convenient expression is

$$a=\frac{e}{B}+p,$$

p, the current in the external circuit, being easily obtained by means of an ammeter or other current measurer placed in that circuit, and e the terminal E.M.F. being obtained by a voltmeter attached to the terminals of the dynamo, as in the case of the series machine.

To obtain the total E.M.F. of the machine observe as before the terminal E.M.F. and current in the external circuit, then

$$E=e+aA=e+A\left(\frac{e}{B}+p\right)$$
$$=\frac{e\,(A+B)+ABp}{B}.$$

While the series dynamo gives its greatest E.M.F. and current when short circuited, the shunt, on the other hand, gives a very small E.M.F. and current when thus treated, as the small current generated by the residual magnetism of the field

Digitized by Google

magnets all goes through the short circuit instead of round the field magnet coils.

Again, while a series dynamo gives practically no E.M.F. when on open circuit (*i.e.*, when the external resistance is infinite), a shunt dynamo gives its greatest E.M.F. in this condition. On this account a shunt machine should be short-circuited before it is switched on to a circuit of incandescent lamps, and then the short circuit taken off; or a resistance may be put into the lamp circuit sufficient to prevent the extra high E.M.F., derived from the machine running on open circuit, from making the lamps light up above their normal candle-power at the instant the machine is first switched on. Of course this resistance can be cut out immediately the machine is once on to the lamps.

The shunt machine is exceedingly useful where we have a varying external resistance, such as a number of incandescent lamps arranged in parallel arc, because the greater the external resistance the larger is the current round the field magnets in proportion to the current in the external circuit. Thus, with a shunt dynamo, as the number of lamps in parallel circuit is reduced by some of them being switched off, the terminal E.M.F. will increase. To keep this constant either the speed must be diminished, or, as is more usually done, resistance must be added to the field magnet circuit by means of a large resistance box, which is kept in series with the field magnets, so that more or less resistance can be added as required. One end of the field magnet wire is disconnected from the brush or terminal to which it is attached, and connected to one terminal of the resistance box, while the other terminal of the latter is connected to the brush or terminal of the dynamo, from which the field magnet wire was disconnected.

(TO BE CONTINUED.)

OLD CABLE STORIES RETOLD.—V.

BY F. C. WEBB.

THE CAGLIARI, MALTA, AND CORFU CABLES.

I ended my last article on the Atlantic Expedition of 1857 rather abruptly. I cannot help adding a few general remarks here. First, as regards the melting of the gutta percha at East Greenwich, it seems to me this never should have been allowed to take place. That a cable exposed to the rays of the sun ran considerable risk was so well known to me that I always, when landing cable at Lowestoft, covered it with a thick layer of hay, and had water pumped over it to keep the hay wet and cool by evaporation, and this work of pumping water over the hay was the only work carried on by our men on Sundays when in harbour. But there was another danger which the Atlantic cable incurred. The cable was passed through tanks of hot Stockholm tar; these tanks were heated by jets of gas under them. On my first visit to Messrs. Glass and Elliot's yard I arrived there at dinner hour, and found the cable leading from some six or seven machines, which were stopped, still in the tar tanks, and although the gas was turned down the tanks were quite hot to the hand, and must have been at a temperature considerably above blood heat. I was greatly astonished, and wrote to Mr. Bright, and received a note thanking me for the information, and saying it should be attended to. Who was responsible for the hot tar tanks, or the exposure of the cable to the sun? Was it the contractors or the company?

As regards the paying-out gear, it was designed by Mr. Bright and Mr. De Bergue, and I was told, on commencing to criticise the drawings, that nothing could be altered except the size of the V sheaves. That machine, although it was very ingenious in some respects, has never been used since, and it was an entire departure from what had been previously used. Indeed, the machine made for the 1858 expedition (which consisted of two independent drums with four or five V scores on each) has never been repeated. A return has been made to the drum and knife machine as used on the earlier cables, in some cases, it is true, with the "Appold" (or rather "Amos") brake, and in some cases with the ordinary brake straps arranged in various ways as regards the manner in which the strap is attached to the lever or is attached to the frame. But this subject could not be discussed without diagrams.

Passing on to history, or rather personal experience, the Atlantic Company had to reduce expenses, and as I had only an agreement which expired with the failure of the 1857 expedition, whilst the other three engineers had agreements which bound the company to keep them on till the completion of the cable, I had to look out for other work, and was engaged by Messrs. Newall and Co., who had engaged to lay the Cagliari, Malta, and Corfu cables, and had also to complete a four-conductor cable which they had attempted to lay between Bona (in Algeria) and Chia Bay near Cape Spartivento, the extreme southern point of the Island of Sardinia. The cable had been laid to within about 15 miles of Chia, when they ran short of four-conductor cable. They therefore spliced on some 10 miles of single wire cable which they had on board, and paid out till that ran short, and the end was let go a few miles from Cape Spartivento.

On October 21st, 1857, I started for Marseilles with Mr. Newall, and arrived there on the 23rd. The Liverpool steam tug "Blazer" (Captain Parry) was there, and the brake, 8ft. in diameter, was being fitted on the quarter deck. There was a length of 20 miles of four-conductor cable in a circular wooden structure in her hold, with proper cone and rings. We went on board on the evening of the 24th, and were about to start when there was a delay caused by a young Frenchman, who had to receive payment for the coal which had just been placed on board. Mr. Newall had naturally drawn a bill on his own firm for the amount of the coal bill, but the young Frenchman wanted, I suppose, for some particular personal profit of his own, to get a part of the sum paid in gold, and began by asking for a portion of the payment in gold. This was refused. He then began lowering his terms as regards the amount of gold, but in proportion as his terms lowered, his temper, or pretence of temper, increased. When he had got down to about £75 in gold, he was stamping about the cabin. I was translating the conversation between him and Mr. Newall, who was reclining on a sofa. At last the Frenchman began the trial of taunts. "*Comment,*" he said, "*des gen-tel-mans, voyageant comme vous, vous n'avez pas même cinquante livres en or.*" I translated this. "I wish I had him down a coal mine in the north," said Mr. Newall, *sotto voce*, and stroking his beard to keep his temper. I am afraid there would have been very little left of the Frenchman if Mr. Newall had had his wish. The little Frenchman, finding even his final grand taunt useless, gradually subsided, and carried away his bill, which, it is almost needless to remark, was his full and proper payment, and indeed it was not likely that Mr. Newall would use the £150 in gold he had provided on board for petty expenses at hotels, boats, &c., in paying coal bills. To carry gold enough to pay coal bills in telegraph expeditions would nearly sink the ship.

We went over to Bona, arriving on the 27th, and left there one of Messrs. Siemens's staff, with an induction coil instrument to speak to us when we hooked the cable off Spartivento. We started back same night for Spartivento, and arrived there on morning of 28th, and dredged without success for the cable. We had no picking up gear of any kind and no bow sheave, but I rigged up a temporary bow sheave. The next day (29th) we grappled again, got cable one mile from end, hove it up, cut it, and buoyed the short piece, and then hauled in the other nine miles by hand, came to four conductor cable, and made splice during night on to cable on board. The next morning (30th) we paid out towards shore, and landed the end.

I landed to bathe for the first time in Italian waters, and I was all alone. I was always devotedly fond of Italian opera, and seeing a strange gentleman, with long black moustache and piercing black eyes (who I soon knew afterwards as the Chevalier Franchesi, in charge of the telegraph) advancing towards me on the sea beach, I felt that now or never was the time to make use of some of the phrases I had gathered from the recitatives and duets in Italian operas. Taking my cap off and bowing in as near

Digitized by Google

approach as I could to the exquisitely graceful bows I had seen the late Signor Mario make to various Queens and Kings in "The Huguenots," "Favorita," &c., I began boldly with "Salute Signore." "Aha! parlate Italiano," said Signor Franchesi delighted, and he launched forth in the purest Italian—for he was of an old Milanese family—a torrent of the "soft bastard Latin" that made me ignominiously cry for quarter by asking, "Vous parlez Français Monsieur?" and I had to take to that useful language for the rest of our acquaintance. But I was intent on recognising anything I could in the way of Italian that I was at all familiar with, and I can well recollect that the only words that struck me as familiar were when Signor Franchesi, seated before a double-needle instrument in the open air with a coloured handkerchief over his head to keep away the mosquitoes, and trying to speak to Cagliari with a failing battery, suddenly exclaimed, "Sacrrremento!! mi manca la pila." I was at once reminded of "Mi manca la voce!" in "Semiramide," and reflected on the difference in the situation, and what would have been the effect on the audience if that energetic "Sacrrremento!" had prefaced the words in the celebrated quartet?

On the 31st we left for Cagliari, where Messrs. Newall's ship "Elba," with the cable to be laid between Cagliari, Malta, and Corfu was to meet us. We arrived there in the middle of the night, landed, and were making our way quietly up the solitary streets, when we were fetched back by gendarmes, and placed in a kind of cage, like wild beasts, on account of sanitary ideas, until the captain was fetched from the ship, and certain papers were examined. We were at last released, and then had to knock for about an hour at the Hotel della Concordia to gain admittance, as nobody was expected at that hour from anywhere.

(TO BE CONTINUED.)

ON GLOBE LIGHTNING.*

BY M. GASTON PLANTÉ.

Some years ago I described, under the title of "The Moving Electric Spark," a particular phenomenon produced by the

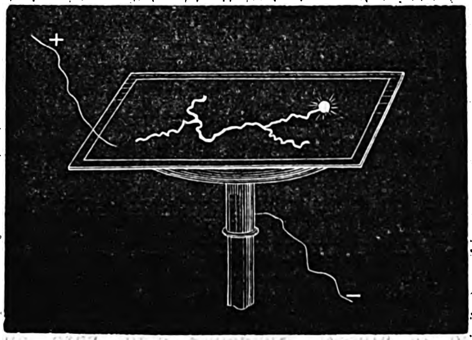

FIG. 1.

passage of an electric current of high tension. If a condenser, with very thin mica plate, be connected by its two armatures with the electrodes of a secondary battery of 800 couples, the condenser can be pierced, owing to the high tension of the current, and as under these conditions the quantity of current is far greater than with a source of static electricity, the effect is not confined to the production of a crackling spark; a small incandescent globule is formed, owing to the fusion of the matter of the condenser itself, and this globe moves slowly at the surface, following the points where the insulating plate which separates the armatures offers less resistance, and describing a most capriciously sinuous course (Fig. 1).

The experiment can be made to last for one or two minutes; it only ceases when the battery is so far discharged that the globule can no longer be maintained in a molten state between the two armatures. The slow motion of this little globule is

* From the *Comptes Rendus* for August 11.

accompanied by a strong crackling noise, and when the condenser is made to stick to the surface of a plate of hard caoutchouc a shrill and strident noise is heard, something like that produced by a fast revolving saw when cutting metal. The condenser is at the same time sawn and cut open over the whole course followed by the sparking globule. I have pointed out the analogy between these effects and those produced by globe lightning. Still better to imitate the conditions under which the natural phenomenon is produced, I lately increased the tension of the dynamical source of electricity, and used the current from a secondary battery of 1,600 couples, the electromotive force of which during the first moments of discharge was about 4,000 volts. Suppressing, on the other hand, the plate of mica and the metal armatures, since there are in the atmosphere but masses of air and vapour of water, I operated simply with the damp electrified surfaces separated by a layer of air. These damp surfaces were composed of pads or discs of filter paper moistened with distilled water.

When these were connected with the poles of the battery, a small ball of fire appeared which ran from one side to the other between the two surfaces, and appeared and disappeared spontaneously at intervals during several minutes. As the battery did not discharge so rapidly as with the metal armatures, the experiment lasted longer. The intervals were due to the fact that, when the globule of fire had dried different points of the damp surfaces, owing to the heating effect it produced, and had driven off the aqueous vapour whose presence diminished the resistance of the interval between the surfaces, the current was interrupted at these points; but the effect then reappeared at other points which remained damp, and so on to the end. These experiments appear to me to confirm the explanations which I have already offered with regard to globe lightning,* and I think I may conclude to-day with greater certainty that globe lightning is a slow and partial discharge, either direct or by induction (*influence*) of the electricity of thunder clouds, when this electricity abounds in exceptional quantities, and the cloud itself, or the damp column of strongly electrified air which forms so to speak the electrode of it, is in close proximity to the ground, even so close as to all but touch it, or to be separated by a thin layer

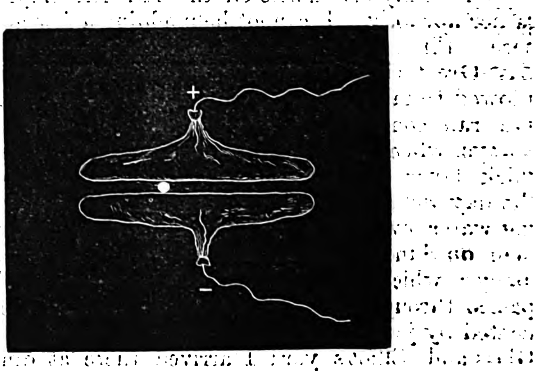

FIG. 2.

of insulating air. Under these conditions the electric flow, by reason of its abundance, or more exactly the ponderable matter which it traverses, collects, as in the experiments I have just described, in the form of a globe of fire. It is in some sort an electric egg, without a glass envelope, which is formed with the rarefied and incandescent elements of the air and the vapour of water. This globe of lightning does not constitute a kind of bomb charged with electricity; it is not dangerous of itself, as the curious stories of Babinet and different observers prove; for the least current of air is sufficient to displace it, as in the above experiments. A light breath on the globule will cause it to disappear for the moment, but its presence is none the less formidable, for it draws electricity from the thundercloud, with which it is connected in a hidden though sometimes visible manner, like waterspouts, and indicates the place where the discharge will take place.

* *Comptes Rendus*, 3rd May, 1875; 21st August, 1876; 1st October, 1877; and 19th August, 1878.

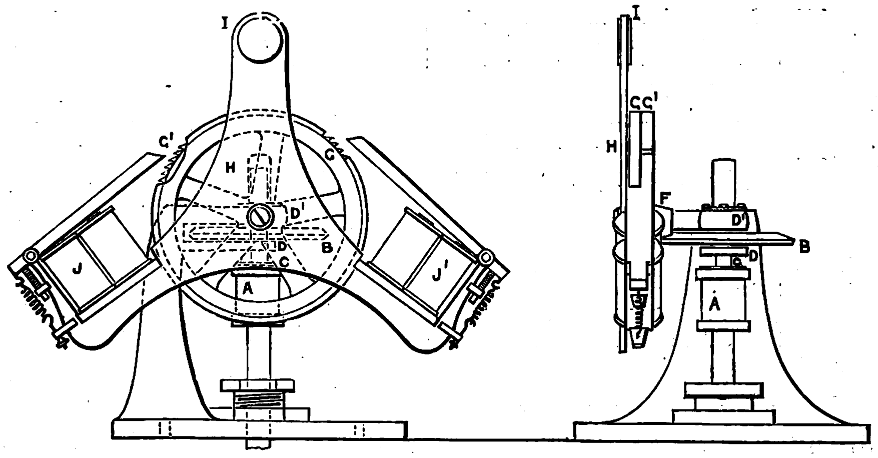
If the layer of air which separates the cloud from the earth is not traversed, the globe of fire disappears without noise, as has often been observed; or if a portion of the thundercloud is depressed towards the earth or other point, lightning may fall later on, at the same time that the globe disappears. But, if the layer of air is pierced, the natural result is, at the same point where the globe appeared, a stroke of lightning accompanied by thunder, proceeding not from the small quantity of electricity enclosed in the small mass of rarefied and luminous air which forms the globe, but from the sharp discharge of all the electricity, or a large portion thereof, contained in the thundercloud. The slow and capricious movement of these lightning globes is explained, like that of the globules of electric fire produced in the above experiments, by the variations in the resistance of the layer of air which separates them from the earth, and by the natural tendency of the electric discharge to seek the line of least resistance in its passage to earth.

Regarding the globes of fire which sometimes appear in the midst of the clouds themselves, and of which Arago has cited several examples, the experiment cited above (Fig. 2) gives an exact representation, although on a reduced scale, and it is sufficient to see it to understand the natural phenomenon.

In this way can be explained the various effects of globe lightning or thunder balls, which seemed to be an enigma so long as comparison could only be made with the effects produced by apparatus generating static electricity, where the quantity of electricity at work is too small to present analogous phenomena, but which become, on the contrary, easy of comprehension when we compare them with the effects produced by a source of dynamic electricity uniting at once quantity and tension.

THE PORTE-MANVILLE ELECTRIC GOVERNOR.

We have more than once pointed out the necessity of having engines which will govern when employed for electric light purposes. The aim of engineers is to obtain engines that shall run with absolute constancy, and when change is necessary the action to be dead beat. So far as as we know no governer yet in use is dead beat. The one herewith illustrated seems, however, to go a long way towards solving the problem, and its use up to the present supports the claims of the inventors. Its action will be readily understood from the following:—



Porte-Manville Governor.

The bevel-wheel B runs between two collars, D and D^1, being thus free to revolve without vertical motion; the boss of the wheel is tapped, and has a threaded spindle, C, running through it; part of the spindle is cut square, and passes through a square hole in the collar D, which prevents the spindle turning with the wheel, and only allows it to be screwed up and down. It will thus be seen that when the bevel-wheel turns the valve is either opened or shut.

Movement is given to the bevel-wheel by a spur wheel, to which are attached two ratchet wheels, G G^1, with their teeth cut in opposite directions.

Upon the same spindle as the spur and ratchet wheels, but unattached to them, is the three-armed carriage H, which is kept oscillating about its centre by the upper arm I being attached to a reciprocating part of the engine.

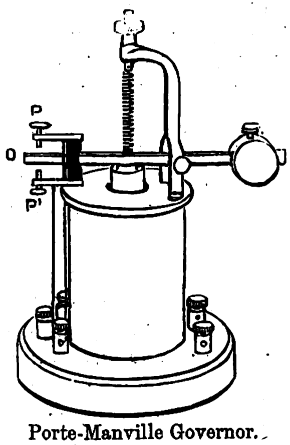
On the other two arms of the carriage are electro-magnets J and J^1, with their armatures prolonged into pawls, the pawl of one magnet being over one ratchet and the pawl of the other magnet over the other ratchet.

If, now, a current is sent over the left-hand magnet, its armature is attached, and engages its own ratchet wheel, which turns the whole system in the direction that raises the valve. If the current passes over the other magnet, the reverse takes place, and the valve closes.

The governor may be controlled in two ways:—

1. If it is desired to keep the speed of the machine constant a tachometer, K, is used, on the glass of which is mounted two contact plates, L L^1, separated by a very small division which is placed opposite the speed on the tachometer dial at which the machinery is to run. If now the speed drops at all the needle comes in contact with the lower plate, sends the current over the magnet that opens the valve until the machinery runs again at the proper speed, when the needle regains its position between the two plates, and the valve is left untouched until either the pressure of steam or the work again alters; the reverse takes place should the speed of the machinery rise.

2. If it is desired to keep the E.M.F. or current constant, a solenoid relay, M, is used either in shunt or in series with the main, the contact arm O is adjusted with the proper current to keep midway between the contacts P P^1. Should the current increase the solenoid is sucked down, makes contact with the lower point, and the current is sent through that electro-magnet which cuts off steam. When the current decreases the reverse takes place.



Porte-Manville Governor.

It will be noticed that with the Porte-Manville governor no action takes place unless there be a variation in the governing forces, and is consequently dead beat.

INTERNATIONAL INVENTIONS EXHIBITION.

Whatever else may be said for the Health Exhibition it has certainly contributed very largely to healthy enjoyment during a season when indoor recreation has been far from healthy or enjoyable. Its success in partially emptying all London theatres while the thermometer stood at 85° cannot be regarded otherwise than as an unmixed boon, both to the few who have attended them and the many who have gone to the Healtheries instead. Such indeed—partly owing to an almost unprecedented summer, partly to the novel attractions of the Exhibition itself—has been the extraordinary run upon South Kensington that it will surprise no one to hear of a fresh experiment in the same direction to be tried next year. The Commissioners are hardly likely to fail, and are almost sure to succeed, whatever they may hit upon in the way of an excuse for promenading the magnificent grounds and buildings of the Royal Horticultural Gardens. But the Prospectus just issued for next year is attractive in itself, more so than that which has formed the nominal object of the exhibition this year. In point of popular interest an Exhibition of Inventions from all parts of the world ought to have the advantage over the dry and too generally unattractive subject of Health. In this wicked world great reward always awaits him who invents a new pleasure. The Exhibition Commissioners have invented one already, and if they are mindful to include it among the inventions next year there will be no falling off in public acknowledgment.

The Exhibition of 1885 is one which will afford greater openings for the display of apparatus and appliances in which our readers are interested than has been possible at any former exhibition at South Kensington. It is to include inventions of all kinds, not previously shown there, introduced since the year 1862; and the group devoted to electrical appliances is as comprehensive as could be desired, besides the places they will find under the heads of Railway Signalling, Illumination, and Philosophical Instruments. The Electrical group is divided into twelve classes, comprising Generators, Conductors, Testing and Measuring apparatus (Telegraphic and Telephonic), Electric Lighting, Electro-Metallurgy and Electro-Chemistry, Distribution and Utilisation of Power, Electric Signalling, Lightning Conductors, Electro-Medical apparatus, Electrolytic processes, and, lastly, Electro-Thermic apparatus. What a wide field for inventive exhibitors this grouping offers will be obvious at a glance, covering as it does the whole area of telegraphic enterprise, from submarine cables and the apparatus for laying them to the construction of telephone lines and the instruments for working them. And in respect to Electric Lighting, the choice does not seem to be narrowed by the condition above alluded to limiting the exhibits to objects not previously shown at the three preceding exhibitions unless under "exceptional circumstances." We should suppose that the lighting systems employed for illuminating those exhibitions would be regarded as "exceptional" adjuncts, not as actual exhibits. For the other classes we have named, the scope is equally judicious and extensive. Some unusual regulations are laid down with regard to space, as the Commissioners appear to be apprehensive of more applicants than they can find room for; but this will not materially affect the display of electrical appliances in their entirety.

Some good practical reason has no doubt induced the Commissioners to draw a line for Inventions at a particular year. "Division I. (Inventions)," says the prospectus, "will be devoted to illustrations of apparatus, appliances, processes, and products invented or brought into use since 1862." The period between that time and 1885 is spoken of as "a quarter of a century," which is not strictly the fact; possibly the limitation has something to do with the Patent Laws, for among the regulations we find one stating that "untried and unpatented inventions will not be accepted unless recommended by a competent authority." There are many valuable and tried inventions that have not been patented even since 1862. Probably what is meant is that when an alleged invention has neither been tried nor patented it will have to come with good credentials; which is quite proper, although on the other hand we demur to the implied inference that all inventions patented have therefore been "tried," especially under the harum-scarum system which now goes by the name of Patent Law.

But for the regulation just referred to, we think that a highly instructive historical group might have been got together of inventions, dating from remote ages down to the mysterious 1862. Models are recommended by the Commissioners in preference to actual machinery with a view to economising space, and our historic group would have lent itself admirably to illustration by model. Perhaps, however, nobody cares about ancient inventions sufficiently to reconstruct them in miniature for our edification. Or, perhaps, there are some people to whom such generosity to our forefathers would prove unwelcome and even painful. Still, for the curious observer a collection of ancient inventions which have been invented over and over again "since 1862"—if the Commissioners could only find room for them—would have been a striking addition to any Exhibition professedly devoted to International Invention. We notice that Division II. (Music) is to have its Historic Collection; probably for the sufficient reason that musical invention would be very inade-

quately represented by the productions of modern times. In this division the Commissioners extend their view back to "examples of Musical Instruments of a date not earlier than the commencement of the present century." But, as the tin whistle and barrel organ would probably exhaust this Class, there is also to be the Historic Class. For similar reasons we should have liked to have seen a Historic Class for Inventions.

In the main the exhibition, apart from its musical feature, will be confined to inventions which are the outcome of scientific discovery. Electricians and Electrical Engineers will have no fault to find with this restriction, as the science of Electricity has contributed probably more than any other branch of investigation in modern times to the multiplication of inventions and their application "to the purposes of daily life." Electrical inventors—and their name is legion—should lose no time in availing themselves of this opportunity, as applications for space must reach the Secretary by 15th September. Commissioners of Foreign Governments are being appointed, and it is hoped and expected there will be numerous applications from abroad. We trust that Englishmen will not prove to be behind their foreign competitors in ingenuity, especially as we are admitted to be ahead of them in scientific knowledge.

CORRESPONDENCE.

PRACTICAL TELEPHONY.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: Would you kindly state what subjects you think are necessary for a telephone inspector who wishes to make some progress in his profession.

I have been studying machine construction, mathematics, theoretical mechanics, and electricity, and am going to study telegraphy and chemistry.

Besides paying attention to his business and reading the electrical papers, do you think these are sufficient?

Is the telephone profession one you would recommend a youth to follow? Has it good prospects?

Your kind attention to this in your earliest issue will oblige not only myself but many others.—Yours, &c.,

Sandholes, Paisley, 19th August, 1884. WENDUR.

[Perhaps someone engaged in the work would answer our correspondent.—ED. *E.*]

THE AMALGAMATION OF ZINC.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: While fully appreciating all that poor Sturgeon has done for the allied sciences of electricity and magnetism, I am not prepared to admit that the use of amalgamated zinc in the voltaic battery was originated by him, as I find is stated in Dr. Joule's letter, on page 188 of *The Electrician* for July 5th, 1884. His writings and lectures tended no doubt to its general introduction, but the credit of its discovery belongs to another, as I have shown in my "History of Electric Telegraphy."

On page 218 of this work I say:—"The first mention of amalgamated zinc in voltaic arrangements occurs in Sir H. Davy's Bakerian lecture for 1826, in which he simply remarked that 'zinc in amalgamation with mercury is positive with respect to pure zinc,' without any allusion to the beneficial employment of it in the construction of batteries. Kemp, of Edinburgh, was the first to employ amalgamated zinc and copper in the regular construction of batteries. (*See* his papers in Jameson's *New Edinburgh Phil. Journal* for December, 1828."

In further support of my contention I beg to refer those interested in the question (1) to "Ronalds' Catalogue," p. 265, under heading Kemp; and (2) to Sturgeon's own "Annals of Electricity, &c.," Vol. I., pp. 81-8.

The first published observations of Sturgeon on this subject are, as stated on page 189 of your journal, contained in his "Experimental Researches in Electro-Magnetism, Galvanism, &c.," which appeared in 1830.

Owing to my distance from London this letter will be long in reaching you, and will in consequence lose much of its interest. Still, as I know you like to be accurate, I hope you will give it a place in your journal.—Yours, &c.,

J. J. FAHIE.

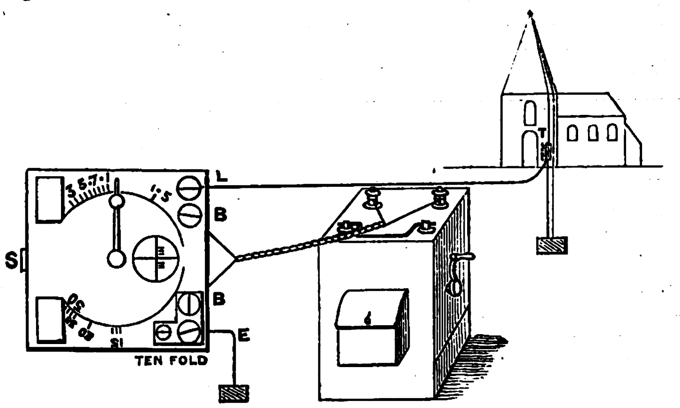
Teheran, Persia, July 29, 1884.

SIEMENS' APPARATUS FOR TESTING THE RESISTANCE OF LIGHTNING RODS.

The apparatus consists of a magneto-inductor contained in a wooden box, and a small bridge board sliding into a recess at the bottom of the box. To the latter are affixed a German silver ring, a pointer, which also acts as a battery key, a small galvanometer, four terminals marked L, B, B, E, and beneath the board a constant resistance.

It is advisable when erecting a lightning rod that a loose copper wire be connected to the point of same, running down parallel with it to the base; a connection may then be made to this which would save the trouble of climbing up to the point each time the lightning rod had to be tested.

For economy sake when erecting a lighting rod, two ropes having the same sectional area as the single rope intended to be fitted might be used, both of them being connected to the earth plate, and acting as a single conductor. One of the ropes could then have a connection screw fitted at the base T, so that it could be disconnected from earth for testing as required.



Siemens' Lightning Rod Testing Apparatus.

When a lightning rod is to be tested, terminal L has to be connected to the point of the rod or the loose wire below, terminal E to a reliable earth, and terminals B B to the inductor. Then, by turning the inductor handle and pressing down the pointer on the board, a current is sent through the bridge, and if a deflection be shown on the galvanometer, the pointer (still being pressed down) must be turned to the left or right until the needle stands at zero. The graduations round the ring have been so arranged that in this position the pointer will stand at the figure corresponding to the resistance in ohms of the lightning rod and its earth connection.

The board must be so turned before the test is made that the needle of the galvanometer swings freely and stands at zero, and it must be placed as far from the inductor as the leading wire supplied with the instrument will allow, that the galvanometer may not be affected by the magnetism of the magnets in the inductor. There is a small brass slide, S, at the back of the bridge board which by withdrawing sets the needle into action, and by pushing in lifts it off again. When measuring higher resistances the screw marked "ten-fold" must be taken out; the instrument will then measure ten-fold the resistances marked on it, *i.e.*, from 1 up to 500 ohms.

DR. JOULE.

A short time ago we gave a short biography of Mr. Sturgeon from the "Centenary of Science in Manchester," issued by the Philosophical Society of Manchester, in commemoration of its hundredth anniversary. We now take from the same source the biographical notes on Dr. Joule, a man whom England is delighted to honour:—

"Almost concurrent with later chemical search on the constituents of matter we see an inquiry in physics, where also atoms have done full duty, and without which the existence of gases, for example, has been found to be difficult to conceive. The condition may be shortly described in a summary serving as an introduction to the works of the late Thomas Graham, Master of the Mint.

"'When we arrive at this point we pass to the next important stage, namely, the motion of gaseous molecules, if not of atoms, and the beginning of the attempt to define it precisely. The first definite ideas are by D. Bernouilli. They are explained in his "Hydrodynamics," which although published in Strasburg in 1738, were previously worked at when he was Professor in St. Petersburg.

"'D. Bernouilli says: "The chief peculiarities of fluids are these: first, they are heavy; second, they expand in all directions unless they are confined; and third, they allow themselves to be compressed more and more, according to the increased force applied." Speaking of a vessel of air with a weighted cover, and which he illustrates with a diagram, he says, "So the minute bodies, whilst they impinge on the cover E F, keep it up by their continually repeated strokes, and form an elastic fluid which expands itself when the weight is removed or diminished. We shall consider the corpuscles enclosed in the hollow of the cylinder as infinite in number, and when they occupy the space E C D F we shall say that they constitute the natural air."

"'Davy and Count Rumford entered the field when this theory of gaseous motion was forgotten, and inaugurated a new theory of heat founded on molecular activity. That heat is immaterial was no rare opinion last century, or since Lord Bacon spoke of it as "motus et nihil aliud." However, atomic motion ceased from the time of Rumford to be a vague idea. Davy spoke definitely when, without calling in the aid of repulsions, he supposed that in solids the particles are in a vibratory motion, the particles of the hottest bodies moving with greatest velocity and through the greatest space; that in fluids and elastic fluids, besides the vibratory motion which must be considered greatest in the last the particles have a motion round their own axes with different velocities, the particles of elastic fluids moving with the greatest quickness; and that in ethereal substances the particles move round their own axes and separate from each other, penetrating in right lines through space. Temperature may be conceived to depend on the velocity of the vibrations, increase of capacity on the motion being performed in greater space, &c.'

"This is evidently the work of Rumford and Bernouilli, with additions after passing later through an original and powerful mind.

"We may take the next step and go to Herapath. At p. 14, Vol. I., he says:—

"'*Theory of Gases.*—From these considerations it follows that if a number of small bodies be enclosed in any hollow body, and be continually impinging on one another and on the sides of the enclosing body, and if the motions of the bodies be conserved by an equivalent action in the sides of the containing body, then will these small bodies compose a medium, whose elastic force will be like that of air and other gaseous bodies; for if the bodies be exceedingly small, the medium might, like any æriform body, be compressed into a very small space; and yet if it had no other tendency than what would arise from the internal collision of its atoms, it would, if left to itself, extend to the occupation of a space of almost indefinite greatness. And its temperature remaining the same, its elasticity would also be greater when occupying a less, and less when occupying a greater space; for in a compressed state the number of atoms striking against a given portion of the containing vessel must be augmented, and the space in which the atoms have to move being less, their motions or periods must be shorter, and the number of them in a given time consequently greater; on both of which accounts the elasticity is greater the greater the compression. Besides, when other things are the same, the elastic force augments with an augmentation of temperature and diminishes with a diminution; for an increase of temperature, according to our theory, must necessarily be attended with an increase of velocity, and therefore with an increase in the number of collisions.'

"'Dr. Joule continued the subject, and introduced it into the region of experiment and observation, or, in other words, to the science of modern times. Joule might have added that the view he adopted is not only in accordance with the known laws of the elasticity of gases, but conforms to the ratio of the specific heats of gases. The mathematical development continued to make progress in the hands of Clausius, Clerk Maxwell, Holtzmann, and others, taking us to new fields, &c.'

"In 'Some Remarks on Heat and the Constitution of Elastic Fluids,' by J. P. Joule, F.R.S., &c., Mem. Lit. and Phil. Soc., Vol. IX., Second Series, p. 111, read October 3rd, 1848, we find:—

"'I have myself endeavoured to prove that a rotary motion such as that described by Sir H. Davy will account for the law of Boyle and Mariotte, and other phenomena presented by elastic fluids; nevertheless, since the hypothesis of Herapath—in which it is assumed that the particles of a gas are constantly flying about in every direction with great velocity, the pressure of the gas being owing to the impact of the particles against any surface presented to them—is somewhat simpler, I shall employ it in the following remarks on the constitution of elastic fluids; premising, however, that the hypothesis of a rotary motion accords equally well with the phenomena.

"'Let us suppose an envelope of the size and shape of a cubic foot to be filled with hydrogen gas, which, at 60° temperature and 30in. barometrical pressure, will weigh 36·927 grains. Further, let us suppose the above quantity to be divided into three equal and indefinitely small elastic particles, each weighing 12·309 grains; and further, that each of these particles vibrates between opposite sides of the cube, and maintains a uniform velocity except at the instant of impact. It is required to find the velocity at which each particle must move so as to produce the atmospherical pressure of 14,831,712 grains on each of the square sides of the cube. In the first place it is known that if a body moving with the velocity of $32\frac{1}{6}$ft. per second be opposed during one second by a pressure equal to its weight, its motion will be stopped, and that, if the pressure be continued one second longer, the particles will acquire the velocity of $32\frac{1}{6}$ft. per second in the contrary direction. At this velocity there will be $32\frac{1}{6}$ collisions of a particle of 12·309 grains against each side of the cubical vessel in every two seconds of time; and the pressure occasioned thereby will be $12{\cdot}309 \times 32\frac{1}{6} = 395{\cdot}938$ grains. Therefore, since it is manifest that the pressure will be proportional to the square of the velocity of the particles, we shall have for the velocity of the particles requisite to produce the pressure of 14,831,712 grains on each side of the cubical vessel,

$$v = v\left(\frac{14{,}831{,}712}{395{\cdot}938}\right)32\tfrac{1}{6} = 6{,}225\text{ft. per second.}$$

"'The above velocity will be found equal to produce the atmospheric pressure, whether the particles strike each other before they arrive at the sides of the cubical vessel, whether they strike the sides obliquely, and, thirdly, into whatever number of particles the 36·927 grains of hydrogen are divided.

"'If only one-half the weight of hydrogen, or 18·4635 grains, be enclosed in the cubical vessel, and the velocity of the particles be as before, 6,225ft. per second, the pressure will manifestly be only one-half of what it was previously; which shows that the law of Boyle and Mariotte flows naturally from the hypothesis.

"'The velocity above-named is that of hydrogen at the temperature of 60°; but we know that the pressure of an elastic fluid at 60° is to that at 32° as 519 is to 491. There-

Digitized by Google

fore the velocity of the particles at 60° will be to that at 32° as $\sqrt{519}$, $\sqrt{491}$; which shows that the velocity at the freezing temperature of water is 6,055ft. per second.

"'In the above calculations it is supposed that the particles of hydrogen have no sensible magnitude, otherwise the velocity corresponding to the same pressure would be lessened.

"'Since the pressure of a gas increases with its temperature in arithmetical progression, and since the pressure is proportional to the square of the velocity of the particles, in other words, to their *vis viva*, it follows that the absolute temperature, pressure, and *vis viva* are proportional to one another, and that the zero of temperature is 491° below the freezing point of water. Further, the absolute heat of the gas, or in other words, its capacity, will be represented by the whole amount of *vis viva* at a given temperature. The specific heat may therefore be determined in the following simple manner:—

"'The velocity of the particles of hydrogen, at the temperature of 60°, has been stated to be 6,225ft. per second, a velocity equivalent to a fall from the perpendicular height of 602,342ft. The velocity at 61° will be 6,225 $\sqrt{\frac{520}{519}} = 6{,}230{\cdot}93$ft. per second, which is equivalent to a fall of 603,502ft. The difference between the above falls is 1,160ft., which is therefore the space through which 1lb. of pressure must operate upon each pound of hydrogen in order to elevate its temperature one degree. But our mechanical equivalent of heat shows that 770ft. is the altitude representing the force required to raise the temperature of water one degree; consequently the specific heat of hydrogen will be $\frac{1160}{770} = 1{\cdot}506$, calling that of water unity.

"'The specific heats of other gases will be easily deduced from that of hydrogen; for the whole *vis viva* and capacity of equal bulks of the various gases will be equal to one another, and the velocity of the particles will be inversely as the square root of the specific gravity. Hence the specific heat will be inversely proportional to the specific gravity, a law which has been arrived at experimentally by De la Rive and Marcet.

"'In the following table I have placed the specific heats of various gases, determined in the above manner, in juxtaposition with the experimental results of Delaroche and Berard reduced to constant volume:—

	Experimental specific heat.		Theoretical specific heat.
Hydrogen	2·352	...	1·506
Oxygen	0·168	...	0·094
Nitrogen	0·195	...	0·107
Carbonic oxide	0·158	...	0·068

"'The experimental results of Delaroche and Berard are invariably higher than those demanded by the hypothesis. But it must be observed that the experiments of Delaroche and Berard, though considered the best that have hitherto been made, differ considerably from those of other philosophers. I believe, however, that the investigation undertaken by M. V. Regnault, for the French Government, will embrace the important subject of the capacity of bodies for heat, and that we may shortly expect a new series of determinations of the specific heat of gases, characterised by all the accuracy for which that distinguished philosopher is so justly famous. Till then, perhaps, it will be better to delay any further modifications of the dynamical theory, by which its deductions may be made to correspond more closely with the results of experiment.'

"We have thus got to the motion of atoms, but the result of this motion was also taken up by Joule, and we give him without difficulty the honour of showing its relations first in one very important direction, namely, heat. We have the pleasure of knowing that he went still further, and showed that whilst the heat itself resulted in force, that force had a definite limit, and could be estimated by the amount of chemical action or by the combinations taking place between the elements. In other words, he showed the connection between chemical action, electricity, heat, and mechanical force. The long train of papers on this subject written by Dr. Joule would astonish many who receive his results in a few lines, and are satisfied with their simplicity; but it would also be a very simple thing if, after living to maturity in a pit, with artificial light only, we were to come up and see the sun. How simply we should then get light—no candle used, no wax, no oil, no paraffin; the sun laughs at all our methods of illumination, and we, too, may laugh at ourselves when we think how short was our view in the direction indicated before Dr. Joule discovered the mechanical equivalent of heat. To show the fullest early form in which the author approached the subject we quote farther on. (*See* Mem. of the Lit. and Phil. Soc. of Manchester, Vol. VII., Second Series, pp. 103, 104, and 110.) We shall further quote a paper read January 24, 1843, his 20th paper on heat, electricity, and magnetism, though still a youth.

"When speaking of Dr. Joule we must not forget to put before ourselves clearly the position taken up by Faraday in the development of measurable quantity, a position which is gained by the vantage ground of the atomic theory, and stands between that of Dalton's and Joule's, to whose wider generalisations it tended. In his 'Experimental Researches in Electricity,' § 704 (ed. 1839), we find one of his papers read in January, 1834: 'I have already said, when engaged in reducing common and voltaic electricity to one standard of measurement, and, again, when introducing my theory of electro-chemical decomposition, that the chemical decomposing action of a current is constant for a constant quantity of electricity, notwithstanding the greatest variation in its sources, in its intensity, in the size of the electrodes used, in the nature of the conductors (or non-conductors, 307) through which it passes, or in other circumstances.'

"'§ 705. I endeavoured upon this law to construct an instrument which should measure out the electricity passing through it, and which, being interposed in the course of the current used, should serve at pleasure either as a *comparative standard* of effect or as a *positive measure* of the subtle agent.'

"§ 706. . . . 'Water therefore, acidulated by sulphuric acid, is the substance I shall generally refer to, although it may become expedient in peculiar cases or forms of experiment to use other bodies.' In § 843 it is said, 'I expect to find in some salts, as the acetate of mercury and zinc, solutions favourable for this use.'

"In § 866, speaking of the decomposition of water, he says, 'For an equivalent of zinc oxidised an equivalent of water must be decomposed.'

"'§ 918. All the facts show us that that power commonly called chemical affinity can be communicated to a distance through the metals and certain forms of carbon; that the electric current is only another form of the forces of chemical affinity; that its power is in proportion to the chemical affinities producing it; that when it is deficient in force it may be helped by calling in chemical aid, the want in the former being made up by an equivalent of the latter; that, in other words, "*the forces termed chemical affinity and electricity are one and the same.*"'

"That equivalents exist is no proof of oneness, but we see here great progress made by Faraday in the consideration of the unity of power and the relation of important forms of power.

"We shall quote here some of Joule's early papers.

"*On the Heat Evolved during the Electrolysis of Water.* January 26, 1843. By James Prescott Joule. Vol. VII., Second Series, *Memoirs* of the Literary and Philosophical Society of Manchester, pp. 101, 103, 104, 110.

"'1st. In an electrolytic cell, there are three distinct obstacles to the voltaic current. The first is resistance to conduction, the second is resistance to electrolysis without chemical change, arising simply from the presence of chemical repulsion, and the third is resistance to electrolysis accompanied by chemical changes.

"'2nd. By the first of these (the resistance to conduction) heat is evolved exactly as it is by a wire, according to the resistance and the square of the current; and it is thus that a part of the heat belonging to the chemical actions of the battery is evolved. By the second, a reaction on the intensity of the battery occurs, and wherever it exists heat is evolved

Digitized by Google

exactly equivalent to the loss of heating power in the battery arising from its diminished intensity. But the third resistance differs from the second, inasmuch as the heat due to its reaction is rendered latent and is thus lost by the circuit.

"'3rd. Hence it is that, however we arrange the voltaic apparatus, and whatever cells of electrolysis we include in the circuit, the whole caloric of the circuit is exactly accounted for by the whole of the chemical changes.

"'4th. As we discovered by Faraday, the quantity of current electricity depends upon the number of atoms which suffer electrolysis in each cell, and the intensity depends upon the sum of chemical affinities. Now both the mechanical and heating powers of a current are (*per* equivalent of the electrolysis in any one of the battery cells) proportional to its intensity. Therefore the mechanical and heating powers of a current are proportional to each other.

"'5th. The magnetic electrical machine enables us to convert power into heat, by means of the electric currents which are induced by it. And I have little doubt that by interposing an electro-magnetic engine in the circuit of a battery, a diminution of the heat evolved *per* equivalent of chemical change would be the consequence, and this in proportion to the mechanical power obtained.*

"'I have shown also that the *modus operandi* is resistance to conduction.

"'There are many phenomena which cannot be accounted for by the theory which recognises heat as a substance; and there are several, which though sometimes adduced as triumphant objections to the other theory, tend, when rightly considered, only to confirm it. The heat of fluidity may very naturally be regarded as the momentum, or mechanical force necessary to overcome the aggregation of particles in the solid state. The heat of vaporisation may be regarded, partly as the mechanical force requisite to overcome the aggregated condition of atoms in the fluid state, and partly as the force requisite to overcome atmospheric pressure. Again, the heat of combination is only the manifestation, in another form, of the mechanical force with which atoms combine; on the other hand, the phenomena of electrolysis by the voltaic battery give us positive proof that the mechanical force of the current requisite to procure the decomposition of an electrolyte is the equivalent of the heat due to the recombination of the elements. *Thus it appears that electricity is a grand agent for conveying heat and the ordinary forms of mechanical power into one another.*'

"'*On a New Method of Ascertaining the Specific Heat of Bodies.* Read December 2, 1845. *Memoirs* of Philosophical Society of Manchester, Vol. VII., Second Series, p. 562.

"'When any body, capable of conducting the voltaic electricity, is placed in the circuit of a battery, the quantity of heat evolved by it in a given time is proportional to its resistance to conduction and the square of the quantity of transmitted electricity. Consequently, if a wire traversed by a voltaic current be made to communicate to any body the heat which it evolves, the capacity for heat of that body and the wire taken together will be directly proportional to the square of the quantity of electricity transmitted in a given time to the resistance of the wire and to the time, and inversely proportional to the increase of temperature of the body. Hence we derive the general equation,

$$y = \frac{Cc^2rt}{h} \quad . \; . \; . \; . \; . \; . \; . \; . \quad (1)$$

where y is put for the capacity, c for the voltaic current, r for the resistance of the wire, t for the time, and h for the increase of temperature.

"'If we make the time and the resistance of the wire constant, the above equation becomes simplified to

$$y = \frac{Cc^2}{h} \quad . \; . \; . \; . \; . \; . \; . \; . \quad (2)$$

"'If the current and time are constant, we have

$$y = \frac{Cr}{h} \quad . \; . \; . \; . \; . \; . \; . \; . \quad (3)$$

* I am preparing for experiments to test the accuracy of this proposition.—February 18, J. P. J.

"'I have made several series of experiments, using the same conducting wire as a source of heat, a constant interval of time, and a variable current of electricity. The method adopted in these experiments was to try the effect of a wire traversed by a current of electricity—first, when it was immersed in water, and afterwards when it was immersed in another liquid. Hence I obtained two determinations of y in equation 2, one of them for water, the other for the liquid. The relation between these two quantities gave, of course, the capacity of the liquid compared with that of the water.'

"Without pretending to say that it was impossible to arrive at Joule's conclusions without the atomic theory of Dalton, we may say distinctly that it was not attained without its aid. The idea of full portions, *units of measure* in Dalton's mind, developed itself gradually into *units of force* in the mind of Joule, and it is in this form that we received it from the hand of one illustrious member still active amongst us. To say that the two are the most successful descendants of the great thinkers who have grappled with the subject of atoms for three thousand years is but to express a simple fact; and to assert that Dalton and he have made the great leading discoveries on the subject is simply to follow history. From one we learn the order in which the ultimate particles of bodies move, from the other we learn the force and relation of their movements in those great phenomena, heat, electricity, and mechanical force.

"It is of course impossible to deny great honour to many men who have laboured on heat. We have great admiration for the work of Dulong and Petit, great illustrators of atomic action. We may delight in the speculative ideas of Clausius, Helmholtz, Clerk Maxwell, and Sir William Thomson, but we must remember that these men represent another department of atomic study.

"They take the Daltonian atom as granted. They take it also as Joule, Dalton's pupil, made it—a measure of power, and they seek to go further in studying its physical properties. We have here a follower worthy of the prophet. Dalton's pupil has become the master of many learners."

A TELEGRAPHER'S PRACTICAL JOKE.*

BY WITT MASTER.

In any large office where there are so many people employed as in the main office of the Western Union Company, New York, the various cliques that are formed afford an interesting study to the close observer.

There will be one clique of perhaps twenty persons, all having a certain amount of affinity for each other, and all of whom will act and think together, somewhat unanimously, on a great many different subjects.

It is not necessary that they should be of one political or religious belief, for every phase of political and religious creed may be represented in the clique. Within this clique there may be two distinct cliques, composed of those whose tastes and inclinations run still more closely together, and again and again the circle will divide or contract until we find it composed of rings of two or three fraternal and congenial spirits, those confiding in one another their troubles and pleasures, their failures and successes in their business and domestic lives.

Of course these cliques of the first larger kind run to various hobbies; some of them will favour athletics, some politics, others music, others scientific studies and so on, and it is about as difficult to divert the attention of the athletic loving from a base-ball match to a musical festival as to induce the embryo politician to attend a scientific lecture, and *vice versa*. But when a hint is thrown out that a joke is being or is about to be perpetrated on any one in the numerous cliques, it is amusing to watch the eagerness with which every one aids and abets the prime mover in his effort to carry out the joke successfully.

One of the best and most prolonged of these happened quite recently.

It appears that one of a party of four cronies who regularly

* There is perhaps more truth in this account of a joke than would be generally supposed, and we should not wonder if St. Martin's-le-Grand could supply a number of joking experiences.—ED. *E.*

Digitized by Google

sit at a certain table in the lunch room in the Western Union Building, and whom I shall designate as "the victim," was detained for a few minutes by the visit of a friend from the country. The victim, as he sat down, gave expression to the wish that the next time any of his friends called they would do so at a more convenient season than the lunch half-hour, and especially that they would not call when under the slightest influence of liquor, which he intimated was one of the failings of his friend. He further incautiously remarked that his friend was Thompson, from Cold Spring, N.Y., and that he Thompson, and his wife, had come down to attend a wedding in Brooklyn.

This was sufficient basis on which to build a joke, and his hearers lost little time in putting one into execution, as follows:

About half an hour after dinner the victim received a telegram, purporting to be from the Fifth Avenue Hotel, which read:—

"I am having a rollicking time. Meet me here at five o'clock. THOMPSON."

The victim was seen to stick the message hastily in his pocket, and then he wrote an answer to the effect that a previous engagement would prevent acceptance of invitation.

Half an hour later the victim was called to the ostensible hotel wire, and the operator there informed him that a man by the name of Thompson was acting very boisterously, and had already broken several windows of the hotel. The hotel operator further stated that Mr. T. was shouting that he and his friend (the victim), of the Western Union, could clean out the entire hotel. The operator concluded by asking the victim to come up at once to the hotel. "But what good can I do?" wailed the victim over the wire. "You may be able to pacify him," was the reply, to which was added, "Wait a moment; I will see you again."

After another delay the victim was recalled to the hotel wire, and was informed that they had succeeded in quieting Mr. Thompson, and that a couple of porters were now bringing him to the victim's office. This horrified the victim, who conjured up a disgraceful scene. He therefore obtained leave to go down stairs for a few minutes on the plea of sudden illness, but in reality with the hope of intercepting his boisterous friend.

After waiting half an hour and finding no sign of Mr. Thompson's arrival, he ventured to leave his post of sentry and returned to his desk, but scarcely was he seated before he was again called to the hotel wire, this time to be informed that his friend had become almost unmanageable; but as he had expressed a desire to return home at once, the porters had taken him to the Grand Central Depôt, where he had got aboard the 3:30 p.m. train for Cold Spring, N.Y.

This was a great relief to the victim, but his thoughts at once turned to his friend's wife, who was now awaiting her truant husband's company to the wedding. The victim felt it to be his duty to call and inform Mrs. Thompson of her husband's whereabouts. He therefore provided himself with a substitute, but before leaving the office he received another message from Mr. Thompson, stating that "the robbers at the hotel had stolen his hat; would not the victim call and get it, or report it to the police?"

On his way to Brooklyn, he called to see the proprietor of a cigar store, who was a mutual friend of all the parties, to whom he related the above occurences, and they both concluded that Mr. Thompson was undoubtedly crazy from drink.

The cigar dealer and the victim then decided to go together to where Mrs. T. was stopping, to break the unpleasant news to her.

They reached their destination in due time, and talked of the weather and everything but the real object of their call, both gentlemen fearing to broach the painful topic, and each hoping the other would do so first. While they were thus hesitating, a rap was heard at the door, and Mr. Thompson entered, sober and in his right mind, and expressed his surprise and pleasure at meeting the visitors.

The cigar dealer looked at the victim inquiringly for an explanation, but the latter, having at last grasped the fact that he had been somewhat imposed upon by his office mates, winked at his friend and immediately recollected an engagement they both had further down the street, and drew his friend off with him.

It is, of course, unnecessary to say that all the messages and conversations upon the wire were concocted, and carried on by the victim's friends in the office, over a dozen of whom were in the secret and were watching his every movement.—*The Operator.*

THE BRITISH ASSOCIATION MEETING AT MONTREAL.

The following is the Presidential Address by Lord Rayleigh, F.R.S., delivered at the B. A. meeting at Montreal, on Wednesday, August 27:—

It is no ordinary meeting of the British Association which I have now the honour of addressing. For more than fifty years the Association has held its autumn gathering in various towns of the United Kingdom, and within those limits there is, I suppose, no place of importance which we have not visited. And now, not satisfied with past successes, we are seeking new worlds to conquer. When it was first proposed to visit Canada, there were some who viewed the project with hesitation. For my own part I never quite understood the grounds of their apprehension. Perhaps they feared the thin edge of the wedge. When once the principle was admitted there was no knowing to what it might lead. So rapid is the development of the British Empire, that the time might come when a visit to such out-of-the-way places as London or Manchester could no longer be claimed as a right, but only asked for as a concession to the susceptibilities of the English. But seriously, whatever objections may have at first been felt were soon outweighed by the consideration of the magnificent opportunities which your hospitality affords of extending the sphere of our influence and of becoming acquainted with a part of the Queen's dominion which, associated with splendid memories of the past, is advancing daily by leaps and bounds to a position of importance such as not long ago was scarcely dreamed of. For myself, I am not a stranger to your shores. I remember well the impression made upon me, seventeen years ago, by the wild rapids of the St. Lawrence, and the gloomy grandeur of the Saguenay. If anything impressed me more, it was the kindness with which I was received by yourselves, and which I doubt not will be again extended not merely to myself, but to all the English members of the Association. I am confident that those who have made up their minds to cross the ocean will not repent their decision, and that, apart altogether from scientific interests, great advantage may be expected from this visit. We Englishmen ought to know more than we do of matters relating to the Colonies, and anything which tends to bring the various parts of the Empire into closer contact can hardly be overvalued. It is pleasant to think that this Association is the means of furthering an object which should be dear to the hearts of all of us; and I venture to say that a large proportion of the visitors to this country will be astonished by what they see, and will carry home an impression which time will not readily efface.

To be connected with this meeting is to me a great honour, but also a great responsibility. In one respect especially I feel that the Association might have done well to choose another president. My own tastes have led me to study mathematics and physics rather than geology and biology, to which naturally more attention turns in a new country, presenting as it does a fresh field for investigation. A chronicle of achievements in these departments by workers from among yourselves would have been suitable to the occasion, but could not come from me. If you would have preferred a different subject for this address, I hope, at least, that you will not hold me entirely responsible.

At annual gatherings like ours the pleasure with which friends meet friends again is sadly marred by the absence of those who can never more take their part in our proceedings. Last year my predecessor in this office had to lament the untimely loss of Spottiswoode and Henry Smith, dear friends of many of us, and prominent members of our Association. And now, again, a well-known form is missing. For many years Sir W. Siemens has been a regular attendant at our meetings, and to few indeed have they been more indebted for success. Whatever the occasion, in his presidential address of two years ago, or in communications to the physical and mechanical sections, he had always new and interesting ideas, put forward in language which a child could understand, so great a master was he of the art of lucid statement in his adopted tongue. Practice with science was his motto. Deeply engaged in industry, and conversant all his life with engineering operations, his opinion was never that of a mere theorist. On the other hand, he abhorred rule of thumb, striving always to master the scientific principles which underlie rational design and invention.

It is not necessary that I should review in detail the work of Siemens. The part which he took during recent years in the development of the dynamo machine must be known to many of you. We owe to him the practical adoption of the method, first suggested by Wheatstone, of throwing into a shunt the coils of the field-magnets, by which a greatly improved steadiness of action is obtained. The same characteristics are observable throughout—a definite object in view and a well-directed perseverance in overcoming the difficulties by which the path is usually obstructed.

These are, indeed, the conditions of successful invention. The world knows little of such things, and regards the new machine or the new method as the immediate outcome of a happy idea. Probably, if the truth were known, we should see that, in nine cases out of ten, success depends as much upon good judgment and perseverance as upon fertility

Digitized by Google

of imagination. The labours of our great inventors are not unappreciated, but I doubt whether we adequately realise the enormous obligations under which we lie. It is no exaggeration to say that the life of such a man as Siemens is spent in the public service, the advantages which he reaps for himself being as nothing in comparison with those which he confers upon the community at large.

As an example of this it will be sufficient to mention one of the most valuable achievements of his active life—his introduction, in conjunction with his brother, of the Regenerative Gas Furnace, by which an immense economy of fuel (estimated at millions of tons annually) has been effected in the manufacture of steel and glass. The nature of this economy is easily explained. Whatever may be the work to be done by the burning of fuel, a certain *temperature* is necessary. For example, no amount of heat in the form of boiling water, would be of any avail for the fusion of steel. When the products of combustion are cooled down to the point in question, the heat which they still contain is useless as regards the purpose in view. The importance of this consideration depends entirely upon the working temperature. If the object be the evaporation of water or the warming of a house, almost all the heat may be extracted from the fuel without special arrangements. But it is otherwise when the temperature required is not much below that of combustion itself, for then the escaping gases carry away with them the larger part of the whole heat developed. It was to meet this difficulty that the regenerative furnace was devised. The products of combustion, before dismissal into the chimney, are caused to pass through piles of loosely stacked fire-brick, to which they give up their heat. After a time the fire-brick, upon which the gases first impinge, becomes nearly as hot as the furnace itself. By suitable valves the burnt gases are then diverted through another stack of brickwork, which they heat up in like manner, while the heat stored up in the first stack is utilised to warm the unburnt gas and air on their way to the furnace. In this way almost all the heat developed at a high temperature during the combustion is made available for the work in hand.

As it is now several years since your presidential chair has been occupied by a professed physicist, it may naturally be expected that I should attempt some record of recent progress in that branch of science, if indeed such a term be applicable. For it is one of the difficulties of the task that subjects as distinct as Mechanics, Electricity, Heat, Optics, and Acoustics, to say nothing of Astronomy and Meteorology, are included under Physics. Any one of these may well occupy the life-long attention of a man of science, and to be thoroughly conversant with all of them is more than can be expected of any one individual, and is probably incompatible with the devotion of much time and energy to the actual advancement of knowledge. Not that I would complain of the association sanctioned by common parlance. A sound knowledge of at least the principles of general physics is necessary to the cultivation of any department. The predominance of the sense of sight as the medium of communication with the outer world brings with it dependence upon the science of optics; and there is hardly a branch of science in which the effects of *temperature* have not (often without much success) to be reckoned with. Besides, the neglected borderland between two branches of knowledge is often that which best repays cultivation, or, to use a metaphor of Maxwell's, the greatest benefits may be derived from a cross fertilisation of the sciences. The wealth of material is an evil only from the point of view of one of whom too much may be expected. Another difficulty incident to the task, which must be faced but cannot be overcome, is that of estimating rightly the value, and even the correctness, of recent work. It is not always that which seems at first the most important that proves in the end to be so. The history of science teems with examples of discoveries which attracted little notice at the time, but afterwards have taken root downwards and borne much fruit upwards.

One of the most striking advances of recent years is in the production and application of electricity upon a large scale—a subject to which I have already had occasion to allude in connection with the work of Sir W. Siemens. The dynamo machine is, indeed, founded upon discoveries of Faraday now more than half a century old; but it has required the protracted labours of many inventors to bring it to its present high degree of efficiency. Looking back at the matter, it seems strange that progress should have been so slow. I do not refer to details of design, the elaboration of which must always, I suppose, require the experience of actual work to indicate what parts are structurally weaker than they should be, or are exposed to undue wear and tear. But with regard to the main features of the problem, it would almost seem as if the difficulty lay in want of faith. Long ago it was recognised that electricity derived from chemical action is, on a large scale, too expensive a source of mechanical power, notwithstanding the fact that, as proved by Joule in 1846, the conversion of electrical into mechanical work can be effected with great economy. From this it is an evident consequence that electricity may advantageously be obtained from mechanical power; and one cannot help thinking that if the fact had been borne steadily in mind the development of the dynamo might have been much more rapid. But discoveries and inventions are apt to appear obvious when regarded from the standpoint of accomplished fact; and I draw attention to the matter only to point the moral that we do well to push the attack persistently when we can be sure beforehand that the obstacles to be overcome are only difficulties of contrivance, and that we are not vainly fighting unawares against a law of Nature.

The present development of electricity on a large scale depends, however, almost as much upon the incandescent lamp as upon the dynamo. The success of these lamps demands a very perfect vacuum—not more than about one-millionth of the normal quantity of air should remain—and it is interesting to recall that, twenty years ago, such vacua were rare even in the laboratory of the physicist. It is pretty safe to say that these wonderful results would never have been accomplished had practical applications alone been in view. The way was prepared by an army of scientific men whose main object was the advancement of knowledge, and who could scarcely have imagined that the processes which they elaborated would soon be in use on a commercial scale and entrusted to the hands of ordinary workmen.

When I speak in hopeful language of practical electricity, I do not forget the disappointment within the last year or two of many oversanguine expectations. The enthusiasm of the inventor and promoter are necessary to progress, and it seems to be almost a law of nature that it should overpass the bounds marked out by reason and experience. What is most to be regretted is the advantage taken by speculators of the often uninstructed interest felt by the public in novel schemes by which its imagination is fired. But looking forward to the future of electric lighting, we have good ground for encouragement. Already the lighting of large passsenger ships is an assured success, and one which will be highly appreciated by those travellers who have experienced the tedium of long winter evenings unrelieved by adequate illumination. Here, no doubt, the conditions are in many respects especially favourable. As regards space, life on board ship is highly concentrated; while unity of management and the presence on the spot of skilled engineers obviate some of the difficulties that are met with under other circumstances. At present we have no experience of a house-to-house system of illumination on a great scale and in competition with cheap gas; but preparations are already far advanced for trial on an adequate scale in London. In large institutions, such as theatres and factories, we all know that electricity is in successful and daily extending operation.

When the necessary power can be obtained from the fall of water, instead of from the combustion of coal, the conditions of the problem are far more favourable. Possibly the severity of your winters may prove an obstacle, but it is impossible to regard your splendid river without the thought arising that the day may come when the vast powers now running to waste shall be bent into your service. Such a project demands of course the most careful consideration, but it is one worthy of an intelligent and enterprising community.

The requirements of practice react in the most healthy manner upon scientific electricity. Just as in former days the science received a stimulus from the application to telegraphy, under which everything relating to measurement on a small scale acquired an importance and development for which we might otherwise have had long to wait, so now the requirements of electric lighting are giving rise to a new development of the art of measurement upon a large scale, which cannot fail to prove of scientific as well as practical importance. Mere change of scale may not at first appear a very important matter, but it is surprising how much modification it entails in the instruments, and in the processes of measurement. For instance, the resistance coils on which the electrician relies in dealing with currents whose maximum is a fraction of an ampere, fail altogether when it becomes a question of hundreds, not to say thousands, of amperes.

The powerful currents which are now at command constitute almost a new weapon in the hands of the physicist. Effects which in old days were rare and difficult of observation may now be produced at will on the most conspicuous scale. Consider for a moment Faraday's great discovery of the "Magnetisation of Light," which Tyndall likens to the Weisshorn among mountains, as high, beautiful and alone. This judgment (in which I fully concur) relates to the scientific aspect of the discovery, for to the eye of sense nothing could have been more insignificant. It is even possible that it might have eluded altogether the penetration of Faraday, had he not been provided with a special quality of very heavy glass. At the present day these effects may be produced upon a scale that would have delighted their discoverer, a rotation of the plane of polarisation through 180° being perfectly feasible. With the aid of modern appliances, Kundt and Röntgen in Germany, and H. Becquerel in France, have detected the rotation in gases and vapours, where, on account of its extreme smallness, it had previously escaped notice.

Again, the question of the magnetic saturation of iron has now an importance entirely beyond what it possessed at the time of Joule's early observations. Then it required special arrangements purposely contrived to bring it into prominence. Now in every dynamo machine the iron of the field magnets approaches a state of saturation, and the very elements of an explanation of the action require us to take the fact into account. It is indeed probable that a better knowledge of this subject might lead to improvements in the design of these machines.

Notwithstanding the important work of Rowland and Stowletow, the whole theory of the behaviour of soft iron under varying magnetic conditions is still somewhat obscure. Much may be hoped from the induction balance of Hughes, by which the marvellous powers of the telephone are applied to the discrimination of the properties of metals, as regards magnetism and electric conductivity.

The introduction of powerful alternate currents in machines by Siemens, Gordon, Ferranti, and others, is likely also to have a salutary effect in educating those so-called practical electricians whose ideas do not easily rise above ohms and volts. It has long been known that when the changes are sufficiently rapid, the phenomena are governed much more by induction, or electric inertia, than by mere resistance. On this principle much may be explained that would otherwise seem paradoxical. To take a comparatively simple case, conceive an electro-magnet wound with two contiguous wires, upon which acts a given rapidly periodic electromotive force. If one wire only be used, a certain amount of heat is developed in the circuit. Suppose now that the second wire is brought into operation in parallel—a proceeding equivalent to doubling the section of the original wire. An electrician accustomed only to constant currents would be sure to think that the heating effect would be doubled by the change, as much heat being developed in each wire separately as was at first in the single wire. But such a conclusion would be entirely erroneous. The total current, being governed practically by the self-induction of the circuit, would not be augmented by the accession of the second wire, and

Digitized by Google

the total heating effect, so far from being doubled, would, in virtue of the superior conductivity, be halved.

During the last few years much interest has been felt in the reduction to an absolute standard of measurements of electromotive force, current, resistance, &c., and to this end many laborious investigations have been undertaken. The subject is one that has engaged a good deal of my own attention, and I should naturally have felt inclined to dilate upon it, but that I feel it to be too abstruse and special to be dealt with in detail upon an occasion like the present. As regards resistance, I will merely remind you that the recent determinations have shown a so greatly improved agreement, that the Conference of Electricians assembled at Paris, in May, have felt themselves justified in defining the ohm for practical use as the resistance of a column of mercury of 0deg. C., 1 square millimetre in section, and 106 centimetres in length—a definition differing by a little more than 1 per cent. from that arrived at 20 years ago by a committee of this Association.

A standard of resistance once determined upon can be embodied in a "resistance coil," and copied without much trouble, and with great accuracy. But, in order to complete the electrical system, a second standard of some kind is necessary, and this is not so easily embodied in a permanent form. It might conveniently consist of a standard galvanic cell, capable of being prepared in a definite manner, whose electromotive force is once for all determined. Unfortunately, most of the batteries in ordinary use are for one reason or another unsuitable for this purpose, but the cell introduced by Mr. Latimer Clark, in which the metals are zinc in contact with saturated zinc sulphate and pure mercury in contact with mercurous sulphate, appears to give satisfactory results. According to my measurements, the electromotive force of this cell is 1·435 theoretical volts.

We may also conveniently express the second absolute electrical measurement necessary to the completion of the system by taking advantage of Faraday's law, that the quantity of metal decomposed in an electrolytic cell is proportional to the whole quantity of electricity that passes. The best metal for the purpose is silver, deposited from a solution of the nitrate or of the chlorate. The results recently obtained by Professor Kohlrausch and by myself are in very good agreement, and the conclusion that one ampere flowing for one hour decomposes 4·025 grains of silver can hardly be in error by more than a thousandth part. This number being known, the silver voltameter gives a ready and very accurate method of measuring currents of intensity, varying from 1-10 ampere to four or five amperes.

The beautiful and mysterious phenomena attending the discharge of electricity in nearly vacuous spaces have been investigated and in some degree explained by De la Rue, Crookes, Schuster, Moulton, and the lamented Spottiswoode, as well as by various able foreign experimenters. In a recent research Crookes has sought the origin of a bright citron-coloured band in the phosphorescent spectrum of certain earths, and after encountering difficulties and anomalies of a most bewildering kind, has succeeded in proving that it is due to yttrium, an element much more widely distributed than had been supposed. A conclusion like this is stated in a few words, but those only who have undergone similar experience are likely to appreciate the skill and perseverance of which it is the final reward.

A remarkable observation by Hall, of Baltimore, from which it appeared that the flow of electricity in a conducting sheet was disturbed by magnetic force, has been the subject of much discussion. Mr. Shelford Bidwell has brought forward experiments tending to prove that the effect is of a secondary character, due in the first instance to the mechanical force operating upon the conductor of an electric current when situated in a powerful magnetic field. Mr. Bidwell's view agrees in the main with Mr. Hall's division of the metals into two groups according to the direction of the effect.

Without doubt the most important achievement of the older generation of scientific men has been the establishment and application of the great laws of thermo-dynamics, or, as it is often called, the mechanical theory of heat. The first law, which asserts that heat and mechanical work can be transformed one into the other at a certain fixed rate, is now well understood by every student of physics, and the number expressing the mechanical equivalent of heat resulting from the experiments of Joule, has been confirmed by the researches of others, and especially of Rowland. But the second law, which practically is even more important than the first, is only now beginning to receive the full appreciation due to it. One reason of this may be found in a not unnatural confusion of ideas. Words do not always lend themselves readily to the demands that are made upon them by a growing science, and I think that the almost unavoidable use of the word equivalent in the statement of the first law is partly responsible for the little attention that is given to the second. For the second law so far contradicts the usual statement of the first, as to assert that equivalents of heat and work are not of equal value. While work can always be converted into heat, heat can only be converted into work under certain limitations. For every practical purpose the work is worth the most, and when we speak of equivalents, we use the word in the same sort of special sense as that in which chemists speak of equivalents of gold and iron. The second law teaches us that the real value of heat, as a source of mechanical power, depends upon the temperature of the body in which it resides; the hotter the body in relation to its surroundings, the more available the heat.

In order to see the relations which obtain between the first and the second law of thermo-dynamics, it is only necessary for us to glance at the theory of the steam engine. Not many years ago calculations were plentiful, demonstrating the inefficiency of the steam engine on the basis of a comparison of the work actually got out of the engine with the mechanical equivalent of the heat supplied to the boiler. Such calculations took into account only the first law of thermo-dynamics, which deals with the equivalents of heat and work, and have very little bearing upon the practical question of efficiency, which requires us to have regard also to the second law. According to that law the fraction of the total energy which can be converted into work depends upon the relative temperatures of the boiler and condenser; and it is therefore manifest that, as the temperature of the boiler cannot be raised indefinitely, it is impossible to utilise all the energy which, according to the first law of thermo-dynamics, is resident in the coal.

On a sounder view of the matter, the efficiency of the steam engine is found to be so high that there is no great margin remaining for improvement. The higher initial temperature possible in the gas engine opens out much wider possibilities, and many good judges look forward to a time when the steam engine will have to give way to its younger rival.

To return to the theoretical question, we may say with Sir W. Thomson, that though energy cannot be destroyed, it ever tends to be dissipated, or to pass from more available to less available forms. No one who has grasped this principle can fail to recognise its immense importance in the system of the Universe. Every change—chemical, thermal, or mechanical—which takes place, or can take place, in Nature does so at the cost of a certain amount of available energy. If, therefore, we wish to inquire whether or not a proposed transformation can take place, the question to be considered is whether its occurrence would involve dissipation of energy. If not, the transformation is (under the circumstances of the case) absolutely excluded. Some years ago, in a lecture at the Royal Institution, I endeavoured to draw the attention of chemists to the importance of the principle of dissipation in relation to their science, pointing out the error of the usual assumption that a general criterion is to be found in respect to the development of heat. For example, the solution of a salt in water is, if I may be allowed the phrase, a downhill transformation. It involves dissipation of energy, and can therefore go forward; but in many cases it is associated with the absorption rather than with the development of heat. I am glad to take advantage of the present opportunity in order to repeat my recommendation, with an emphasis justified by actual achievement. The foundations laid by Thomson now bear an edifice of no mean proportions, thanks to the labours of several physicists, among whom must be especially mentioned, Willard Gibbs and Helmholtz. The former has elaborated a theory of the equilibrium of heterogeneous substances, wide in its principles, and we cannot doubt far-reaching in its consequences. In a series of masterly papers Helmholtz has developed the conception of *free energy* with very important applications to the theory of the galvanic cell. He points out that the mere tendency to solution bears in some cases no small proportion to the affinities more usually reckoned chemical, and contributes largely to the total electromotive force. Also in our own country Dr. Alder Wright has published some valuable experiments relating to the subject.

From the further study of electrolysis we may expect to gain improved views as to the nature of the chemical reactions, and of the forces concerned in bringing them about. I am not qualified—I wish I were—to speak to you on recent progress in general chemistry. Perhaps my feelings towards a first love may blind me, but I cannot help thinking that the next great advance, of which we have already some foreshadowing, will come on this side. And if I might without presumption venture a word of recommendation, it would be in favour of a more minute study of the simpler chemical phenomena.

Under the head of scientific mechanics it is principally in relation to fluid motion that advances may be looked for. In speaking upon this subject I must limit myself almost entirely to experimental work. Theoretical hydro-dynamics, however important and interesting to the mathematician, are eminently unsuited to oral exposition. All I can do to attenuate an injustice to which theorists are pretty well accustomed is to refer you to the admirable reports of Mr. Hicks, published under the auspices of this association.

The important and highly practical work of the late Mr. Froude in relation to the propulsion of ships is doubtless known to most of you. Recognising the fallacy of views then widely held as to the nature of the resistance to be overcome, he showed to demonstration that, in the case of fair-shaped bodies, we have to deal almost entirely with resistance dependent upon skin friction, and at high speeds upon the generation of surface waves by which energy is carried off. At speeds which are moderate in relation to the size of the ship, the resistance is practically dependent upon skin friction only. Although Professor Stokes and other mathematicians had previously published calculations pointing to the same conclusion, there can be no doubt that the view generally entertained was very different. At the first meeting of the Association which I ever attended, as an intelligent listener, at Bath in 1864, I well remember the surprise which greeted a statement by Rankine that he regarded skin friction as the only legitimate resistance to the progress of a well designed ship. Mr. Froude's experiments have set the question at rest in a manner satisfactory to those who had little confidence in theoretical prevision.

In speaking of an explanation as satisfactory in which skin friction is accepted as the cause of resistance, I must guard myself against being supposed to mean that the nature of skin friction is itself well understood. Although its magnitude varies with the smoothness of the surface, we have no reason to think that it would disappear at any degree of smoothness consistent with an ultimate molecular structure. That it is connected with fluid viscosity is evident enough, but the *modus operandi* is still obscure.

Some important work bearing upon the subject has recently been published by Professor O. Reynolds, who has investigated the flow of water in tubes as dependent upon the velocity of motion and upon the size of the bore. The laws of motion in capillary tubes, discovered experimentally by Poiseuille, are in complete harmony with theory. The resistance varies as the velocity, and depends in a direct manner upon the constant of viscosity. But when we come to the larger pipes and higher velocities with which engineers usually have to deal, the theory which presupposes

Digitized by Google

a regularly stratified motion evidently ceases to be applicable, and the problem becomes essentially identical with that of skin friction in relation to ship propulsion. Professor Reynolds has traced with much success the passage from the one state of things to the other, and has proved the applicability under these complicated conditions of the general laws of dynamical similarity as adapted to viscous fluids by Professor Stokes. In spite of the difficulties which beset both the theoretical and experimental treatment, we may hope to attain before long to a better understanding of a subject which is certainly second to none in scientific as well as practical interest.

As also closely connected with the mechanics of viscous fluids, I must not forget to mention an important series of experiments upon the friction of oiled surfaces, recently executed by Mr. Tower for the Institution of Mechanical Engineers. The results go far towards upsetting some ideas hitherto widely admitted. When the lubrication is adequate, the friction is found to be nearly independent of the load, and much smaller than is usually supposed, giving a coefficient as low as $\frac{1}{1000}$. When the layer of oil is well formed, the pressure between the solid surfaces is really borne by the fluid, and the work lost is spent in shearing, that is, in causing one stratum of the oil to glide over another.

In order to maintain its position, the fluid must possess a certain degree of viscosity proportionate to the pressure; and even when this condition is satisfied, it would appear to be necessary that the layer should be thicker on the ingoing than on the outgoing side. We may, I believe, expect from Professor Stokes a further elucidation of the processes involved. In the meantime, it is obvious that the results already obtained are of the utmost value, and fully justify the action of the Institution in devoting a part of its resources to experimental work. We may hope, indeed, that the example thus wisely set may be followed by other public bodies associated with various departments of industry.

I can do little more than refer to the interesting observations of Professor Darwin, Mr. Hunt, and M. Forel on Ripplemark. The processes concerned would seem to be of a rather intricate character, and largely dependent upon fluid viscosity. It may be noted, indeed, that most of the still obscure phenomena of hydro-dynamics require for their elucidation a better comprehension of the laws of viscous motion. The subject is one which offers peculiar difficulties. In some problems in which I have lately been interested, a circulating motion presents itself of the kind which the mathematician excludes from the first when he is treating of fluids destitute altogether of viscosity. The intensity of this motion proves, however, to be independent of the coefficient of viscosity, so that it cannot be correctly dismissed from consideration as a consequence of a supposition that the viscosity is infinitely small. The apparent breach of continuity can be explained, but it shows how much care is needful in dealing with the subject, and how easy it is to fall into error.

The nature of gaseous viscosity, as due to the diffusion of momentum, has been made clear by the theoretical and experimental researches of Maxwell. A flat disc moving in its own plane between two parallel solid surfaces is impeded by the necessity of shearing the intervening layers of gas, and the magnitude of the hindrance is proportional to the velocity of the motion and to the viscosity of the gas, so that under similar circumstances this effect may be taken as a measure, or rather definition, of the viscosity. From the dynamical theory of gases, to the development of which he contributed so much, Maxwell drew the startling conclusion that the viscosity of a gas should be independent of its density—that within wide limits the resistance to the moving disc should be scarcely diminished by pumping out the gas, so as to form a partial vacuum. Experiment fully confirmed this theoretical anticipation, —one of the most remarkable to be found in the whole history of science, and proved that the swinging disc was retarded by the gas, as much when the barometer stood at half an inch as when it stood at thirty inches. It was obvious, of course, that the law must have a limit, that at a certain point of exhaustion the gas must begin to lose its power; and I remember discussing with Maxwell, soon after the publication of his experiments, the whereabouts of the point at which the gas would cease to produce its ordinary effect. His apparatus, however, was quite unsuited for high degrees of exhaustion, and the failure of the law was first observed by Kundt and Warburg, as pressures below 1 mm. of mercury. Subsequently the matter has been thoroughly examined by Crookes, who extended his observations to the highest degrees of exhaustion as measured by M'Leod's gauge. Perhaps the most remarkable results relate to hydrogen. From the atmospheric pressure of 760 mm. down to about ½ mm. of mercury the viscosity is sensibly constant. From this point to the highest vacua, in which less than one-millionth of the original gas remains, the coefficient of viscosity drops down gradually to a small fraction of its original value. In these vacua Mr. Crookes regards the gas as having assumed a different ultra-gaseous condition; but we must remember that the phenomena have relation to the other circumstances of the case, especially the dimensions of the vessel, as well as to the condition of the gas.

Such an achievement as the prediction of Maxwell's law of viscosity has, of course, drawn increased attention to the dynamical theory of gases. The success which has attended the theory in the hands of Clausius, Maxwell, Boltzmann and other mathematicians, not only in relation to viscosity, but over a large part of the entire field of our knowledge of gases, proves that some of its fundamental postulates are in harmony with the reality of Nature. At the same time, it presents serious difficulties; and we cannot but feel that while the electrical and optical properties of gases remain out of relation to the theory no final judgment is possible. The growth of experimental knowledge may be trusted to clear up many doubtful points, and a younger generation of theorists will bring to bear improved mathematical weapons. In the meantime we may fairly congratulate ourselves on the possession of a guide which has already conducted us to a position which could hardly otherwise have been attained.

In Optics attention has naturally centred upon the spectrum. The mystery attaching to the invisible rays lying beyond the red has been fathomed to an extent that, a few years ago, would have seemed almost impossible. By the use of special photographic methods Abney has mapped out the peculiarities of this region with such success that our knowledge of it begins to be comparable with that of the parts visible to the eye. Equally important work has been done by Langley, using a refined invention of his own based upon the principle of Siemens's pyrometer. This instrument measures the actual energy of the radiation, and thus expresses the effects of various parts of the spectrum upon a common scale, independent of the properties of the eye and of sensitive photographic preparations. Interesting results have also been obtained by Becquerel, whose method is founded upon a curious action of the ultra-red rays in enfeebling the light emitted by phosphorescent substances. One of the most startling of Langley's conclusions relates to the influence of the atmosphere in modifying the quality of solar light. By the comparison of observations made through varying thicknesses of air, he shows that the atmospheric absorption tells most upon the light of high refrangibility; so that to an eye situated outside the atmosphere, the sun would present a decidedly bluish tint. It would be interesting to compare the experimental numbers with the law of scattering of light by small particles given some years ago as the result of theory. The demonstration by Langley of the inadequacy of Cauchy's law of dispersion to represent the relation between refrangibility and wave-length in the lower part of the spectrum must have an important bearing upon optical theory.

The investigation of the relation of the visible and ultra-violet spectrum to various forms of matter has occupied the attention of a host of able workers, among whom none have been more successful than my colleagues at Cambridge, Professors Liveing and Dewar. The subject is too large both for the occasion and for the individual, and I must pass it by. But, as more closely related to optics proper, I cannot resist recalling to your notice a beautiful application of the idea of Doppler to the discrimination of the origin of certain lines observed in the solar spectrum. If a vibrating body have a general motion of approach or recession, the waves emitted from it reach the observer with a frequency which in the first case exceeds, and in the second case falls short of, the real frequency of the vibrations themselves. The consequence is that, if a glowing gas be in motion in the line of sight, the spectral lines are thereby displaced from the position that they would occupy were the gas at rest—a principle which, in the hands of Huggins and others, has led to a determination of the motion of certain fixed stars relatively to the solar system. But the sun is itself in rotation, and thus the position of a solar spectral line is slightly different according as the light comes from the advancing or from the retreating limb. This displacement was, I believe, first observed by Thollon; but what I now desire to draw attention to is the application of it by Cornu to determine whether a line is of solar or atmospheric origin. For this purpose a small image of the sun is thrown upon the slit of the spectroscope, and caused to vibrate two or three times a second, in such a manner that the light entering the instrument comes alternately from the advancing and retreating limbs. Under these circumstances a line due to absorption within the sun appears to tremble, as the result of slight alternately opposite displacements. But if the seat of the absorption be in the atmosphere, it is a matter of indifference from what part of the sun the light originally proceeds, and the line maintains its position in spite of the oscillation of the image upon the slit of the spectroscope. In this way Cornu was able to make a discrimination which can only otherwise be effected by a difficult comparison of appearances under various solar altitudes.

The instrumental weapon of investigation, the spectroscope itself, has made important advances. On the theoretical side we have for our guidance the law that the optical power in gratings is proportional to the total number of lines accurately ruled, without regard to the degree of closeness, and in prisms that it is proportional to the thickness of glass traversed. The magnificent gratings of Rowland are a new power in the hands of the spectroscopist, and as triumphs of mechanical art seem to be little short of perfection. In our own report for 1882, Mr. Mallock has described a machine, constructed by him, for ruling large diffraction gratings, similar in some respects to that of Rowland.

The great optical constant, the velocity of light, has been the subject of three distinct investigations by Cornu, Michelson, and Forbes. As may be supposed, the matter is of no ordinary difficulty, and it is therefore not surprising that the agreement should be less decided than could be wished. From their observations, which were made by a modification of Fizeau's method of the toothed wheel, Young and Forbes drew the conclusion that the velocity of light *in vacuo* varies from colour to colour to such an extent that the velocity of blue light is nearly two per cent. greater than that of red light. Such a variation is quite opposed to existing theoretical notions, and could only be accepted on the strongest evidence. Mr. Michelson, whose method (that of Foucault) is well suited to bring into prominence a variation of velocity with wave length, informs me that he has recently repeated his experiments with special reference to the point in question, and has arrived at the conclusion that no variation exists comparable with that asserted by Young and Forbes. The actual velocity differs little from that found from his first series of experiments, and may be taken to be 299,800 kilometres per second.

It is remarkable how many of the playthings of our childhood give rise to questions of the deepest scientific interest. The top is, or may be understood, but a complete comprehension of the kite and of the soap bubble would carry us far beyond our present stage of knowledge. In spite of the admirable investigations of Plateau, it still remains a mystery why soapy water stands almost alone among fluids a material for bubbles. The beautiful development of colour was long ago ascribed to the interference of light, called into play by the gradual thinning of the film. In accordance with this view the tint is determined solely by the thickness

Digitized by Google

of the film and the refractive index of the fluid. Some of the phenomena are, however, so curious as to have led excellent observers like Brewster to reject the theory of thin plates, and to assume the secretion of various kinds of colouring matter. If the rim of a wine glass be dipped in soapy water, and then held in a vertical position, horizontal bands soon begin to show at the top of the film, and extend themselves gradually downwards. According to Brewster these bands are not formed by the "subsidence and gradual thinning of the film," because they maintain their horizontal position when the glass is turned round its axis. The experiment is both easy and interesting; but the conclusion drawn from it cannot be accepted. The fact is that the various parts of the film cannot quickly alter their thickness, and hence when the glass is rotated they re-arrange themselves in order of superficial density, the thinner parts floating up over, or through, the thicker parts. Only thus can the tendency be satisfied for the centre of gravity to assume the lowest possible position.

When the thickness of a film falls below a small fraction of the length of a wave of light, the colour disappears, and is replaced by an intense blackness. Professors Reinold and Rücker have recently made the remarkable observation that the whole of the black region, soon after its formation, is of uniform thickness, the passage from the black to the coloured portions being exceedingly abrupt. By two independent methods they have determined the thickness of the black film to lie between seven and fourteen millionths of a millimetre; so that the thinnest films correspond to about one-seventieth of a wave-length of light. The importance of these results in regard to molecular theory is too obvious to be insisted upon.

The beautiful inventions of the telephone and the phonograph, although in the main dependent upon principles long since established, have imparted a new interest to the study of Acoustics. The former, apart from its uses in every day life, has become in the hands of its inventor, Graham Bell, and of Hughes, an instrument of first-class scientific importance. The theory of its action is still in some respects obscure, as is shown by the comparative failure of the many attempts to improve it. In connection with some explanations that have been offered, we do well to remember that molecular changes in solid masses are inaudible in themselves, and can only be manifested to our ears by the generation of a to and fro motion of the external surface extending over a sensible area. If the surface of a solid remains undisturbed, our ears can tell us nothing of what goes on in the interior.

In theoretical acoustics progress has been steadily maintained, and many phenomena which were obscure twenty or thirty years ago have since received adequate explanation. If some important practical questions remain unsolved, one reason is that they have not yet been definitely stated. Almost everything in connection with the ordinary use of our senses presents peculiar difficulties to scientific investigation. Some kinds of information with regard to their surroundings are of such paramount importance to successive generations of living beings, that they have learned to interpret indications which, from a physical point of view, are of the slenderest character. Every day we are in the habit of recognising, without much difficulty, the quarter from which a sound proceeds, but by what steps we attain that end has not yet been satisfactorily explained. It has been proved that when proper precautions are taken we are unable to distinguish whether a pure tone (as from a vibrating tuning fork held over a suitable resonator) comes to us from in front or from behind. This is what might have been expected from an *a priori* point of view; but what would not have been expected is that with almost any other sort of sound, from a clap of the hands to the clearest vowel sound, the discrimination is not only possible but easy and instinctive. In these cases it does not appear how the possession of two ears helps us, though there is some evidence that it does; and even when sounds come to us from the right or left, the explanation of the ready discrimination which is then possible with pure tones is not so easy as might at first appear. We should be inclined to think that the sound was heard much more loudly with the ear that is turned towards than with the ear that is turned from it, and that in this way the direction was recognised. But, if we try the experiment, we find that, at any rate with notes near the middle of the musical scale, the difference of loudness is by no means so very great. The wave-lengths of such notes are long enough in relation to the dimensions of the head to forbid the formation of anything like a sound shadow in which the averted ear might be sheltered.

In concluding this imperfect survey of recent progress in physics, I must warn you emphatically that much of great importance has been passed over altogether. I should have liked to speak to you of those far reaching speculations, especially associated with the name of Maxwell, in which light is regarded as a disturbance in an electro-magnetic medium. Indeed, at one time, I had thought of taking the scientific work of Maxwell as the principal theme of this address. But, like most men of genius, Maxwell delighted in questions too obscure and difficult for hasty treatment, and thus much of his work could hardly be considered upon such an occasion as the present. His biography has recently been published, and should be read by all who are interested in science and in scientific men. His many-sided character, the quaintness of his humour, the penetration of his intellect, his simple but deep religious feeling, the affection between son and father, the devotion of husband to wife, all combine to form a rare and fascinating picture. To estimate rightly his influence upon the present state of science, we must regard not only the work that he executed himself, important as that was, but also the ideas and the spirit which he communicated to others. Speaking for myself as one who in a special sense entered into his labours, I should find it difficult to express adequately my feeling of obligation. The impress of his thoughts may be recognised in much of the best work of the present time. As a teacher and examiner he was well acquainted with the almost universal tendency of uninstructed minds to elevate phrases above things; to refer, for example, to the principle of the conservation of energy for an explanation of the persistent rotation of a fly-wheel, almost in the style of the doctor in "Le Malade Imaginaire," who explains the fact that opium sends you to sleep by its soporific virtue. Maxwell's endeavour was always to keep the facts in the foreground, and to his influence, in conjunction with that of Thomson and Helmholtz, is largely due that elimination of unnecessary hypothesis which is one of the distinguishing characteristics of the science of the present day.

In speaking unfavourably of superfluous hypothesis, let me not be misunderstood. Science is nothing without generalisations. Detached and ill-assorted facts are only raw material, and in the absence of a theoretical solvent have but little nutritive value. At the present time and in some departments, the accumulation of material is so rapid that there is danger of indigestion. By a fiction as remarkable as any to be found in law, what has once been published, even though it be in the Russian language, is usually spoken of as "known," and it is often forgotten that the rediscovery in the library may be a more difficult and uncertain process than the first discovery in the laboratory. In this matter we are greatly dependent upon annual reports and abstracts, issued principally in Germany, without which the search for the discoveries of a little-known author would be well-nigh hopeless. Much useful work has been done in this direction in connection with our Association. Such critical reports as those upon hydro-dynamics, upon tides, and upon spectroscopy, guide the investigator to the points most requiring attention, and in discussing past achievements contribute in no small degree to future progress. But though good work has been done, much yet remains to do.

If, as is sometimes supposed, science consisted in nothing but the laborious accumulation of facts, it would soon come to a standstill, crushed, as it were, under its own weight. The suggestion of a new idea, or the detection of a law, supersedes much that had previously been a burden upon the memory, and by introducing order and coherence facilitates the retention of the remainder in an available form. Those who are acquainted with the writings of the older electricians will understand my meaning when I instance the discovery of Ohm's law as a step by which the science was rendered easier to understand and to remember. Two processes are thus at work side by side, the reception of new material and the digestion and assimilation of the old; and as both are essential, we may spare ourselves the discussion of their relative importance. One remark, however, should be made. The work which deserves, but I am afraid does not always receive, the most credit is that in which discovery and explanation go hand in hand, in which not only are new facts presented, but their relation to old ones is pointed out.

In making oneself acquainted with what has been done in any subject it is good policy to consult first the writers of highest general reputation. Although in scientific matters we should aim at independent judgment, and not rely too much upon authority, it remains true that a good deal must often be taken upon trust. Occasionally an observation is so simple and easily repeated that it scarcely matters from whom it proceeds; but as a rule it can hardly carry full weight when put forward by a novice, whose care and judgment there has been no opportunity of testing, and whose irresponsibility may tempt him to "take shots," as it is called. Those who have had experience in accurate work know how easy it would be to save time and trouble by omitting precautions and passing over discrepancies, and yet, even without dishonest intention, to convey the impression of conscientious attention to details. Although the most careful and experienced cannot hope to escape occasional mistakes, the effective value of this kind of work depends much upon the reputation of the individual responsible for it.

In estimating the present position and prospects of experimental science there is good ground for encouragement. The multiplication of laboratories gives to the younger generation opportunities such as have never existed before, and which excite the envy of those who have had to learn in middle life much that now forms part of an undergraduate course. As to the management of such institutions there is room for a healthy difference of opinion. For many kinds of original work, especially in connection with accurate measurement, there is need of expensive apparatus; and it is often difficult to persuade a student to do his best with imperfect appliances when he knows that by other means a better result could be attained with greater facility. Nevertheless it seems to me important to discourage too great reliance upon the instrument maker. Much of the best original work has been done with the homeliest appliances; and the endeavour to turn to the best account the means that may be at hand develops ingenuity and resource more than the most elaborate determinations with ready-made instruments. There is danger otherwise that the experimental education of a plodding student should be too mechanical and artificial, so that he is puzzled by small changes of apparatus much as many school boys are puzzled by a transposition of the letters in a diagram of Euclid.

From the general spread of a more scientific education we are warranted in expecting important results. Just as there are some brilliant literary men with an inability, or at least a distaste practically amounting to inability, for scientific ideas, so there are a few with scientific tastes whose imaginations are never touched by merely literary studies. To save these from intellectual stagnation during several important years of their lives is something gained; but the thorough-going advocates of scientific education aim at much more. To them it appears strange, and almost monstrous, that the dead languages should hold the place they do in general education; and it can hardly be denied that their supremacy is the result of routine rather than of argument. I do not myself take up the extreme position. I doubt whether an exclusively scientific training would be satisfactory; and where there is plenty of time and a literary aptitude I can believe that Latin and Greek may make a good foundation. But it is useless to discuss the question upon the supposition that the majority of boys attain either to a knowledge of the languages or to an appreciation of the writings of the ancient authors. The contrary is notoriously the truth, and the defenders of the existing system usually

Digitized by Google

take their stand upon the excellence of its discipline. From this point of view there is something to be said. The laziest boy must exert himself a little in puzzling out a sentence with grammar and dictionary, while instruction and supervision are easy to organise and not too costly. But when the case is stated plainly few will agree that we can afford so entirely to disregard results. In after life the intellectual energies are usually engrossed with business, and no further opportunity is found for attacking the difficulties which block the gateways of knowledge. Mathematics, especially if not learned young, are likely to remain unlearned. I will not further insist upon the educational importance of mathematics and science, because with respect to them I shall probably be supposed to be prejudiced. But of modern languages I am ignorant enough to give value to my advocacy. I believe that French and German, if properly taught, which I admit they rarely are at present, would go far to replace Latin and Greek from a disciplinary point of view, while the actual value of the acquisition would in the majority of cases be incomparably greater. In half the time usually devoted, without success, to the classical languages, most boys could acquire a really serviceable knowledge of French and German. History and the serious study of English literature, now shamefully neglected, would also find a place in such a scheme.

There is one objection often felt to a modernised education, as to which a word may not be without use. Many excellent people are afraid of science as tending towards materialism. That such apprehension should exist is not surprising, for unfortunately there are writers, speaking in the name of science, who have set themselves to foster it. It is true that among scientific men, as in other classes, crude views are to be met with as to the deeper things of Nature; but that the life-long beliefs of Newton, of Faraday, and of Maxwell are inconsistent with the scientific habit of mind is surely a proposition which I need not pause to refute. It would be easy, however, to lay too much stress upon the opinions of even such distinguished workers as these. Men who devote their lives to investigation cultivate a love of truth for its own sake, and endeavour instinctively to clear up, and not, as is too often the object in business and politics, to obscure a difficult question. So far the opinion of a scientific worker may have a special value; but I do not think that he has a claim superior to that of other educated men to assume the attitude of a prophet. In his heart he knows that underneath the theories that he constructs there lie contradictions which he cannot reconcile. The higher mysteries of being, if penetrable at all by human intellect, require other weapons than those of calculation and experiment.

Without encroaching upon grounds appertaining to the theologian and the philosopher, the domain of natural science is surely broad enough to satisfy the wildest ambition of its devotees. In other departments of human life and interest true progress is rather an article of faith than a rational belief; but in science a retrograde movement is, from the nature of the case, almost impossible. Increasing knowledge brings with it increasing power, and great as are the triumphs of the present century we may well believe that they are but a foretaste of what discovery and invention have yet in store for mankind. Encouraged by the thought that our labours cannot be thrown away, let us redouble our efforts in the noble struggle. In the Old World and in the New recruits must be enlisted to fill the place of those whose work is done. Happy should I be if, through this visit of the Association, or by any words of mine, a larger measure of the youthful activity of the West could be drawn into this service. The work may be hard and the discipline severe, but the interest never fails, and great is the privilege of achievement.

THE TELEPHONE AND THE POST OFFICE.

A special meeting of the Glasgow Chamber of Commerce was held on Monday afternoon for the purpose of hearing a statement and suggestions by Mr. William Alexander Smith in reference to the telephone companies and the Post Office. Mr. J. M'Laren presided. We take the following report of the proceedings from the *Glasgow Herald*:—

The CHAIRMAN said that at the last meeting of the Chamber he stated that he had had a communication from Mr. W. A. Smith in regard to the Post Office telephonic arrangements, asking him to bring the matter before the directors. It was thought at the time that as Mr. Fawcett had the matter under consideration, and had promised to make a statement in the House of Commons on the subject, it was not desirable that any representation should be made. Mr. Fawcett had since made his statement, which was considered generally satisfactory. But Mr. Smith had had another interview with the convener of the Home Committee, the result of which was that a meeting of the committee was convened. At that meeting the subject was discussed, and it was thought that Mr. Smith had made out a sufficient case for calling the directors together. The present meeting had accordingly been called for the purpose of hearing Mr. Smith, and of coming to any resolution that might be thought desirable.

The SECRETARY then read the minutes of the meeting of the Home Committee, which recommended that the directors should agree to the ollowing resolutions:—"The directors of the Chamber, while viewing with satisfaction the liberal nature of Mr. Fawcett's proposals in regard to the use of the telephone in this country, after experience of which it is earnestly hoped may in future enable further facilities to be conceded without loss of revenue to the Post Office Department, respectfully submit for Mr. Fawcett's consideration—first, that the charging of a royalty of 10 per cent. on the rentals of private lines should not be insisted on, in respect that it places an undue burden upon the use of the telephone; second, that the running of wires between the Post Office telegraph stations and telephone exchanges for the purpose of receiving and despatching telegrams to and from subscribers to such exchanges should be sanctioned and encouraged, and that in all cases where telephone companies are prepared to bear the cost of such wires and guarantee to the Department due payment on telegrams so transmitted, no burden should be imposed on this facility to the development of the Post Office revenue."

Mr. KING, the convener of the Home Committee, in moving the adoption of the minute, said that Mr. Smith made a long statement to the committee, and recommended that the directors should memorialise Mr. Fawcett on the two points embraced in the resolution while the matter was still in dependence, and before the regulations for the future working of the telephone were reduced to writing. It seemed to the committee that by adopting these resolutions the committee would be taking a step which would likely be attended by a good result, inasmuch as the sanctioning of the connection of the wires of subscribers to the exchange with the telegraphs would involve no loss of revenue to the Telegraph Department, but was rather likely to be in its favour. On the other hand it was a new proposal on the part of Mr. Fawcett to impose a tax in respect of private wires, the revenue from which had hitherto been untaxed. Mr. Fawcett did not seem to be very strong on this subject, because in making the proposal that the royalty should be extended to private wires he said the object was not so much to increase the revenue as to simplify the accounts. If this was the sole purpose of the tax he thought it would be easy to make such arrangements as would satisfy him that the returns were just returns, and that they could be easily checked.

The minute was thereafter adopted, and it was agreed that Mr. Smith should be heard.

Mr. SMITH was accordingly introduced, and addressed the meeting. Having referred to the resolutions which the committee had agreed to recommend for adoption, he said it was almost necessary that he should in the first place allude to the royalty that had hitherto been paid by the telephonic companies to the Post Office. That royalty amounted in all to 10 per cent. on the gross receipts—a very large sum. It might be said that this was a matter with which the Chamber had nothing to do, that it was a question entirely for the telephone companies. But in the offer which he made to the Postmaster-General he distinctly stated that whatever reduction of royalty might be granted would be entirely given to the public. He was not speaking for the companies, but for the public, as would be seen when he had said that this royalty amounted to the profit on more than double the nominal increase of all the telegraphic messages in this country, or to more than 5s. in the £ of the net earnings of the companies. Were anything like the same tax imposed upon other industries, such as railways, it would be sufficient in the case, for example, of the North British Railway Company to sweep away all the dividend on the ordinary stock, and to leave them short of money to pay their preference dividends. The reason why he asked them to consider the question in a manner that might appear urgent was that Mr. Fawcett had not said his last word upon the question. He had been good enough to indicate that he would consider the two important points on which he (the speaker) had asked the Chamber to move; and they would readily understand that after Mr. Fawcett's final statement it would be almost impossible for him to move. The point to which he desired to call attention was that the Telephonic Exchanges should be connected with the central telegraph system of the Post Office. Mr. Fawcett, in all the arguments he had urged against the proposal, had said that he must protect the public revenue, that he was trustee on behalf of the Post Office, and that having bought the telegraphs he must make them pay, no matter how private industry might languish. But this particular demand was one that could do nothing but bring the Post Office net revenue. Another reason why he asked the Chamber to move in the matter was that about three years ago he submitted to St. Martin's-le-Grand an offer to make the experiment in Glasgow, and in that offer he came under an obligation to pay all the expense of running the wires to George-square, to pay the rental of a room, to pay the cost of the operators necessary to take in the messages, and to guarantee to the Department by depositing £500, £1,000, or whatever sum might be required. Furthermore, he undertook to free them from all liability as to the correct transmission of telegrams so sent through the telephone. The answer he got was that any firm which desired this facility should pay five guineas per annum—the price of 105 messages—and that thereafter they would be allowed to pay for telegrams like any ordinary individual. Of course, they would see that when the expense was to be on the Company, and the revenue was to go to the Government, the Company did not see their way to ask subscribers to pay an additional five guineas per annum. It was useless for Mr. Fawcett or the permanent heads of departments to say that this facility could not be granted. Newcastle had now just what the St. Martin's-le-Grand officials refused to concede to Glasgow three or four years ago. In the Newcastle Exchange there were five or six boxes in which operators sat for no other purpose than taking in telegrams from subscribers to the telephone system. He thought it must be quite clear to all that he had no desire to speak on behalf of the telephone companies. There was no proposal that the companies should receive any portion of the price of these telegrams, although in America they did allow the telephone companies 20 per cent. on the receipts from said companies. The companies were willing to go to the expense of providing their subscribers with additional facilities, hoping to reap an indirect benefit. By what had been called a mere accident of the drafting of an Act of Parliament the Postmaster-General was enabled to substantiate his claim to impose a royalty on telephonic exchanges, but by no Act under the sun could he demand payment of an additional royalty. There was nothing at present enacted to prevent anyone running private telephone wires and ignoring the Postmaster-General altogether. That argument, he thought, spoke for itself. He had only further to ask them to remember that when the telephone was first submitted to the Postmaster-General the scientific heads of the department said it was a mere toy, and of no use at all. The invention was then

Digitized by Google

taken up by others, and since its adoption every obstacle had been thrown in the way of its development by the Post Office, not by Mr. Fawcett, but by those under him. Mr. Fawcett had swept away with a liberal hand many of the absurd restrictions placed upon it. But while he had been giving with the right hand he had been taking away with the left, and the additional royalty would amount to fully 25 per cent. more than had hitherto been exacted from the telephone companies. He thought, in the interest of the public, action should be taken at once to get him to forego this additional royalty, which would be just a tax on the public. The telephone companies were not philanthropic companies, they wanted to make money if they could, and the royalty, if imposed, would affect the charges. In conclusion, he repeated that the whole trouble which threatened them was simply the outcome of the fear that the heads of certain departments in the Post Office had of the development of the telephone.

Several questions having been put to Mr. Smith in further exposition of the subject,

Mr. KING moved that the Chamber memorialise the Postmaster-General in the terms recommended by the committee.

Sir JAMES WATSON seconded the motion.

Mr. W. M'EWEN said he did not wish to raise any objection to the motion, but if they were to allow a tax to be imposed on public telephones and to object to a tax on private telephones, he failed to see where the principle applied.

Mr. SMITH said in the one case the Postmaster-General had an Act of Parliament at his back, in the other there was no such Act.

Sir JAMES WATSON thought the fact that it was a new tax altogether put it in a different position.

The resolutions were thereafter unanimously adopted, and the meeting separated.

COMPANIES' MEETINGS.

Pilsen, Joel, and General Electric Light Company (Limited and Reduced).

The third ordinary general meeting of the shareholders of the above Company was held on Thursday, at the Cannon-street Hotel, under the presidency of Sir Rawson W. Rawson, K.C.M.G., C.B.

The SECRETARY (Mr. E. T. Gregory) read the notice convening the meeting, and the report of the directors was taken as read. It stated, *inter alia*, that "The directors are glad to inform the shareholders that they have successfully carried out the first special resolution passed at the general meetings held in March last, and they congratulate them on the fact that the 11,530 fully paid shares owned by the Union Company, and 370 out of the 470 held by other parties, are now surrendered, leaving only 100 fully paid shares on the register. This relieves the Company from a heavy liability, and is practically a large reduction, amounting to 60 per cent., off the price originally paid for the patents. The second special resolution, viz., to reduce the liability on the partly paid shares by £1, is being carried out as rapidly as the legal formalities will admit."

The CHAIRMAN: In moving the adoption of this report, I think I shall consult your convenience by not detaining you with any long remarks. The Board have carried out the intention which they expressed at the last general meeting, that they would carry on the business of the Company to the best of their ability for another year in the expectation of being able, during that time, to place the business of the Company on a sound and profitable basis, and that if they failed to do that they would come to the shareholders, lay their case before them, and leave them to decide, with the more extended view which they may have of what is likely to occur in the electrical world, whether the Board should continue to carry on the business, or should adopt measures for limiting the expenditure and avoiding further loss of money. The Board deplore with you the result of last year's working. It has not been from any negligence or inattention on their part. They have done their best in the interests of the Company. They have devoted their time and their best services to the shareholders without any reference to personal considerations, at a very great expenditure of time, and, I can assure you, with a very large expenditure of anxiety. We have done our best, but the impediments to success in electrical work you are all familiar with, I am sorry to say, by the failing of so many other companies, whose example in many respects I hope we shall not follow. We have, however, evidence of the difficulty of companies carrying on electrical work with a profit at the present time. We anticipated when we met last year that the public during the winter would have set their minds again on electrical work, but, as we have stated in our report, the difficulties created by the Act of Parliament, the existing state of trade, the general depression, and the indisposition of persons to involve themselves in new and uncertain expenditure, have all combined to hinder their having installations during the last winter. At the present time there is a better prospect, but not such a prospect as would induce us at once to embark in any new installations with a risk of involving the shareholders in further expenditure, and rendering it necessary to call upon them for a further contribution. The directors were, we believe, in entire harmony with the shareholders that it is not expedient to take any action which will incur the risk of a further call. The last call was made for the purpose of carrying out a special object, a most important object, agreed to by the shareholders unanimously in March—to reduce the liability towards the fully paid shareholders. We have succeeded in completing that arrangement, and the shareholders are entirely free from any obligation beyond the balance of the debts which they owed on the 30th of June and the credits which they possessed at the same date. The total indebtedness at that time was stated at about £4,000 and our credits at about £3,000, and consequently the Company is at present liable upon its existing assets to the extent of £1,000. Therefore, under these circumstances, we see that we can save the shareholders from any risk of further calls if they combine with the directors in the action that we have proposed. We have laid before the shareholders with perfect frankness and honesty the exact position of the Company. We have also, after the best consideration that we could give, suggested a line of policy which we believe our shareholders are prepared to adopt. We hope they will act with us to-day in this matter by adopting that policy as set forth in the report. I wish to say one word personal to myself. At our meeting in March I said I saw a rift in the clouds —that I believed at that time there was a chance of our being able to carry on the business at a profit before the winter. I must confess my thorough disappointment in that matter. I do not see at the present time the prospect of our carrying on with the capital already expended—the chance of our being able to do a business which will yield a profit and a dividend for the shareholders; and therefore it is better that we should make the arrangement here suggested, to cut down expenditure, to avoid all future expenditure, until there is some opening, and if there be no opening, that we should come and tell you so. We are united with the shareholders in our determination not to involve the risk of a further call. I believe—and I think most of my co-directors are firmly of that opinion—that there is a future for electric lighting, and that that future is hastening on. We believe that the work of the last two years by our own Company, and by other companies, has cleared the way of many of the difficulties attending upon the installation of electric lighting. We believe that electric lighting may be carried on not only successfully, but also profitably. It will, however, require a great deal of management, and a great deal of economy, it will require a much cheaper factory than we have been involved in from the beginning; it will require a much more simple organisation than that under which we exist to secure a profit. For these reasons we have suggested that we should stop all expenditure, that we should have a limited—a smaller—number of directors to look after the affair, that we should try and engage other capable persons to carry on what necessary business we are under obligation to execute—namely, our contracts for installation, so that we may not be required to keep up a factory and the expense of engines and staff there; and we believe that, adopting that course and waiting for the development of electric lighting, we may still be able to save a considerable sum for our shareholders. Upon these grounds we come with considerable confidence—having communicated with many of the principal shareholders—before you with the proposals which you will have to consider to-day. There is one matter I ought to have mentioned. There is an omission in the report—that General Hopkinson, who was one of our original directors, resigned his seat a year ago, after our first meeting, and we did not consider it expedient to fill up his place. His engagements prevented him from giving any very regular attendance to our affairs, and he was not very sanguine as to the prospect of success. Although we regretted exceedingly the loss of his very valuable advice and support, we were obliged to accept his resignation. The report mentions that one of our directors has not the same view as ourselves with regard to the course to be adopted. Mr. Fellows, who has devoted a great deal of attention to the work of the Company, and who has been most regular in his attendance both at the Board and the factory, having looked into the business of the factory with great diligence and very great interest, does not agree with us as to the policy of our placing our seats at the Board at your immediate disposal; nor does he believe that he is bound to do so under the circumstances attending the modification in that article of our Articles of Association. We believe that it was intended that our continuance in office should be limited to the year 1884; but Mr. Fellows is of a different opinion. He believes it was intended that it should be limited to the year 1886, and he has thought it his duty to continue in his position, although his colleagues, taking a different view, have thought it their duty to tender their resignation; in fact to resign at the present meeting, for the purpose of enabling you to make such appointments for the future direction as may insure your confidence. Though we believe we have not forfeited your confidence, yet we wish to have the renewal of it by the nomination of those gentlemen, either in or out of the Board, who in your opinion would be most likely to carry on the business for your advantage. With these remarks, I move:—"That the report and the general accounts for the past year be adopted."

Mr. HORACE W. SCRIVEN seconded the motion.

Mr. JOEL stated that the directors in the report had expressed their belief that "no company has fared better in this country than ourselves." He, however, thought that the Anglo-American Company, by good management, had fared better than this Company, which, however, he believed had practically the best lamp in the market, and which, he thought, started better than any other company. Moreover, there was no Stock Exchange speculation in connection with the Company, and he contended that they might have done better. Private firms had done a great deal of electric work, and successfully, and in fact though there had been a considerable amount of work to do this Company had not done it. In the previous year there was a turn over by the Company of £3,000, and a loss of £6,000, and in the past year there had been a turn over of £6,000 and a loss of £11,000. His opinion was that that loss had been incurred because the directors had ignored technical assistance, and had tried to conduct a technical business without technical advice. He had been asked to resign, and had parted from the Company for the last 18 or 20 months. Holding 600 shares in the Company, he felt that it was very hard that he had not been allowed to assist in the work it had to do. He felt sure that had he been adviser to the Company as their managing engineer, the loss of £11,000 would not have

Digitized by Google

been incurred. They had colonial patents all over the world, but, as far as he knew, nothing had been done with them. He was in favour of all manufacturing business being given up by the directors, the closing of the factory and the office, and the manufacture of the patents on royalties. He then asked a series of twelve questions, and afterwards stated that at their first and second meetings it was said that the money to be spent on experiments would be reduced to a minimum, though he had reason to believe that a great deal of money had been spent in that manner. In the original prospectus a long list was given of the employers of the Pilsen lamp. He had written to all of them, and had asked their opinion of the lamp. In reply he had received 35 letters, out of which 33 were splendid testimonials.

After a few observations from Mr. BLAYDON,

Mr. QUILTER expressed his opinion that the facts stated in the present and the preceding reports had demonstrated that under the present condition of affairs the Company stood very little chance of making a profit. A previous speaker had said that the Company had suffered from the want of technical advice, but he himself was interested in companies now where there had been too much technical advice. As to the future of the electric light, they still believed in it, their faith being only lost in the mode in which they were at present trying to bring out that future. The Legislature had clearly made a great error in the restrictions it had imposed on electric lighting companies.

Mr. J. ROSS warmly expressed his belief in the Pilsen lamp, and said he believed there was a chance of ths Company living, and at no very distant date.

Mr. BELFOUR asked a question as to the item of arrears of calls, £8,261.

The CHAIRMAN, replying, stated that the interest on the arrears had been paid. A considerable portion of the arrears had been paid since the 30th of June. He could not say that all the arrears were good. As to the first call, the amount raised had been beyond their expectations. As to Mr. Joel's questions, that was neither the time nor the place to give a reply to them; nor could the shareholders be judges between the Board and Mr. Joel on many of the points raised by that gentleman. He must say that they had not found what was called technical advice of so much advantage to the Company as to enable them to dispense with practical judgment and sound economical administration.

Mr. JOEL said that as a shareholder he was interested in replies being given to his questions.

The CHAIRMAN asked how Mr. Joel could expect an answer to a series of twelve questions, each of which would require ten minutes to reply to, and without any notice having been given that such questions were going to be put.

Mr. QUILTER stated that for his own part he would object to some of the questions being replied to at a public meeting.

The CHAIRMAN stated that he would be glad to give Mr. Joel every reasonable answer to his questions, but not at that meeting.

Mr. SCRIVEN maintained that Mr. Joel should have sent in a notice to the directors that he was going to put the questions which he had submitted. The directors had always employed the best technical talent they could obtain, and he thought the chief cause of disappointment to Mr. Joel had been that they had not considered that his was the best advice of the kind which they could obtain.

The CHAIRMAN then put the motion in the usual way, and declared it carried on the show of hands.

Mr. EDWARD ELLIS, to assist in carrying out the proposals which had been made by the directors, moved a resolution to the effect that the number of the directors should be reduced to four, or, if Mr. Fellows continued in office, five.

Mr. RAWSON seconded the motion, which was carried.

Mr. ELLIS next proposed that the four gentlemen to be appointed as directors on the new Board (besides Mr. Fellows) should be Sir R. W. Rawson, Mr. Scriven, Mr. Alfred Parrish, and Mr. N. Whateley.

The motion having been seconded,

Mr. QUILTER argued that it would be better only to fill up three of the seats instead of four, observing that he did not know Mr. Whateley, against whom, however, he had nothing to say.

Mr. ELLIS stated that Mr. Whateley had acted on the committee of shareholders for the last eighteen months, and had assisted in carrying out a great many of the proposals which had been placed before the shareholders, and principally the one of reducing the paid-up capital and cancelling the paid-up shares.

Mr. D. PARRISH (a director) supported the election of Mr. Whateley.

Mr. QUILTER moved as an amendment, "That only three directors be elected at the present meeting, and that the remaining vacancy be filled up afterwards and subject to the shareholders' approval at their next meeting."

Mr. BARKER seconded the amendment, which was carried, 13 voting for it and 11 against.

It was next resolved that Sir R. W. Rawson, Mr. Scriven, and Mr. Alfred Parrish should be the three gentlemen appointed.

On the motion of the CHAIRMAN a resolution was passed rescinding article 86 of the Articles of Association, fixing the remuneration of the directors at £1,500 a year. Continuing, the Chairman stated that he was informed by the legal adviser of the Company that there remained nothing to be done now but to pass a resolution adjourning the meeting. He therefore moved: "That this meeting be adjourned to the 12th of September at half-past one o'clock at the Company's offices, St. Stephen's-chambers, Telegraph-street, for the consideration of the remuneration of the Board of Directors and the election of auditors for the ensuing year."

The motion was seconded and carried.

A SHAREHOLDER then proposed, and Mr. BELFOUR seconded, a resolution asking Mr. Fellows to resign.

Mr. FYFE objected to such a request.

The SOLICITOR stated that Mr. Fellows could be put out of office by an extraordinary resolution, of which, however, notice must be given, which had not been done. The resolution, therefore, would have no legal effect.

The resolution was put by the Chairman and declared carried.

A vote of thanks to the Chairman was next passed, and the proceedings then terminated.

Digitized by Google

NOTES.

ANTI-BURGLAR ELECTRICITY.—The Brussels mail carts are now provided with electrical alarms, which give immediate warning to the driver of any attempt to get at the contents.

SCIENTIFIC CONGRESS.—The meeting of the Association Française pour l'Avancement des Sciences commenced at Blois on 4th inst., under the presidency of M. Bouquet de la Grye; and the session will last until the 14th.

PHILADELPHIA EXHIBITION.—The International Electric Exhibition was opened in Philadelphia on Tuesday. The British Government was represented at the opening ceremony by Captain H. R. De Wolski, of the Royal Engineers.

THUNDERSTORM.—On Tuesday last Dundee and the surrounding district was visited by a thunderstorm of considerable violence. A heavy hailstorm followed; the stones were exceptionally large, many of them being a quarter of an inch in diameter.

ELECTRIC LIGHT at NUREMBURG.—We learn that, besides Herr Brunner's bank and several shops, the Royal Industrial School is soon to be provided with a complete system of electric light. A central station with Schuckert machines is also in construction.

ELECTRIC LIGHT AT LEIPSIG.—It is reported that the electric lighting of the Mars-la-Tour panorama at Leipsig has been given to the Brush Company, whose price was £300 lower than that of Siemens, Fein, and others. The Brush Company have undertaken to supply from 10 to 16 arc lights with a dynamo and a steam engine for £500.

THE ELECTRIC LIGHT AT THE BRITISH MUSEUM.—It appears that the electric lighting in the reading room of the British Museum has been so far improved, in the direction of securing greater steadiness, as to stop the complaints that were so rife, and also to cause the attendance of a progressively larger number of readers in the evening.

CUBA SUBMARINE TELEGRAPH COMPANY.—The number of messages passing over the lines of this company during the month of August was 2,916, estimated to produce £2,375, against 2,470 messages, producing £2,315 in the corresponding month of last year. The traffic receipts for the month of May, estimated at £2,950, realised £2,973.

ELECTRIC ILLUMINATION OF THE ACROPOLIS AT ATHENS.—A grand effect is reported to have been produced by the judicious disposition of a few electric regulators on the highest points of the Acropolis at Athens. In this way not only was the Acropolis itself illuminated, but the light was also thrown on the various temples and other ruins that surround it.

THE ELECTRIC LIGHT AND AMBULANCE OPERATIONS.—It is reported from Geneva that some experiments have been made by the Red Cross Societies with the electric light, the object being to demonstrate its usefulness after a battle in facilitating search for the wounded, and also the burying of the dead. The apparatus used was drawn by two horses only.

UNIVERSITY COLLEGE, BRISTOL.—We notice that special arrangements are made by the college for those who desire to study in order to make themselves proficient as electrical engineers. The special courses more particularly relate to electric lighting, transmission of power, telephony, electrolysis, &c. These special courses are under the direction of Professor S. P. Thompson.

LEGAL.—In the case of Saunders and Son *v.* The United Telephone Company, the defendant company submitted to a perpetual injunction restraining the company from stretching, placing, or affixing over or upon, or to the roof or other part of the warehouses of the plaintiffs, situate in Cannon-street or Budge-row, any overhead wires. Mr. Oswald appeared for the plaintiffs, and Mr. Crosskey for the defendants.

THE LATE MR. SCUDAMORE.—The will (dated Feb. 2, 1883) of Mr. Frank Ives Scudamore, C.B., formerly of the General Post Office, but late of Therapia, Constantinople, who died on Feb. 8 last, was proved on the 23rd ult. by Sherwin Scudamore, the value of the personal estate exceeding £5,000. The testator leaves all his real and personal estate to his wife, Mrs. Jane Ellen Moore Scudamore, absolutely.—*Illustrated London News.*

CHINA.—The Eastern Telegraph Company notifies that in consequence of hostilities having commenced at Foochow, telegrams for this place can only be accepted at the sender's risk to go from Shanghai by Chinese Government land lines, at the rate of 10s. per word. The company also notify later the interruption of the Chinese land lines beyond Chining, thus cutting off telegraphic communication with Tientsin and Pekin.

ELECTRIC LIGHT FOR FRENCH LIGHTHOUSES.—The luminous intensity of the forty electric lighthouses which are to be placed on the French coast has been calculated so as to secure, during ten months of the year, an illuminating power that oil lighting only effects during six months. To obtain this result, the light must be equal to 125,000 carcels—say 1,250,000 candles—a luminous intensity that neither oil nor gas can supply practically.

AN EMPIRE WITHOUT A CROWN.—There is only one thing wanting in the magnificent Empire Theatre, opened in Leicester-square a few months ago; and that is the electric light. But we are informed that, after the experience of the late sultry weather, this desideratum will be supplied by next summer. As it is, the glass flowers of the gas brackets are remarkably suggestive of incandescent lamps; and there is an electric call from the stage to the handsome *foyer*.

GREAT NORTHERN TELEGRAPH COMPANY.—The Chinese Telegraph Administration notifies that from 1st September until further notice private telegrams to stations on the Chinese land lines (Pekin, Tientsin, Hankow, Foochow, &c.) must be written in plain English language. Commercial telegrams in code or cipher are not accepted. The above restrictions do not refer to neutral Governments' telegrams nor to telegrams to the cable stations, Shanghai, Amoy, and Hong Kong.

EARTHQUAKE IN LOWER AUSTRIA.—A shock of earthquake was felt on Monday last at the watering places of Baden, Voeslau, and Gainfarn, in Lower Austria. It extended over a distance of ten miles in a south-easterly direction as far as Weiner Neustadt. The tremor was so strong that the congregation in a church at Weiner Neustadt, in which service was proceeding at the time, were panic-stricken, and rushed out of the edifice. The thermal springs at Voeslau experienced a marked rise in temperature during the shock.

THE TOWN HALL, BIRMINGHAM.—During the forthcoming concerts to be held in this hall, the electric light will be used.

Digitized by Google

It will be remembered that great pains were taken to discover the ideas of performers as well as listeners as to the acceptability of the electric light, with a general concensus of opinion in its favour. The replies have been published by Messrs. Winfield and Crompton, and were referred to by Mr. Crompton in his recent paper at the Health Exhibition. The lighting will be carried out by Messrs. Winfield and Crompton, as before.

ELECTRIC LIGHT IN THEATRES.—The Paris Châtelet, noted for its splendidly mounted extravaganzas, is to be added to the list of theatres in which electricity supersedes gas for illumination. It is said that considerations of safety have, in this case, had quite as much to do with the decision as a desire for increased effect. The works are already in progress, the steam engine for driving the dynamos being already erected. Incandescent lamps are used on the stage of the Berlin Opera House; but the project of illuminating the auditorium has been indefinitely postponed.

THE MIDLAND BRUSH COMPANY.—The following appears in the *London Gazette* of Sept. 2:—"Notice is given that the Brush Midland Electric Light and Power Company (Limited and Reduced), at extraordinary general meetings held on the 28th of November and 24th of December, 1883, passed a special resolution reducing its capital, which was confirmed by an Order of the High Court of Justice, Chancery Division, bearing date the 28th day of July, 1884, and the said Order was, pursuant thereto, duly registered with the Registrar of Joint Stock Companies on the 20th day of August, 1884."

TELEGRAPH LINE TO BOKHARA.—*The Times* correspondent from St. Petersburg writes that it is rumoured permission has been given to extend the Russian telegraph system from Katta-Kurgan to Bokhara. The Ameer had previously refused his permission. In any case, the union of Tashkend and Bokhara by telegraph is regarded by the Russians as a very important matter for Russian commerce as well as Russian policy. Competition on the Bokharan markets with English goods brought by way of India will be immensely promoted and facilitated, think the Muscovite merchants, by this telegraphic advance, and the Russian Government will possess a telegraph outpost in Bokhara of great importance.

ELECTRICAL EXCURSION TO AMERICA.—The scientific mission organised by Dr. Cornelius Herz, of *La Lumière Electrique*, started from Havre for New York about a week ago. The party, which consists of Messieurs Abdank-Abakanowicz, Bertrand, G. Duché, Auguste Gnerout, O. Kern, and D. Napoli, will remain at Philadelphia during September to study the Electrical Exhibition. It will then split up into several sections, which will traverse the United States as far as San Francisco, and also Canada, in order to obtain materials for a work on the industrial application of electricity in America. The members are to meet at New Orleans, whence they will proceed to Havana, so as to return to France by the end of the autumn.

TELEPHONE COMPANIES AND THE POSTMASTER-GENERAL.—The Postmaster-General has notified to the various telephone companies that he is now prepared to issue licenses in conformity with the concessions announced in the House of Commons on the 7th of last month. In addition to these important concessions, he has also conceded to the telephone companies the privilege of connecting the various telephone systems with the postal telegraph offices, thus enabling telephone subscribers to transmit telegrams directly from their own offices to any part of the United Kingdom or abroad free of any extra charge. The Postmaster-General has also abandoned his claims for a royalty of 10 per cent. to the State on all private wires.

OVERHEAD WIRES ON PRIVATE PROPERTY.—Advices from York state that, in the recent case heard before the County Court judge, between Mrs. Gutch, of Holgate Lodge, and the Postmaster-General, the former objected to the placing of overhead wires and posts in her park, on the ground of their unsightliness, their obstruction of light from lamps, and the singing of the wires when agitated by the wind. Her request that the wires might be carried underground had been refused on the score of expense. As the result of arbitration, the Postmaster-General has been authorised to place and maintain telegraph posts and wires along the north-east of the road leading from York to Boroughbridge as far as the passes by the side of Holgate Lodge, but the wire is to be only one-third the diameter of that generally used.

THE ELECTRIC RAILWAY AT EDINBURGH.—At the recent visit of the Prince and Princess of Wales to the Forestry Exhibition, Edinburgh, says the *Jewish World*, "Mr. Binko (a co-religionist), the patentee of the electric railway, was introduced by the Marquis of Lothian. Mr. Binko had the honour of explaining to their Royal Highnesses the mechanism of the the railway and the manner in which the cars were propelled. The royal party ventured to travel in the electric car which had been especially prepared for them by the inventor, the ingenious appliances of which greatly interested them on their alighting. Miss Binko presented the Princess of Wales with an electric bouquet. Mrs. Binko also presented the Princess Louise with a similar bouquet."

PATENTS FOR INVENTIONS.—A Parliamentary return shows that the number of applications for letters patent during the year 1883 was 5,993, being 248 less than the preceding year. On these applications there were 3,958 letters patent sealed, but, deducting 63 letters patent, the patentees having neglected to file final specifications in pursuance thereof, there remained 3,895 letters patent in force. A table giving the results of applications for the year 1852 shows that about 65 per cent. of the applications for patents from that year to 1883 became valid; that of the valid patents obtained upon the applications from 1852 to 1876, 30 per cent. paid the third year's stamp duty of £50, and continued in force to the end of the seventh year; and that about 10½ per cent. paid the seventh year's stamp duty of £100, and consequently remained in force for the full term of fourteen years.

TRAMCAR DRIVEN BY ELECTRICITY.—Mr. Holroyd Smith's system of electric tramway, which was described and illustrated in our columns (Vol. XI., p. 487), was tried lately at the Cornbrook Telegraph Works, Manchester, where the plant has been constructed. The car ran along a temporary track laid down in a field near the works, and was perfectly under control, the motion being very smooth and even. The current was obtained from a Siemens generator at the works. Mr. Smith believes he has overcome the difficulty of keeping clear the centre track, along which runs the instrument for collecting the electricity from the continuous conductors and transmitting it to the dynamo in the car. He has also devised means for minimising the difficulty caused by an accidental breakage of the collector. It is calculated that the working expenses with this system will be 2d. per car per mile, as against 10d. for horse traction.

ELECTRIC MOTOR FOR STEERABLE BALLOONS.—The great difficulty in propelling and directing the course of balloons has been hitherto the impossibility of obtaining a motor of suf-

Digitized by Google

ficient power commensurate with the requisite lightness. But it seems, according to a letter from Kiel, published by the *Cologne Gazette*, that Dr. Woelfert has made two successful attempts at aerial navigation with a balloon, cigar-shaped, like that of Captain Renard, driven by a special electric-motor only one-fourth the carrying capacity. The contents of the trial balloon is 500 centimetres or 17,658 cubic feet. Inflated with ordinary lighting gas it will carry a load of 350 kilogrammes or nearly 7cwt.; but filled with hydrogen it will lift more than double that weight. One of the voyages lasted two and a half hours, during which Dr. Woelfert is said to have made his way against a north-east wind blowing from two to three metres, or 6½ft. to 10ft., per second.

THE "ST. JAMES'S" ON MR. FAWCETT'S CONCESSIONS.—Mr. Fawcett's concessions to the telephone companies, says the *St. James's Gazette*, go rather beyond what he foreshadowed in the House of Commons, and are good as far as they go. The companies are to pay 10 per cent. upon their gross receipts, except for private wires, and permission is given for the wires of the companies to be connected with the post offices. On the other hand, every telephone company must obtain a licence, the granting or refusal of which is entirely within the discretion of the Post Office, and the latter will not at any time admit any obligation to give way-leave over its own wires to, or erect new trunk wires for, the companies. "There is no doubt that the use of telephones will," in the opinion of the above-named journal, "remain less general, and therefore less beneficial, in consequence of the monopoly given by statute to the Post Office, than it would be if the companies were permitted to carry on their business free from any restrictions."

A TELEGRAPH WANTED.—The other day a deputation from the inhabitants of the Upper Hastings and Manning district waited upon the Hon. J. Norton, Postmaster-General, New South Wales, to urge the establishment of some system of communication, telegraphic or telephonic, between that district and Sydney, by way of Port Macquarie. Messrs. J. H. Young and C. J. Roberts, the members for the district, introduced the deputation. Mr. J. H. Young said that the inhabitants of the Upper Hastings and Manning district suffered great inconveniences for want of some system of communication for connecting the various towns and villages on the Hastings River with one another and Port Macquarie. The farmers and those engaged in carrying on the river traffic annually suffered heavy pecuniary losses owing to the absence of telegraphic communication with Port Macquarie. Many of the farmers lost £50 and £100 per year for want of proper means of obtaining prompt and reliable information concerning the markets. The Postmaster-General thought the deputation had made out a good case, and he would give the matter his careful consideration, and, after consultation with the Superintendent of Telegraphs, would see what could be done to meet what seemed to be a deeply felt want.

NEWCASTLE-ON-TYNE.—The electric light formed a prominent feature in the city illuminations on the occasion of the visit of the Prince and Princess of Wales to Newcastle-on-Tyne on August 20th and 21st. Three powerful arc lights, each of 8,000 candle-power, were shown in different parts of the city; one of these was placed in the beautiful lantern tower of St. Nicholas Cathedral, being visible for many miles around. The effect produced was very fine, and much admired by the large crowds which gathered to see it. The light shining through the stone tracery threw dark shadows across the sky, taking the shape of a gigantic cross when viewed from any side of the tower. The other two lights were placed in the principal street, one of them being just opposite to the gas office, where an extensive gas illumination was exhibited. The contrast was very striking, the superior brilliancy and purity of the electric light giving rise to much comment. All these installations were carried out for the different parties by Messrs. J. H. Holmes and Co., electric light engineers, Newcastle-on-Tyne. The same firm has also lighted a polytechnic exhibition at Hetton, co. Durham, for four weeks, by means of 45 Swan lamps and one arc lamp worked in parallel circuit from the same dynamo, with perfect success, attracting large numbers of people to whom the electric light was a novelty.

DEATH OF MRS. EDISON.—A correspondent writes, Will you do me the kindness of inserting the following paragraph in the next edition of *The Electrician*? It is an extract from the *Evening Telegram*, New York, August 12, 1884:—"Death of Mrs. Edison.—Mrs. Mary Stilwell Edison, the wife of Thomas A. Edison, the electrician, was buried this morning at Menlo Park. Her remains were placed in a casket, which rested in the centre of the parlour. Around it were ranged many beautiful floral tributes, while cut flowers were strewn on the remains and on the floor underneath. Shortly after eleven o'clock Mr. Edison, who had remained in his room, was conducted to the parlour by Mr. Samuel Insull, his private secretary. The doors were closed, and he was left alone with the dead. Intense silence prevailed, which was broken only by the sobs of a strong man. At half-past twelve o'clock the Rev. Mr. Mason, of the Presbyterian Church, Metuchen, New Jersey, entered, and read the funeral service of the dead. At its conclusion the people assembled in front of the casket to take a last look at the face of the deceased. The casket was then closed. The pallbearers, ten in number, forming on either side, with relatives to the number of forty and a throng of friends, the procession moved up to the railroad station, where a train was in waiting to convey the funeral party to Fairmount Cemetery in Newark. There the remains were placed in the receiving vault pending the decision of Mr. Edison as to their final resting place. There were no services at the cemetery. There were present at the funeral many of the representative business men of this city, as well as a number of Mr. Edison's *employés*."

ELECTRICITY VERSUS COMPRESSED AIR.—Mr. Radcliffe Ward writes to the *Pall Mall Gazette*, in answer to Colonel Beaumont's criticism, as follows:—"As the Leytonstone trials were arranged for and carried out by me with a purely experimental car brought from Belgium by Mr. Philippart, I beg to observe as follows:—Colonel Beaumont must know perfectly well that the lumbering, heavy Leytonstone car by no means represents the existing electrical appliances obtainable even in the open market. Colonel Beaumont has no foundation in fact for making the statement that the efficiency was 1 per cent. of the initial power. Those who know anything of the subject are aware that this is an absurd statement to put forward to damage electricity as compared with compressed air. For those who do not understand let me observe that both electricity and compressed air as applied to tramway work act as reservoirs for energy produced from an extraneous source—say, a stationary steam engine. Now, compressed air appliances are both more costly and weigh more than electrical appliances for a given power stored and operated. I believe that Colonel Beaumont claims to run eight miles with one charge on a moderately level road; an electric car has actually run 20 miles in Paris over various grades with one charge. Yet the compressed air car represents the work of years and much money spent on developing it; only a comparatively small amount of time and money has

Digitized by Google

been given to the electric car, yet it already runs more than double the distance. However possible, from a purely mechanical point of view, it may be to work the underground trains by ponderous compressed air-engines, such cannot compete for economy with an electric system with electric engines and accumulators."

ELECTRICAL CONFERENCE.—The National Electrical Commission, *Science* states, met in Philadelphia on August 7. It was decided that the Conference to be conducted by the Commission will meet on Monday, September 8, to be then continued from day to day, as may be found necessary. The invitations to the Conference will be confined to physicists of eminence, and to experts in the practical management of electrical appliances and apparatus. It is proposed to extend special invitations to prominent foreign visiting electricians. It was also decided to issue a circular inviting the conferees to submit a paper to be read before the Conference. It is not definitely known what subjects will be discussed at the Conference, but the following matters have been suggested: The sources of electrical energy; the theoretical conditions necessary to the most efficient construction of the dynamo-electric machine for the various purposes of practical work; the electrical transmission of energy; the systems of arc and incandescent lighting; the theory of the electric arc, storage batteries, electro-metallurgy; lighthouses for the coast; applications of electricity to military and mining engineering; lightning protection; induction in telephone lines, and the problem of long-distance telephoning; the question of underground wires; atmospheric electricity; earth currents and terrestrial magnetism; photometry and standards for photometric measurements; the ratio of the electro-magnetic to the electrostatic system of units, and the electro-magnetic theory of light; and finally, on account of the pressing necessity for accurate and uniform electrical measurements, it is probable that the question of establishing a National Bureau of Physical Standards will receive proper attention.

ANTWERP INTERNATIONAL EXHIBITION.—The Lords of the Committee of Council on Education have received information through the Foreign Office that the international exhibition at Antwerp will be a national and governmental undertaking, under the immediate patronage of His Majesty the King of the Belgians. The president of the exhibition will be his Royal Highness the Count of Flanders, and the vice-president the Minister of Agriculture, Industry, and Commerce. The committee will consist of 450 members, and the Belgian Parliament will be asked to vote a sum of money for the commission. The State will nominate the jury and regulate its functions. The exhibition will be opened on May 2, 1885, and will embrace five principal divisions or sections, namely:—1. Education, including the fine arts and art applied to industry. 2. Manufactures. 3. Commerce and navigation, fisheries and pisciculture. 4. Electricity. 5. Agriculture and horticulture, each of which will again be subdivided into groups and classes. The triennial exhibition of painting, sculpture, and architecture, to which artists of all countries will be invited to contribute, will coincide in 1885 with the universal exhibition. The growing importance and favourable geographical position of Antwerp give every reason to hope that the proposed gathering will be largely attended. No effort will be spared to insure the success of the undertaking and to make it worthy of the attention of foreign nations. All necessary measures will, it is stated, be taken on the part of the Belgian Government to protect the patentable inventions, models, drawings, or trade marks which may figure at the exhibition. An influential committee of citizens of Antwerp, under the honorary presidency of the burgomaster, is now actively engaged forwarding this vast enterprise in its various branches.

TELEPHONIC COMMUNICATION FOR MONS, BELGIUM.—The town of Mons is about to be provided with a complete telephone system, in conformity with a convention made in June, 1883, between the Municipality and M. Van Hulle, of Brussels. The latter has given up his rights to M. Kahn, who has entrusted the direction of the work to M. Roder, engineer. The town authorities have given a building for the central office, and also the exclusive right to carry wires over the communal buildings and the less important roads, the Hôtel de Ville, the belfry of the Château and the Collegiate Church of Sainte Waudru being excepted. The concessionaire undertakes to provide twelve gratuitous services for the Municipality, and to accord a reduction of 35 per cent. on the subscriptions of establishments under the control of the City and Provincial Authorities and the Government. The subscription of 150fr. (£6) per annum, is to be reduced by 140fr. (£5 12s.) when the subscriptions exceed 400. The central office, situate in the Rue de la Peine Perdue [*absit omen*] is already arranged for 450 communications. The overhead wires of galvanised steel, fully two millimetres in diameter, are hung on timber frames capable of carrying 100, 140, and even 150 wires. The porcelain insulators are of the type adopted in Switzerland for telephone lines. For lines of long distance, from the central office to the railway station, for instance, the wires are of phosphor bronze, and they are hung on posts. Two tables of communication for fifty subscribers are already placed in the central office. The instruments hitherto fixed in the houses, &c., of the subscribers are carbon transmitters of a type nearly resembling the Crossley or the Ader. Williams's magneto calls are used, fixed on boards, and placed underneath the transmitters. The batteries for actuating the microphones are Leclanché cells with porous vases on connected plates. As a rule, three batteries are reckoned for each subscriber. All the installations have been made with the greatest care, and mainly in view of the great increase of long-distance telephonic communications which is likely soon to take place in Belgium. Like the other chief towns of provinces Mons will be one of the first to be provided with all the instruments included in the Van Rysselberghe system, which will shortly permit the manufacturers and collieryholders of the Borinage [the local name given to the district, otherwise known as the "Couchant (West) de Mons," where the most valuable coal is extracted] to communicate by telephone not only with Brussels and Antwerp, but also with Charleroi, Liege, Verviers, &c.—*Bulletin de la Société Belge d'Electriciens.*

NAVIGATION IN FOGS.—The *Electrical World* of New York suggests the use of telephones to assist in the navigation of vessels during foggy weather. Two telephones are used, one carried on board a small boat acting as a pilot boat, the other on board the ship. Our contemporary says:—"All that is necessary is that the portable telephone reel with one of the telephones shall be carried on board a small ship's boat or steam launch, while the other telephone is retained on the steamer. The small boat can now act as a pilot during the densest fog or on the darkest night. The crew of the small boat or launch can take soundings or other observations, and report at given intervals of time to the steamer with which it is connected by the light telephone cable. Practically, any length of cable can be run out from the telephone reel, but for navigation purposes the boat need only be a few hundred yards ahead.

Digitized by Google

The apparatus is so simple that any able seaman can work it. In this way a steamer or man-of-war can pick her road with safety along a rock-bound coast or through the most dangerous shoals and reefs. If it be assumed that the telephone boat propelled by oars or steam makes only five miles an hour, it will be seen that a ship, instead of lying in a fog, can gain at least a hundred miles a day. The expenses of any of the large passenger steamers are enormous, and the saving on a single day would equip a whole fleet with portable telephone apparatus. Those who have seen the apparatus in operation know that it is practical in the highest degree, and eminently adapted to such a use as we now suggest for it. One need not be very sanguine to look forward to the time when every shipowner will regard a portable telephone as an equipment fully as necessary for his vessel as compasses, telescopes, and life-saving apparatus. Although its chief employment at sea may be that above proposed, many other uses will at once suggest themselves to any one familiar with navigation. For instance, a vessel may lie off shore temporarily, taking in cargo or unloading. At such times means of easy and constant communication are a great desideratum. At present the difficulties in the way of frequent intercourse between ship and shore are numerous and often insurmountable. But with a portable telephone apparatus, conversation can be carried on all day long between the two ends, even in the roughest weather and through the night, and much valuable time can be saved. When she arrives at her destination, all that the ship has to do is to send one end of the line ashore. When she leaves, the only thing to be done is to bring that end on board again in any suitable way."

UNDERGROUND ELECTRICAL RAILWAYS.—The following description of a double line electrical railway, at the Oppel Pit of the Zaukeroda Mines, is condensed from the *Jahrbuch für das Berg und Hüttewesen*. It is laid at a depth of 720 metres and in a straight line, being run over by 660 waggons during the two shifts of eight hours each. The rails are of the contractors' type, weighing about 12lb. a yard; and the gauge is a little over half a metre. One line serves for the full waggons and the other for the empties. The electrical traction exists only for a length of 620 metres, the remaining 50 metres being reserved for making up the trains. The dynamo electric machine (Siemens' D 3) and its steam motor are erected on the surface, 63 metres distant from the shaft. The speed of the dynamo is 750 to 850 revolutions per minute, for 225 to 250 of the engine. The conductors consist of (1) from the dynamo to the shaft, two uncased copper wires 6½ millimetres diameter; (2) extending down the shaft, two copper wires of the same diameter, covered with gutta percha, lead, and galvanised iron wires, secured by holdfasts; but in the return wire the outer casing is omitted; (3) in the heading, two lines of rails of inverted T section, fixed to the roof of the heading by means of insulators. The locomotive, which receives the electricity, is connected to each line of T bars by a small metal cable terminating in a contact. These contacts, drawn along by the engine, clip the leads by means of springs, being capable of easily sliding along the bars. The locomotive is 2·53m. long, 0·8m. wide, 1·50m. high, and weighs a little over 1½ ton. Both ends are similar, and are provided with starting, reversing, and brake levers. Along the heading of the mine are also suspended two small uncovered copper wires, in communication with an electric bell in the engine room on the surface. All the driver has to do, in order to make the bell ring, is to press these two wires together with his hand; and this permits, through preconcerted signals, of ascertaining at what point of the journey there is an acceleration, a stoppage, or a re-starting of the locomotive. The trains consist of 15 trucks, containing nearly half a ton of coal. The journey of 650 metres is made in four minutes on an average, corresponding to a speed of nearly 9ft. a second. When the engine-man on the surface becomes conscious of a stoppage of the locomotive through the increased speed of his own engine, he partly shuts off steam; but as soon as he perceives an increased resistance, he turns on some more steam. The locomotive gives out about 46½ per cent. of the energy of the steam-engine, allowing 25 per cent. for the friction of the gear and wheels. The cost of the installation was £812; and the working expenses, for 660 trucks 16 hours a day, 11s. 8d.

THE TELEPHONE ELECTRIC SIGNALS AT THE BRUSSELS LAW COURTS.—The already important telephonic arrangements of the new Palais de Justice, Brussels, have lately been extended, the office of the public prosecutor's *parquet* and the private rooms of the magistrates being provided with telephonic instruments. All the transmitters in the various courts are put in connection with a central switch in the telegraph office. This is intended to place the magistrates in communication with counsel; and the latter, by means of an instrument of the Bell Telephone Company, are able to correspond with the subscribers of the Brussels, Uccle, and Boitsfort (suburbs of Brussels) lines, and will soon be able to hold converse with their brethren of the bar in Antwerp, Ghent, Liege, Verviers, and other towns. The first telephone instruments were of the Ader system, with De Gilliland magneto calls, but the last transmitters just added are much improved, thanks to a new arrangement of carbon and contacts, devised by M. Van Rysselberge. While the external form is not altered the transmitter is fixed to a board, and the magneto call is placed above the microphone. As to the other electrical appliances fixed in the various courts, their choice and arrangement, and the ingenious combinations devised by the officials appointed to direct the works are calculated to interest those connected with the applications of electricity. A few figures will suffice to give an idea of the importance of these installations:—110 electric calls of the Lippens type, that is adopted by the Belgian Government, are placed in the various courts, and correspond with 26 indicators, forming together 88 numbers, which communicate with 164 small pushes. A special conductor has been chosen to connect these instruments. It is so constructed that the copper wire, a full millimetre in diameter, is sufficiently protected to prevent any fear of oxidation through damp, being covered with nearly 2½ millimetres of gutta percha and plaited cotton paraffinned. The total length of the circuit connecting the whole of these instruments is nearly 30,000 metres (98,426ft.), and there are 600 Leclanché batteries. The contract for supplying all the electrical plant was let by public tender, according to a specification drawn up by a special committee nominated by the Department of Justice, and Mourlon et Cie., of Brussels, secured the work. All the clocks, on the Thomas and Bouckaert systems, work by electricity. Moreover, an indicator of the calling of cases, ingeniously arranged by MM. Richez et Hipmann, is placed in the barristers' library, each court being placed in communication with it by means of a self-acting switch. An electric call gives warning of the commencement of the sitting in a court corresponding to the number which is shown at one of the openings of the indicator. All the electrical instruments, as well as the plant necessary for the telephonic installations, have been put down by the *employés* of the Administration des Télégraphes, under the direction of MM. Dery and Dumont, engineers.—*Bulletin de la Société Belges d'Electriciens.*

THE INDUCTION OF CURRENTS IN CORES.

BY OLIVER HEAVISIDE.

(CONTINUED FROM PAGE 363.)

[ERRATA IN LAST.—Page 362, first column, second line after (76), *for* number *read* member; second line from bottom *read* $r\frac{dv}{dr} = n\frac{dv}{dn}$; second column, first line after (82), *for* numeration *read* summation; and in first equations after (81) introduce factor H_0 on right side.]

This equivalence of total heat to initial magnetic energy can of course be predicted beforehand, as a certain consequence of the elementary laws underlying the structure of our solutions for the magnetic force and the current, and therefore its verification merely serves to show that we have not got upon a wrong track in the pursuit of a mathematical wild goose, which may happen unless proper tests are occasionally applied.

Remarks on Normal Systems.—In (82) the magnetic force (and in (83) the current) is expressed as the sum of a number of terms each of which is the product of a function of r, the distance from the axis, into a function of t, the latter being such as to show a decrease in the magnitude of the term with the time in the same manner as the charge of a condenser decreases when discharged through a conductor of insensible self induction; or as the current decreases in a linear circuit of insensible electrostatic capacity and subject only to its own self induction; or as the momentum of a body decreases when resisted by a force proportional at any moment to its momentum at that moment.

Now, as may be seen from the values of the first four A's given below, the series is very slowly convergent at the start ($t=0$), and a large number of terms would then have to be taken to make the sum come to H_0 within, say, a millionth part. But, owing to the different rates of subsidence of the normal systems, the series soon becomes rapidly convergent. The higher ones subside so rapidly that in a short time, before the first has sensibly altered, only it and a few of the following are of any importance, and as time progresses those left drop out of practical existence one by one till at length, before the magnetic force has fallen to half strength at the centre of the core, the first normal system is left alone. The distribution of magnetic force in the core from the axis outward is then represented simply by the curve v_1 in Fig. 2, which continues to be the distribution during the remainder of the discharge, only falling in strength according to the exponential law. Thus, by considering the first normal system only, calculating the values of A and of D belonging to it, we obtain important information, for we know thereby the solution except for small values of the time. But the neglected terms completely alter the character of the subsidence at the commencement of the discharge, as we may see from the value of A_1, viz., $1{\cdot}667H_0$, which is, at the axis, $\frac{2}{3}$ greater that H_0, the real initial strength, and of A_2, which (negatively) is also greater than H_0. This, however, will be made fully evident from the curves of the magnetic force and current at the axis and boundary. The values of the first four A's are

$$A_1 = 1{\cdot}667H_0,\ A_2 = -1{\cdot}065H_0,\ A_3 = {\cdot}856H_0,\ A_4 = -{\cdot}737H_0.$$

The above remarks concerning the great relative importance of the first normal system of slowest subsidence may, to a certain extent, be generalised. Given any arbitrary distribution to start with, the system of slowest subsidence will soon be left decaying alone, all its companions having faded and gone, unless it should happen that one or more of them be of such great initial strength that their influence continues sensible, masking that of the first system. Or, the initial distribution may not contain the one of slowest subsidence at all, or any number of systems may be absent. But in the various practical cases that arise of initial distributions set up by a battery, the system of slowest subsidence has the greatest amplitude, and the amplitude of the others decreases with their rapidity of subsidence. It is easy, however, by suitably arranged boundary conditions, though they may not always be practicable, to introduce various anomalous peculiarities, quite altering the character of the subsidence, or reversing it, making the force increase.

In the above case the roots na are all real, giving real D's. This is, however, not necessary. The n's may be, some or all, imaginary, when, of course, the corresponding normal systems and their rates of subsidence are imaginary. By pairing two connected imaginary terms, the unreal parts mutually cancel, leaving a real dual system which subsides with oscillations instead of in the former manner. In all cases the finding of the proper normal systems is of primary importance, and in all cases their amplitudes, to make up a given distribution, may be found by the magical process of selection of coefficients by the conjugate property of the normal systems, either as above exemplified, or in a similar, though more general manner.

Example 2.—Coil Circuit Closed. Coil of Negligible Depth.

Let the core be charged as before in the first place, and then be discharged by removing the E.M.F. from the coil circuit, but leaving it closed. There will be a current in the coil (the extra current) in the same direction as the original current, and as the induced current in the core. Its effect, we see at once, is to retard the rapidity of discharge, and to keep up the core's magnetisation longer, if it be magnetisable, in the ordinary sense. The theory makes no distinction between iron and any other metal, except in the value of the coefficient of magnetic permeability. In the last example the boundary condition which settled the values of n and D was $H_a=0$, because there was no current outside the core, the coil current being stopped. (We disregard dielectric currents, to be later considered, as they are of utterly insignificant magnitude in comparison with the conduction currents in coil or core.) Now, there being a current in the coil, the boundary magnetic force is not zero, but stands in a constant ratio to the coil current. The coil current again is proportional to the boundary E.M.F. of induction, and therefore, by Ohm's law, to the boundary core current. Hence the boundary magnetic force and the density of the boundary core current are constrained to preserve their ratio constant during the whole period of the discharge, and the same is true for every normal system of magnetic force with its accompanying current. Determining the value of the constant by (15) and (20), taking a = radius of core filling the coil, and the depth of coil small compared with a, and putting $E=0$, since there is no externally impressed force, we have

$$0 = H + sH'. \quad \ldots \quad (88)$$

where $s = L\rho/2\pi\mu aR$, L being the coefficient of self-induction, R the resistance of the coil circuit, ρ the specific resistance, and μ the permeability of the core.

Put $J_0(nr)$ for H in (88), and we obtain

$$0 = J_0(nr) + s\frac{d}{dr}J_0(nr), \text{ at } r=a.$$

Or, $$J_0(na)/J_1(na) = sn, \quad \ldots \quad (89)$$

by (73). In Fig. 1, giving the curves of J_0 and J_1, we must find the values of na satisfying (89), instead of the places where $J_0=0$. The effect is to shift the position of all the roots to the left, through different distances, say, as in a calculated case, from B_1 to C_1, B_2 to C_2, &c. The value of n_1a is reduced in a far greater ratio than n_2a, &c., and since the time constants of the normal systems vary inversely as $(na)^2$, the effect is to make the first system of still greater relative importance than before.

In the case to be illustrated, I have taken $s=1$ and $a=1$, which corresponds to not unpractical coil data. The determinantal equation (89) is then $J_0(n) = nJ_1(n)$; or, in full,

$$0 = 1 - \frac{3n^2}{2^2} + \frac{5n^4}{2^2 4^2} - \frac{7n^6}{2^2 4^2 6^2} + \ldots$$

The first five roots and their squares are

$$\left.\begin{aligned} n_1 &= 1{\cdot}256, & n_2 &= 4{\cdot}079, & n_3 &= 7{\cdot}155, & n_4 &= 10{\cdot}271, & n_5 &= 13{\cdot}48, \\ n_1^2 &= 1{\cdot}577, & n_2^2 &= 16{\cdot}637, & n_3^2 &= 51{\cdot}203, & n_4^2 &= 105{\cdot}492, & n_5^2 &= 181{\cdot}71, \end{aligned}\right\}; \quad (90)$$

which may be compared with (75) to see the relative and absolute changes in the values of the time constants.

In the first normal system the magnetic force falls only about 40 per cent. from the axis to the boundary, instead of to zero, whilst it subsides nearly four times as slowly. The amount of shifting of the roots by closing the coil circuit depends mainly upon the time constant of the circuit, which varies with the external resistance. Starting with infinite resistance, the roots are at B_1, B_2, &c., corresponding to $J_0(na)=0$. Reduce the resistance; they move to the left, and of course stop when the coil is short circuited. Now, if we could reduce the coil resistance indefinitely without altering the number of wires, say by increasing the specific conductivity, the roots would be given by $J_1(na)=0$, viz., zero, and the values of na at the other places where the curve J_1 in Fig. 1 crosses the axis of abscissæ.

From this we may, without calculation, derive some interesting information. The first normal system $A_1J_0(n_1r)e^{D_1t}$ becomes, with $n=0$, and consequently $D=0$, simply A_1. If then the initial distribution H_0 was constant, we have $H_0=A_1$, and $A_2=A_3=\ldots=0$. The core's induction does not subside at all, being wholly represented by the first normal function, which has become a constant. But should the initial distribution vary in strength from layer to layer, the value of A_1 will be the *mean* strength taken over the section of the core, whilst the departure from the mean strength will be represented by the other normal systems $A_2J_0(n_2r)$, &c. These, having finite time constants, will subside, leaving the mean strength of force, which will remain steady, with no current in the core, but with a current in the coil of the necessary strength to cause the magnetic force, *i.e.*, as given by $H=4\pi N\Gamma$, N being the number of turns of wire per unit length of core, and Γ the current in each of them. (Of course we should rather say that the magnetic force causes the current, but this is a mere question of words. The essential idea, whichever we like to consider as causing the other, is that the magnetic force and the current are inseparably bound.) This is an illustration of Maxwell's theory of the impermeability of a perfect conductor to magnetic induction. Our core is bounded by a perfectly conducting shell, and whatever magnetic induction was in it cannot get out of it; it can merely settle down to a steady state, in case it was previously non-uniformly distributed.

From this we see that with a core of high magnetic permeability, bounded by a coil of high conductivity short-circuited, any irregularities in the initial distribution of induction will quickly vanish, leaving the mean strength to subside at the slow rate of the first normal system, being during subsidence only a trifle less strong at the boundary than at the axis.

There is another case in which we arrive at precisely the same normal systems given by the roots of $J_1(na)=0$, as when the coil resistance becomes infinitely small, but with entirely different resulting phenomena. For, by continuously increasing the specific resistance of the core we shall make the roots pass continuously from those of $J_0(na)=0$ with $\rho=0$, to those of $J_1(na)=0$, with $\rho=\infty$. The last is of course practicable, as it merely means a nonconducting core. But the relation between D and n being $4\pi\mu D=-n^2\rho$, we have, for all the finite values of n, $D=\infty$, *i.e.*, any irregularities in the initial distribution disappear instantaneously, not gradually as in the last case. But for the value $n_0=0$, with $\rho=\infty$, we have D_0 finite. In fact, the determinantal equation, expressed in terms of D instead of n^2, reduces to

$$0=1+LD/R$$

simply, the coefficients of the higher powers of D vanishing. Hence $D_0=R/L$, and the solution is $H=H_0e^{-Rt/L}$, as we know it should be, there being no possibility of induced currents in a nonconducting core to alter the character of the subsidence. The higher normal systems have become ghosts, and gone to that region where exist all the roots save one of an equation of the first degree.

Returning to the general subject of this section, very little modification of the investigation in Example 1 is needed to complete the solution. For, by (89), $v_1/v'_1=v_2/v'_2=\text{constant}$ for every normal system. Thus the right hand member of (76) still vanishes, giving us the same conjugate property (77) as before, and the same expression (78) for A, whose further development is, however, different. Thus, to find its denominator, use (79), remembering that $r\frac{dv}{dr}=n\frac{dv}{dn}$, and $\frac{dv}{d(n^2)}=\frac{1}{2n}\frac{dv}{dn}$; then,

$$\int v^2rdr=\frac{1}{2n^2}\left[r^2(v')^2-v\frac{d}{dr}(rv')\right]=\frac{1}{2n^2}[r^2(v')^2+n^2r^2v^2],\ \text{by (67)}$$

$$=\tfrac{1}{2}a^2[\{J_0(na)\}^2+\{J_1(na)\}^2],\ \text{by (73)},$$

$$=\tfrac{1}{2}a^2(1+s^2n^2)\{J_1(na)\}^2,\ \text{by (89)} \quad . \quad . \quad . \quad (91)$$

which we see returns to (80), when $R=\infty$, making $s=0$. This completes the solution when the initial H_0 is unstated. But H_0 is to be constant; hence, evaluating the numerator of (78), we have the same expression, $H_0aJ_1(na)/n$, as before, and we obtain, generally,

$$A=2H_0\div\{naJ_1(na)(1+s^2n^2)\} \quad . \quad . \quad . \quad (92)$$

which, in the calculated case, becomes, with $s=1$, and $a=1$,

$$A=2H_0\div\{n(1+n^2)J_1(na)\} \quad . \quad . \quad . \quad . \quad (93)$$

which, taken in the formula

$$H=\Sigma AJ_0(nr)e^{Dt},$$

gives us the complete solution at time t, the current being got by differentiation. The magnetic energy per unit length of core at the start is

$$\tfrac{1}{8}\mu a^2H_0{}^2=T=\Sigma\frac{\mu}{8\pi}\int_0^a 2\pi rdr\{AJ_0(nr)\}^2$$

$$=\tfrac{1}{2}\mu H_0{}^2\Sigma n^{-2}(1+s^2n^2)^{-1} \quad . \quad . \quad . \quad . \quad (94)$$

by (89) and (91), no products being required. At time t the corresponding value of T is got by multiplying each term in the summation by e^{2Dt} with the proper value of D.

With $s=1$, as in the calculated case, the proportions of the initial energy going to the first few normal systems we find to be given by

$$\tfrac{1}{8}=\cdot1230+\cdot0017+\cdot00018+\cdot00003+\ldots$$

Thus, although the second and higher normal systems are very important for a short time from the commencement of subsidence, yet the energy of the first system is no less than $\frac{123}{125}$ of the total. The proportion is not so great when the circuit is open (Example 1) being then only $\frac{88}{125}$ of the whole.

Description of Fig. 3.

This is to show the manner of subsidence of the magnetic force at the axis and at the boundary, and of the coil current in three cases.

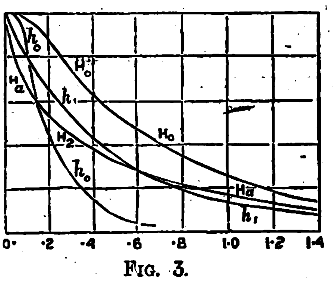

FIG. 3.

Time is measured from left to right, from $t=0$ to $t=1\cdot4$ second, as it happens. Strength of magnetic force (or of current) is measured upwards. The time constant of the coil is $\frac{1}{2}$sec. and its radius 1cm. That is,

$$s=1,\ a=1,\ D=-n^2,\ L/R=\tfrac{1}{2}.$$

As the coil is of very small depth, there must be a great number of turns per cm., or else a soft iron core, to make the time constant so large.

In the first place, suppose that the core is properly divided, to stop the flow of induced currents, and that we start with a steady current in the coil circuit, and, removing the E.M.F., leave it to itself. The curve h_1h_1 shows the manner of its subsidence. It is the ordinary exponential curve, and is given by

Digitized by Google

$h_1 = e^{-2t}$, if the value at the start be taken as unity. The characteristic property is that if the current fall from strength 1 to $\frac{1}{2}$ in the time t, it falls from $\frac{1}{2}$ to $\frac{1}{4}$ in the next interval of time t, from $\frac{1}{4}$ to $\frac{1}{8}$ in the third, and so on. The magnetic force, induction, and the magnetisation, if of soft iron, subside in the same manner in all parts of the core on the usual hypothesis of no retentiveness.

Now undo the insulation of the core, so that an induced current can flow as the coil current subsides, other things being the same. The subsidence of the coil current is now shown by the curve H_aH_a. Comparing this with h_1h_1, there is seen to be a general resemblance, with two notable differences: First, and most important, there is a very sudden drop in the strength of the coil current at the commencement, the curve being nearly vertical. This is the first effect of allowing the core current to flow, it being of considerable density, but practically confined to near the boundary. The current is apparently transferred from the coil to the core. But later on, as the core current travels into the core, the coil current subsides less quickly, and finally we have the second difference, a slower subsidence than when the core was divided.

These two effects are characteristic of induction in general between a primary and a secondary, a sudden drop in the strength of the primary, sometimes of very large amount, accompanying the simultaneous appearance of the secondary current in the same direction, and a later more slow subsidence of what is left of the primary current than if the secondary circuit were interrupted.

The same curve H_aH_a shows the manner of subsidence of the magnetic force at the boundary of the core, and of the density of the induced current close to the coil, for they both keep pace with the coil current just outside.

Under the same circumstances the fall in the strength of the magnetic force at the axis of the core is shown by the curve H_0H_0, whose principal characteristics are the preliminary retardation and the opposite curvature of the first portion of the curve from the remainder. Although, according to the formula, the axial force commences to subside instantaneously, yet for a certain time the fall is so excessively small as to be quite insensible. The terms of the series are alternately positive and negative, and, with small values of t, a very large number of them and careful calculation is required to obtain evidence of any fall at all. But, this dead period got over, the rapidity of subsidence increases fast. Ultimately the curve settles down to be the curve of subsidence of the first normal system.

Between H_aH_a and H_0H_0 lie the curves of subsidence of magnetic force at points between the boundary and the axis; as we pass outward from the axis the length of the dead period decreases, and ceases entirely at the boundary.

So far with the coil circuit closed. Now, starting as before, with the steady current and magnetic force, make the resistance of the coil circuit very great (the E.M.F. to be removed). The current in it disappears at once, and the subsidence of the magnetic force in the core is greatly accelerated, the curve being shown by h_0h_0 for points on the axis, corresponding to H_0H_0 with circuit closed.

If we wish to see how the current and force rise to their final strengths when a steady E.M.F. is put in the coil circuit, initially free from current (as also the core), all we have to do is to turn the diagram (Fig. 3) upside down, and view its reflection in a mirror.

Regarding the dead interval, there is this curious property. At the time $t=0$, the rate of decrease of H at the axis is obviously zero. Not only that, but each of the whole series of successive differential coefficients of H with respect to t is then zero, except the ∞th, and that is infinitely great. This statement requires interpretation, of course, because the number of differential coefficients is infinitely great. The interpretation may be got by considering the core to consist of a finite though very great number, m, of concentric cylinders. Then all the differential coefficients $=0$ except the mth, which is very large. Increase m indefinitely, and we approximate as nearly as we please to the solid core, with the above result.

(TO BE CONTINUED.)

HEALTH EXHIBITION.—VII.

One of the largest exhibits is that of the GULCHER ELECTRIC LIGHT COMPANY. This installation comprises 8 "Gulcher" dynamos of the No. 4 type; 59 "Gulcher" arc lamps, and about 500 Crookes incandescent lamps, detailed as follows: Four compound wound dynamos, specially constructed of a new and approved design, having a terminal E.M.F. of 105 volts, supplying the 350 incandescent lamps in the Dairies. The system of winding in these machines admits of any number of the lamps being turned on or off without perceptibly affecting the remainder or causing injury to the machine. Four dynamos, with a terminal E.M.F. of 70 volts, supplying 50 arc lights of 500 actual candle-power in the Eastern Gallery and Chinese Court, and 1 of 2,300 candle-power outside the Entrance; also 138 incandescent lamps, and 8 500 candle-power arcs in the Chinese Restaurant.

Special attention has been paid to the arrangement of the lamps in the Dairies in order to obtain an artistic effect, and in the Chinese Restaurant also the lighting is strictly in keeping with the character of the building, the arc lamps and the outer row of incandescent lamps under the Verandah being enclosed in Chinese lanterns.

In the Eastern Gallery care has been taken to suspend the lamps in a neat and elegant manner, and in the China Court the arc lamps are enclosed in Chinese lanterns, again to be strictly in keeping with the decorations of the building.

All dynamos giving the same E.M.F. are connected parallel, and, in order to equalise the E.M.F. in each, are arranged so that the electro-magnets of any machine are excited by the current generated in one of the others. The coupling-up is effected by means of a novel switch, and is such that one or more machines may be switched off, still keeping the same relative connections between those left working. The system adopted is to have one more machine than is necessary for doing the work, so that in the event of a machine breaking down this spare one is switched on in its place, whilst the damaged one is cut out of circuit.

There is a further advantage in this method, viz., that any one of the machines may become the spare or "stand by," and thus they may be worked alternately so as to secure even wear and tear in working. It may be mentioned here that the still somewhat novel method may be seen in the Chinese section of arc and incandescent lamps upon the same leads.

The armatures of the dynamos are of the Gramme type, and are constructed as follows:—A flat wooden ring is made up of sections glued together to avoid warping. A number of thin flat rings of charcoal sheet-iron are laid upon each side of the wooden ring, a thin sheet of asbestos paper being placed between each contiguous iron ring. The whole is riveted together with soft iron rivets. The ring thus formed is turned and faced accurately, the centre wooden part being left above the iron sides. The wooden rim left standing above the iron is slotted out in 52 equi-distant places for the wire coils to pass through. This serves as a guide for winding, and also effectually prevents any displacement of the coils. The coils are 52 in number, and their lower portion, viz., that part which embraces the inner annulus of the ring forms a V shape, which enables the ring to be firmly clamped by two gun-metal discs, which are provided with flanged edges for that purpose; a washer of leather is placed between the disc flanges and the coils to protect the latter. The wires connecting the armature coils to the commutator are brought through a steel sleeve, which is shrunk on the spindle and forms the bearing surface. This arrangement permits of the use of an overhanging commutator, which is easy to get at and attend to, and at the same time somewhat reduces the length of the machine. Fig. 1 shows a perspective view of one of the Gülcher machines.

The field magnets consist of four poles arranged alternately north and south, thus dividing the armature into four circuits, and thereby reducing its resistance to $\frac{1}{16}$th of the actual resistance of the wire. At the time when Mr. Gülcher first introduced this machine the form of the pole shoe was peculiar, but latterly it has been imitated. The form referred to is an embracing shoe covering the top of the coil as well as the side

Digitized by Google

faces, thus making the U-shaped shoe which is now so much adopted.

This shape has been thought by many to be of questionable advantage, but according to recent experiences of the company the gain in efficiency appears to be considerable. In the new pattern machine cast-iron pole shoes have been adopted with cylindrical wrought-iron cores. In this pattern the field magnets are arranged nearer the periphery of the armature, the exact position being such that a circle drawn through the axes of the electro-magnets would divide the side of the armature ring into two concentric rings of equal area. The field magnets are method has the effect of balancing the strength of all, and of bringing them to one mean standard. The above connections are made through a novel "exchange" switch supplied to each machine. These switches are so arranged that any number of machines can be coupled up, and any combination of that number can be used at one time, so that in a very large installation it is only necessary to have one spare machine, which may be switched on at a moment's notice, whilst the bad one is cut out without stopping or affecting the lights. Fig. 2 is a diagram of connections showing three machines on and one machine off. The collector is of phosphor bronze, and is made

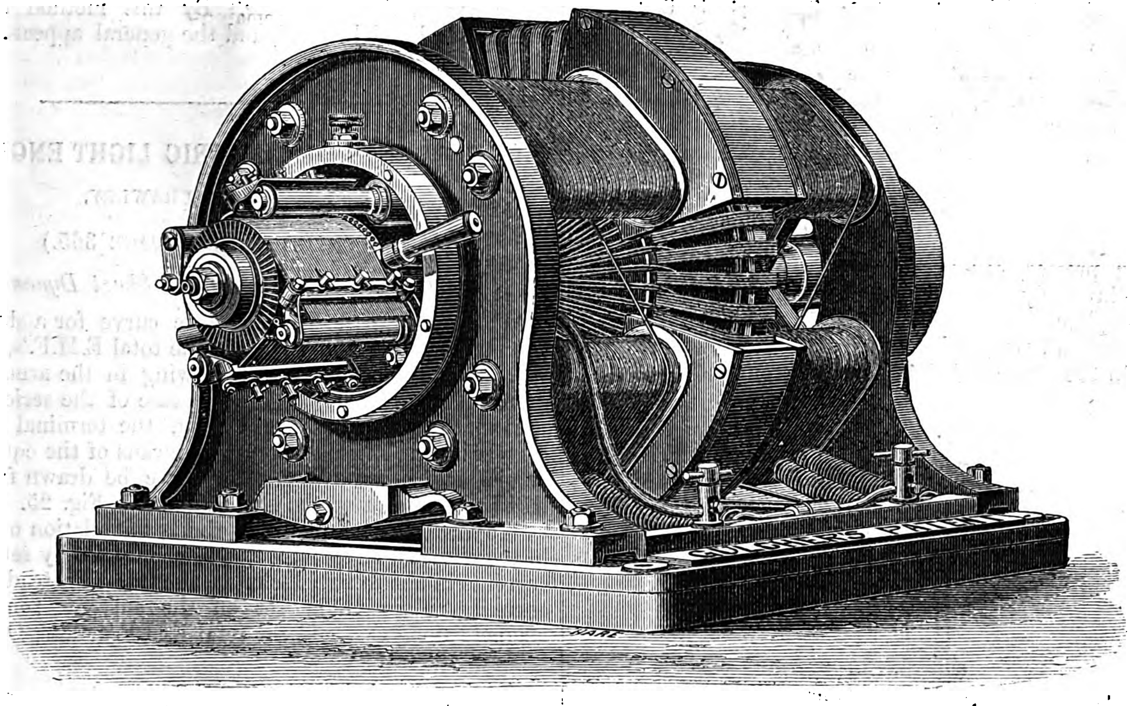

Fig. 1.—The Gülcher Dynamo.

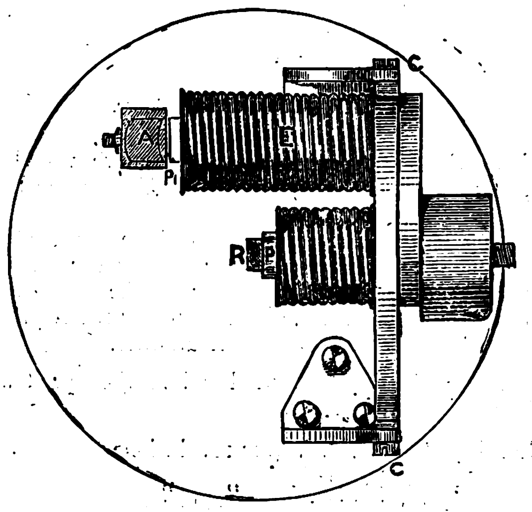

Fig. 3.—Plan—Gülcher Arc Lamp.

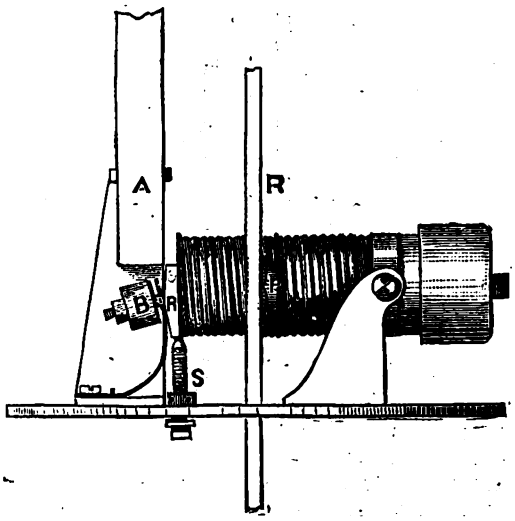

Fig. 4.—Elevation—Gülcher Arc Lamp.

either simple or compound wound as desired, five of those exhibited being compound machines. All the magnet bobbins are connected in multiple arc with each other, the whole being in series with the outer circuit, whilst the shunt wires on the compound bobbins are in series with each other, and the whole connected to the terminals as a shunt to the outer circuit.

All machines intended to give the same E.M.F. are joined in multiple arc, and to secure absolute equality in E.M.F. in each the field magnets are excited in each case by the current generated in the armature of one of the other machines. This in 52 segments insulated from each other by asbestos paper. The spindle is made of cast steel, running in phosphor bronze bearings.

The Gülcher arc lamp regulates entirely by variations in the strength of an electro-magnet, which controls all the actions of the lamp. Referring to the diagram (Fig. 3), E is an electro-magnet of horse-shoe shape, the polar extremity projecting through the short bobbin is sheathed with brass, as will be best seen from (Fig. 4) the elevation, so that when the axis of the magnet is in a horizontal plane, the point, or rather

Digitized by Google

line of contact, will be made on the knife edge of iron, but when the magnet attains the position shown in the diagram, *i.e.*, resting on the stud S, the contact is between the soft iron rod R and the brass sheathing; N is a soft iron nut screwed on to a stud projecting from a brass or other non-magnetic spring, and by its attraction to the magnet pole, against which the

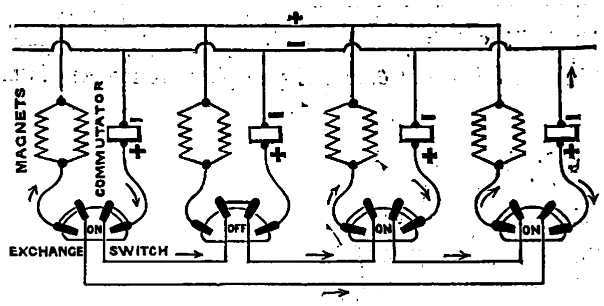

FIG. 2.

brass spring presses, causes friction in proportion to the current, and inversely to the length of the arc. Fig. 5 shows the lamp complete.

The lamps are all arranged parallel, and their action is as follows:—On the current being passed through the electro-

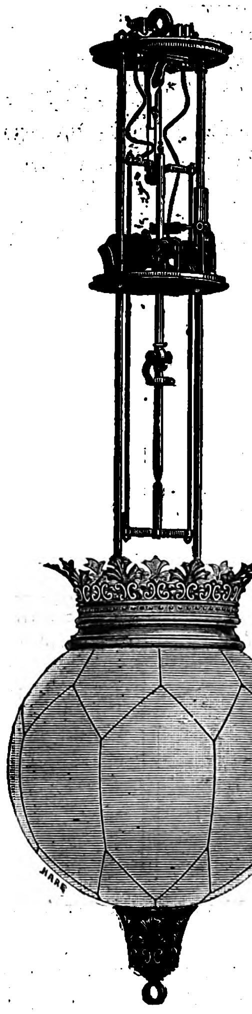

FIG. 5.—Gülcher Arc Lamp.

magnet the long arm is attracted by the fixed armature A, whilst the rod is gripped and lifted by the short end. As the consumption of carbons proceeds the rocking magnet gradually sinks until it attains the position shown in the diagram, the pole piece resting on the stud S. In this position the normal current strength is just sufficient to produce the magnetism required to support the weight of the rod and upper carbon; any increased length of arc and consequent weakening of the current is now followed by a corresponding fall of the rod, and in a well-adjusted lamp there is a practically constant feed in this position. Should the carbons get too close together by an accidental drop, the rocking magnet again lifts as at first. The claims for this lamp are its extreme simplicity and few working parts to get clogged or damaged. A lamp once adjusted is said to be adjusted for all time. The sensitiveness of the magnetic brake enables the lamp to burn most successfully in multiple arc.

The lamps are suspended over pulleys with counterweights by means of the conductor. By this method they can be easily raised and lowered, and the general appearance is neat and elegant.

THE ELEMENTS OF ELECTRIC LIGHT ENGINEERING.

BY C. W. S. CRAWLEY.

(CONTINUED FROM PAGE 365.)

Characteristic Curve for a Shunt Dynamo.

We may draw the characteristic curve for a shunt dynamo by setting off on the axis O Y the total E.M.F.'s, and on O X the total currents (or currents flowing in the armature) which correspond to them, as in the case of the series machine; these values can be found from the terminal E.M.F. and current in the external circuit by means of the equations given before, and if a characteristic curve be drawn from them, it will be somewhat of the shape shown in Fig. 25.

We may also draw a curve giving the relation of the current in the external circuit to the total E.M.F., by setting off the currents in the external circuit along O X instead of the total currents, or we might set off the currents round the field magnets along O X and the total E.M.F.'s along O Y.

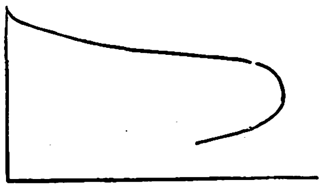

FIG. 25.—Characteristic Curve.

Perhaps the most practically useful curve would be that drawn by setting off the terminal E.M.F.'s along O Y, and the external currents along O X.

In taking observations for any of these curves, the speed should be kept constant if possible; if, however, we cannot do so, we must note the speeds, and employ the following method for finding the total E.M.F. and current for the required speed when the observations are taken at another.

Let n = the required speed and m the speed at which the observations were taken.

Let E_m = total E.M.F. at m revolutions.
C_m = total current " "
E_n = total E.M.F at n revolutions.
C_n = total current " "
e = terminal E.M.F.
A = resistance of armature.

If we maintain the current round the field magnets constant, the total E.M.F. varies as the speed; to maintain this current constant e must remain constant.

Suppose this to be the case, then

$$E_n = E_m \times \frac{n}{m},$$

$$C_n = \frac{E_n - e}{A}, \text{ and } C_m = \frac{E_m - e}{A};$$

therefore $$C_n = C_m \frac{E_n - e}{E_m - e} = C_m \frac{n E_m - m e}{m (E_m - e)}.$$

If we substitute for E_m and C_m their values in terms of the terminal E.M.F. and external current at m revolutions, as obtained in the equation given before, we have

$$E_n = \frac{n\{e(A+B) + A B p\}}{m B}$$

and $$C_n = \frac{e\{n A + B(n-m)\} + n A B p}{m A B}$$

By plotting off C_n along O X and E_n along O Y we can obtain points for the curve at n revolutions.

It may make the above clearer to point out that having found the total C and E corresponding to any terminal E.M.F., e at m revs., we can thence deduce what total C and E will occur at n revs. when the terminal E.M.F. is the same or $= e$. It must be remembered that it is *most* desirable that all points in a curve should be taken at the *same* speed; the methods given for varying speeds being only used when, owing to defective government of the engine, it cannot be kept constant.

Efficiency.

Work in the external circuit or $w = p^2 P$.

Total electrical work or $W = a^2 \left(A + \frac{B P}{B+P}\right)$.

Electrical efficiency or $\frac{w}{W} = \frac{p^2 P}{a^2 \left(A + \frac{B P}{B+P}\right)}$.

Now $$a = \frac{e}{B} + p = \frac{p(B+P)}{B};$$

therefore $$\text{efficiency} = \frac{B^2 P}{(B+P)\{A(B+P) + B P\}}.$$

This equation gives the electrical efficiency of a shunt dynamo in terms of its resistances and that of the external circuit.

Work in electrical horse-power expended in the armature of a shunt dynamo in terms of its internal resistance in ohms, external current in amperes, and terminal E.M.F. in volts

$$= \frac{a^2 A}{746} = \frac{A(e + B p)^2}{746 B^2} \text{ h.p.}$$

That in the field magnets $= \frac{e^2}{746 B}$ h.p.

That in total internal resistance $= \frac{(e + B p)^2 A + e^2 B}{746 B^2}$ h.p.

That in the external circuit $= \frac{e p}{746}$ h.p.

The mechanical efficiency of the shunt dynamo is exactly the same ratio as that of the series, and is therefore measured in the same manner.

Western and Brazilian Telegraph Company.—The traffic receipts of this company for the week ending 29th August were £2,620, after deducting the "fifth" of the gross receipts payable to the London Platino-Brazilian Telegraph Company.

West India and Panama Telegraph Company.—The estimated traffic receipts of this company for the half month ended the 31st August are £2,490, as compared with £2,074 in the corresponding period of 1883.

Eastern Extension Telegraph Company.—The traffic receipts of this company for the month of August amounted to £35,967, and to £38,126 in the corresponding period of 1883.

Direct Spanish Telegraph Company.—The estimated traffic receipts of this company for the month of August are £1,173, against £1,547 in the corresponding period of last year.

Brazilian Submarine Telegraph Company.—The traffic receipts of this company for the week ending the 22nd inst. amounted to £3,219.

ON HALL'S PHENOMENON IN LIQUIDS.

According to M. Anton Roiti, Hall has shown that when a current is passed through a thin plate of metal, there is a transverse E.M.F. induced in the plate, if it is placed with its plane perpendicular to the lines of force of a magnetic field. This is the phenomenon suggested as possible by Maxwell, and expressed by the assumption of a "rotatory coefficient" in the equations of conduction. Hall has determined this coefficient for various metals. The author first experimented with a sheet of silver electrolytically deposited on glass, and in general verified Hall's results. The experiment was then tried in a different way. The main current was passed through a silver wire, A B, 0·03 millimetre in diameter, and about 4 centimetres long, held by two stout copper wires. At right angles to this was a second similar silver wire, C D, forming a cross with the first. This second wire was stretched by two suspended weights, and had stout copper wires similarly attached to it. The plane of the wires was at right angles to the lines of magnetic force, their point of intersection being in the axis of the electro-magnets. The copper terminals of C D were connected with an exceedingly sensitive galvanometer. It was found that if the tension of the wire was considerable, no effect whatever could be observed when the direction of the field was reversed, even with a primary current produced by six Daniell's. This shows that the supposition of a direct effect upon the current is not admissible, and that the phenomenon really depends upon a change in the specific resistance, in the manner considered by Maxwell. In experimenting on liquids, the author found that the polarisation introduced considerable difficulties, but he concludes from experiments with sulphate of zinc solution, that if the concentration of the solution is less than that of maximum electrical conductivity (specific gravity 1·286), the electro-dynamic action produces an increase in the conductivity of the liquid in the direction of C D, and conversely if the concentration is greater than that of maximum conductivity.—Institute of Civil Engineers' *Transactions.*

ON THE ELECTROLYSIS OF SOLID GLASS.

The facts described in the paper of M. E. Warburg in *Wiedmann's Annalen*, says the *Phil. Mag.*, may be summarised in the following manner:—

In the electrolysis of lime-soda glass heated to about 300 degrees between mercury electrodes, a badly conducting layer of silicic acid is formed on the anode side of the glass, which soon reduces the strength of the current to a fraction of its original value. This layer has a greater or less thickness, according as a greater or lesser electromotive force has acted in the circuit in a definite time. It is visible, showing the colours of thin plates, diminishes the surface-conductivity of the glass in the cold to a fraction of its original amount, and at a high temperature, when the mass of the glass has become a conductor, it acts like the dielectric of a condenser whose coatings are the conducting mass of the glass, and the mercury of the anode. The capacity of this condenser was found to be independent of the difference of potentials of the coatings, between 1 and 20 Bunsen elements; and for a square centimetre of the glass used it varied from 0·021 to 0·041 microfarad, according as the layer was formed by 30 or 15 Bunsen elements acting for several hours at 300deg. The formation of this layer may be avoided by using sodium amalgam as anode; the result of the electrolysis may then be quantitatively determined. In this a quantity of sodium is given off at the cathode and absorbed at the anode, so that the weight of the glass does not vary; the weight of the sodium is chemically equivalent to the weight of the silver which is deposited at the same time in the silver voltameter. During electrolysis the glass remains perfectly clear, and it was found that all the properties of the glass were not appreciably altered by electrolysis.

IMPORTANT NOTICE.

*** All communications should be sent to our new offices, 1, Salisbury-court, Fleet-street, E.C., where *The Electrician* is now printed and published.

THE BRITISH ASSOCIATION.

The members and Council of the British Association are this year to be congratulated not only on the fortunate occasion which has carried them to the hospitable and romantic shores of their fellow countrymen in the far West, but in the choice of a president who combines in his own person qualities most highly esteemed by their generous hosts. From the circumstance of his birth, his political associations, as well as his devotion to those objects which the Association is engaged in promoting, Lord Rayleigh is a typical English gentleman whom we are proud to have as our representative at Montreal just now. But in other respects also he has exceptional qualifications for presiding over a gathering which, held in a strange land, must needs be as comprehensive in its character as possible. Lord Rayleigh is a professed physicist; and, to use his own words, the subjects included under the head of physics are so numerous that no one man can do justice to them all; but no living scientist probably would have done them less injustice than this year's President of the British Association.

The presidential address usually provokes some attention at the hands of the English newspapers, and not always of the appreciative sort; but we do not remember any in recent years that has given rise to such lengthened and at the same time such friendly comment as the one just delivered at Montreal. This is to be ascribed partly, no doubt, to the unaggressive tone of the address, a characteristic to which we shall refer again presently; but more particularly to the generally attractive and instructive facts which he has succeeded in bringing together in an intelligible form. Hardly any branch of physics escaped his observation, from Electricity to Spectroscopy, and from Dynamics to Acoustics; and the extent of its reproduction in the public press is testimony to his treatment of these subjects, besides being evidence of a growing and intelligent interest in their study outside the strict boundaries of the scientific world. Electricity, of course, came in for the lion's share of attention; and we note with satisfaction Lord Rayleigh's remarks on the subject of absolute standards of measurement for electromotive force, current, and resistance. As regards resistance, the agreement arrived at by the Conference of Electricians differs only a little more than 1 per cent. from that arrived at twenty years ago by the British Association. A more decided recommendation is given to Mr. Latimer Clark's permanent form of standard cell, whose electromotive force is determined almost once for all. To complete the scheme of electrical measurement Lord Rayleigh recommends the application of Faraday's electrolytic law. The results recently obtained by himself and Professor Kohlrausch, namely, that one ampere flowing for one hour decomposes 4·025 grains of silver, are in such close agreement that they can hardly be in error by more than a thousandth part. This number being known, the silver voltameter gives a ready and accurate method of measuring currents of intensity varying from 1·10 ampere to four or five amperes. With reference to this study of electrolysis, Lord Rayleigh ventured the prediction that we may expect the next great advance in scientific knowledge will come from that direction, with improved views as to the nature of chemical reactions and of the forces concerned in bringing them about.

While sharing the common regret that the application of electricity to the purposes of power and illumination had been somewhat discredited by ignorant and speculating promoters, Lord Rayleigh added words of encouragement, based on scientific knowledge. Assured on sound theoretical grounds that we are on the right track, he recommends us to push the attack persistently when we can be sure, as in this case, that the obstacles to be overcome are only those of contrivance, and that we are not vainly fighting unawares against a law of nature. Referring to the new interest in the study of acoustics awakened by the discoveries of Graham Bell and Hughes, and to the failure of attempts to explain their action, Lord Rayleigh points out that molecular changes in solid masses are inaudible in themselves, and only capable of reaching the ear when their external surface is set in motion; and that if the surface of a solid remains undisturbed our ears can tell us nothing of what goes on in the interior, facts which we should do well to remember in pursuing the investigation of telephonic and microphonic phenomena.

With Lord Rayleigh's concluding observations on the relative value of scientific and literary education there has been a general agreement of public opinion, from which we are in no

Digitized by Google

way disposed to dissent. As against the study of the dead languages his lordship thinks that a scientific training might be preferable; and at all events quite as serviceable in the forming the mind into habits of accurate thought. But when there exists no taste or aptitude for scientific ideas a study of modern languages would be eminently more practical than that of either science or the classics. In any case he doubts whether an exclusively scientific training would prove satisfactory; and so do we, for to a vast number of minds it would be as barren of results—except as mental training for which either will serve indifferently—as is usually the time spent on a classical education. By results, of course, we mean visible results; but there are many indirect advantages from the early study of literature, and its advocates justly esteem them more highly than any likely to be derived from time exclusively devoted to science in early youth. For ourselves we think that such an education would be narrow in almost its worst sense, and would give us, wherever it succeeded, a plentiful crop of prigs. Lord Rayleigh, with gentle derision, calls them "prophets"—self-elected prophets—whose opinions in reality on the general affairs of this life, and especially concerning the higher mysteries of our being, are worth not a bit more than those of other intellectual men educated in the ordinary way. But leaving these points of disputation, no one will deny Lord Rayleigh's claim for science, that it is always progressive, whilst in other departments of human life progress is rather an article of faith than a rational belief. We cannot be sure of our progression in political or social affairs; we know, on the other hand, that increasing knowledge brings increasing power, and a foretaste of fresh triumphs in store for us. This is the message which the British Association has carried to the New World; and we share in the hope that "a larger measure of the youthful activity of the West will be drawn into its service."

CORRESPONDENCE.

ANOTHER SOLUTION.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: The question often arises in the inquiring mind—What is electricity? I have read many so-called explanations of the phenomena, notably Mr. Sprague's and Clerk-Maxwell's, besides several others, but none of them seem to correspond with the manifestations of the phenomenon so entirely as a certain theory of my own which I formed many years ago from a number of different experiments. I have often thought I should like to make my theory public, but as nobody seems to see it in the same way, I have held back, and only just among a few private friends have I mentioned the matter. I will put it as I condensed it in my note-book. Electricity is a decomposition of the negative and positive atoms composing the molecules of ether. I will explain what I mean by the word "ether." Ether is a semi-material imponderable (the word "substance" will not do), I will say "something," corresponding in idea to a very attenuated gas without its material attributes, that fills all space that is not occupied by matter; that every atom of matter is surrounded by a molecule of ether; that the composition of a molecule of ether varies as to its negative and positive atoms according to the matter it is associated with; that the decomposition and (for chemical different) reforming of the molecule of ether causes both chemical and electrical phenomena; that ether attracts matter and matter attracts ether; that energy is different motions of the ether, such as expansion and contraction, decomposition and recomposition of the molecules of ether. Ether is capable of indefinite expansion and contraction. Heat expands the molecules, or to speak more correctly, heat *is* the expansion of the molecules of ether, *i.e.*, if the molecules of ether expand, that constitutes the sensation of heat to us, and likewise the phenomenon of motion through the resistance of the mutual attraction of ether and matter. But I am digressing. The question is, What is electricity? From my experimenting I theorise thus: That every conductor of electricity is composed of molecules; that round every atom composing these molecules is a molecule of ether composed of (in varying relative quantities) negative and positive atoms, and when these molecules are broken or decomposed (say by a primary circuit on a Ruhmkorff) a current of electricity is the result. The negative flowing (and by a series of decompositions) in one direction and one side of the wire round the completed circuit, and the positive atom in the reverse. Electromotive force is the force or violence with which the atoms are separated irrespective of the number of lines of force which are started. Strength of current (old quantity) is the number of lines started and completed in the circuit. I have only room to mention the experiment that convinced me that magnetism and electricity were etheral phenomena. I placed a small compass needle inside a small glass globe; something similar to what they afterwards used for incandescent lamps, and by the aid of a Sprengal I exhausted the air, and hermetically sealed it. I took another globe and needle without the exhaustion and sealing. The two needles were deflected exactly alike by a permanent magnet on the outside. Nothing could account for this but the intervention of ether. Depend upon it they may beat about the bush as long as they like. Ether alone gives a rational clearing up of the mystery. I should have liked to have given a few other ideas of mine connected therewith, but I think I have inflicted enough for once, so I will forbear.—Yours, &c.,

W. ALDRED.

THE PILSEN JOEL ELECTRIC LIGHT COMPANY.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: I notice an error in your report of my remarks made at the Pilsen Joel and General Electric Light Company (Limited), at the general meeting, held last Thursday, the 27th August. From your report it would appear that I had spoken of the Anglo-American Brush Company as having the best lamp in the market, &c., whereas I stated that it was the Pilsen Company whose lamp (the Pilsen arc lamp) was the best, and who had started better than any other company, and who ought, therefore, to have done better than any other company.

Will you kindly insert this letter in your next number?—Yours, &c., HENRY F. JOEL.

Tower-chambers, Moorgate-street, London, E.C.,
Sept. 2, 1884.

FITZGERALD'S METHOD FOR MEASURING THE INTERNAL RESISTANCE OF BATTERIES.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: With reference to your remark in the review of my "Handbook of Electrical Testing," which appeared in your issue of the 23rd August, "we might suggest the addition of . . . FitzGerald's method for measuring the internal resistance of batteries," I would point out that this method has been given in each of the three editions of my book (page 35, 1st edition; page 98, para. 110, 3rd Edition). I may also remark that the method is given in detail on page 314 of Sabine's "The Electric Telegraph," published in 1867.—Yours, &c.,

H. B. KEMPE.

General Post Office, Sept. 1.

[The reply of Mr. Kempe is to a certain extent what might be expected; it ought, however, in my estimation, to have been altogether different in tone and matter. Mr. Kempe does not mention FitzGerald's name at all on page 98, para. 110.

Digitized by Google

Nor is the name to be found in the preface. Mr. Kempe will probably say that Sabine gives the method without acknowledging the author, and that his text is founded upon Sabine's; or perhaps he may say that the method is not FitzGerald's. I know that Mr. FitzGerald claims the method, and I did not imagine that his claim would be disputed. It is evident also that Mr. Kempe understands this claim; hence I should like to know *why* he fails to name FitzGerald in connection with the method. Throughout the work the desire is so evident to give credit that the exception is singular. My impression is that the method was known as FitzGerald's long before Sabine's book was published, but as I cannot verify the impression for the moment, I mention it for what it is worth. I do not care to argue whether Mr. FitzGerald would accept para. 110 as a good description of his method, and am willing to agree that Mr. Kempe thinks it is, and differs as to its value with Mr. Sprague.—THE WRITER OF THE NOTICE.]

TELEPHONING EXTRAORDINARY.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: I have seen your article in *The Electrician* of August 30th on "Telephoning Extraordinary." The same is, I fear, very liable to create a wrong impression. The writer is entirely familiar with the line used, having on several occasions during the past winter experimented over the same distances mentioned in the article.

1st. The distances given between Bologoie and Petersburg are more than *ten times* too great, the distance being about 370 kilometres (*see* Badeker's *Russia*). 2nd. The distance over which they hope to talk (Petersburg to Moscow) suffers the same stretching.

Considering these figures it will be seen that there is nothing at all "extraordinary" in the matter. Telephoning has been done in America and elsewhere over very much longer distances and under circumstances much more unfavourable.

The line experimented upon is remarkably well situated for telephonic work. From St. Petersburg it runs, it is true, upon the same poles with a few telegraph wires, but only for a distance of five or six miles. From there it runs as an entirely distinct line upon separate poles, and removed two or three hundred feet from all other lines. Being, then, as will be seen, most favourably situated, being moreover exceedingly well insulated, is there anything "extraordinary" that talking could be carried on at night when these other wires (three hundred feet distant) were not in use? At the time the writer heard experiments with the Bell-Blake combination, conversation, but very limited, was imagined to be carried on, but no one claimed anything like success for the experiment.

Russia is a great country, and little developed in its resources, but I am one who believes that our English and American electricians understand how much can be got out of the Bell-Blake combination as well as our Russian neighbours.—Yours, &c., VERIPHONE.

[We have referred to the *Bulletin*, and find the figures therein are as we gave them in our note. As our correspondent points out, there is nothing extraordinary in the experiment when the figures are corrected and the conditions stated.—ED. *E.*].

THE PASSAGE OF A CURRENT THROUGH A CONDUCTOR.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: How can the passage of a positive and a negative current through a conductor in opposite directions be explained?

My idea of the subject is this—If you have a *positive current* (if it is possible to imagine one) flowing through a wire or other conductor, it produces a certain effect. Now, suppose that you have *negative current* (the same remark applies here as in the former case) flowing through the same conductor in the *same direction*, an effect is produced *opposite* to the former one.

Therefore if the two currents flowed in the *same direction* in a conductor they would *neutralise each other*; the one, as we have seen above, doing exactly the opposite of the other, but if they pass in *opposite directions* (as they do), they co-operate to produce the *same effect*. Still, however, I meet with the objection that it is almost impossible to imagine two currents flowing through the same conductor at the same time in opposite directions.

Be that as it may, I must let those who cannot "stretch" their imagination keep the same ground. I think, however, that the above reasoning will remove the difficulty which arises from thinking that the positive and negative currents in the same direction produce the same results instead of their being totally opposed to each other. I should like to know if this theory is correct, and whether it has been ventilated before.—Yours, &c., A. T. B.

ON NORMAL ELEMENTS FOR ELECTROMETRIC MEASUREMENTS.*

BY W. H. BEETZ.

In order to measure a difference of potential in absolute units a normal element is required, having a perfectly definite electromotive force, which can either be put together once for all, or can always be set up in exactly the same way and without too much trouble. According to Kittler's experiments†, a Daniell element, having a porous cell, does not at all fulfil these conditions, since its electromotive force is subject to continuous change. On the other hand, an element composed of chemically pure zinc and pure copper, in dilute sulphuric acid and copper-sulphate solution of definite strength, the solutions being placed in connection by means of a siphon-tube terminating in small openings and filled with the same sulphuric acid, has always the same electromotive force, and since it can easily be put together, forms a convenient standard cell. Using concentrated copper-sulphate solution and dilute sulphuric acid of specific gravity 1·075, Kittler found the electromotive force of such an element to be 1·195 volt, which decreased to 1·059 volt when the dilute sulphuric acid was replaced by concentrated zinc-sulphate solution.

Of the Daniell elements hitherto employed for measurement of difference of potential, that of Raoult‡ best fulfils the conditions here laid down; that of Lodge§, employing dilute zinc-sulphate solution, less satisfactorily; whilst combinations containing porous cells, such as that proposed by Buff‖, are still less suited to serve as normal elements.

But none of these are able to maintain a constant electromotive force, as is now desirable for electrometric measurements, since in all gradual diffusion of the liquids takes place. I myself¶ have formerly made use of similarly arranged normal elements for measurements made according to the compensation-method; but they do not answer for electrometric measurements, and I have therefore been obliged continually to renew the element. For the length of time during which unbroken observation with the electrometer is usual, we may rely upon the constancy of the element.

The frequent putting together and taking apart of an element is a labour always willingly avoided. Hence the permanently-connected zinc and mercury element of Latimer Clark** was gladly welcomed. Its electromotive force (1·457 volt) was found nearly constant in different preparations of

the element according to the method described. But it has two undesirable properties: the one is the great variation of electromotive force with change of temperature, which, however, is easily allowed for in calculation, but which does not exist* in the case of the Daniell elements; the other is the great decrease which the electromotive force suffers if the circuit is closed even for a very short time. This may easily occur. An unintentional contact in some of the auxiliary apparatus employed in the measurements, for example in the key which I have described†, is sufficient to render the element useless for one or several days. I obtained a diminution of electromotive force, amounting to 2 per cent., in a Latimer-Clark element in which the circuit had been closed for only half a minute. A Daniell element would have shown scarcely any change under similar conditions.

But this defect of the Latimer-Clark element may be almost entirely remedied by giving to the cell so great a resistance that only an insignificant current can be generated.

A U-tube of 1 centim. diameter and legs 75 centim. long was filled with the paste of mercury-sulphate and zinc-sulphate solution, prepared according to the instructions, but heated so much that after cooling it became hard. The paste was boiled in the tube by means of a water air-pump. The zinc pole was introduced into the upper end of the tube and the mercury pole into the lower, and the openings were closed with paraffin. The element is very convenient for use on the laboratory table, since the two poles may pass through holes bored in the table, the whole body of the tube being protected underneath the table. The internal resistance of the element was 15,700 ohms‡. Its electromotive force was somewhat smaller than given by Latimer Clark. If, in fact, the electromotive force of a normal Daniell cell (with dilute sulphuric acid) be taken as 1·195 volt, then that of my mercury element was 1·442 volt (instead of 1·457 volt). When the element was short circuited, its electromotive force was as follows:—

After 5 minutes	1·440 volt.
„ 1 hour	1·439 „
„ 4 hours	1·439 „
„ 6 „	1·437 „
„ 12 „	1·434 „
„ 48 „	1·408 „

We see therefore that the element resists the influence of polarisation for a long time. Polarisation could indeed only be very slight, since the current which passed through the element has only the intensity of 0·000091 ampere. The electromotive force only diminished 2 per cent. after use for 48 hours, a decrease which is very small indeed compared with the falling off in the usual form of the Latimer-Clark element. It is easy to avoid short-circuiting the element for such a length of time; but if the element has once become enfeebled, it recovers itself only slowly. Thus, after 24 hours I found its strength to be 1·430 volt.

The idea of replacing the fluid of an element by a solid body may be carried out also with a Daniell element. Fine alabaster plaster of Paris was mixed with concentrated copper-sulphate solution to about the consistency employed in making plaster casts, and some more with concentrated zinc-sulphate solution. A U-shaped glass tube, of 4 millim. diameter and with legs 22 centim. long, was partly filled with the one paste, and after it had set was filled up with the other, so that the two were in close contact. A copper wire was introduced into the copper paste before it had set, and a zinc wire into the zinc paste. The upper part of each leg was cleared from plaster and filled up with paraffin.

Several dry Daniell elements thus prepared were compared with an element put together with concentrated solutions of copper sulphate and zinc sulphate, and tested in respect of the effect of change of temperature, and of short-circuiting. Taking the electromotive force of the liquid element as equal to unity, the three dry elements I., II., and III. gave, when measured on different days:—

	I.	II.	III.
	0·996	0·993	1·000
	0·998	0·996	0·996
	1·000	0·999	0·993
	—	0·998	0·998
Mean...	0·998	0·996	0·997

The temperature varied in all these observations by a few degrees only; the small apparent variations in the electromotive force of the dry elements are partly at least accounted for by small changes in the electromotive force of the fluid element, which was put together fresh each time. On the whole, however, the dry element is a little weaker than the fluid element; it contains no amalgamated zinc, because such amalgamated wires are very brittle.

A second series of experiments was concerned with the influence of temperature. The elements II. and III. sometimes at the temperature of the air, sometimes in baths of different temperatures, were compared with the fluid element, which had always a temperature of nearly 20°C. On account of the small conducting power of the dry elements for heat, they remained always three-quarters of an hour in the bath before the measurements were made. If the electromotive force of the fluid element is again taken as unity, that of the dry element was as follows:—

II.		III.	
At 0°	0·996	At 1°	1·007
„ 20	0·993	„ 21	1·000
„ 39	0·983	„ 32	0·995
		„ 55	0·981

The decrease in electromotive force of each of the two elements for low temperatures between 0° and 20° amounted to only 0·015 per cent. for an increase in temperature of 1°. But the temperature-coefficient increases with increase of temperature. With element II. it amounted to 0·053 between 20° and 30°; with element III. to 0·045 between 21° and 32°, and between 32° and 55° even to 0·061. For Latimer-Clark's element, Helmholtz and von Kittler* agree in finding it to be 0·08. Within the narrow limits within which electrometric measurements are commonly made, the influence of temperature upon the electromotive force of the dry Daniell element may be altogether neglected.

The effect of short-circuiting is seen from the following experiments made with elements I., II., III.

The element was short-circuited for a certain length of time, then contact was broken, and the difference of potential measured. We do not thus obtain actually the lowest value which the difference of potential may attain, since this increases even during the few seconds which the measurement requires; but we do obtain the value with which we are actually concerned in our measurements.

The elements I. and II. were scarcely influenced at all by having the circuit closed for half a minute; but element II. sank from 1·000 to 0·997, but quickly recovered itself completely. The following changes were caused by more prolonged closing of the circuit:—

After the lapse of a quarter of an hour the open element had in all cases recovered its former electromotive force.

The dry Daniell elements have therefore this in common with Latimer-Clark's element, that they can be prepared once for all; but they have further this advantage, that they are scarcely at all influenced by temperature; and that an accidental closing of the circuit produces only an insignificant decrease even in elements of small size (about 1 per cent.), which is very soon recovered. If the electromotive force of a Daniell element put together with copper, zinc, concentrated copper-sulphate solution, and concentrated zinc-sulphate solution be taken as 1·059 volt, then the mean electromotive force of a dry Daniell element = 1·056. It must, however, be remembered that the value 1·059 is based upon the assumption that the force of a Latimer-Clark element = 1·457 volt, which estimate is only to be considered as a preliminary one.

The resistance of element I. was 14,600 ohms, of element II. 13,500 ohms. The strength of current passing through a short-circuited element is therefore 0·000072 ampere for element II., and 0·000078 ampere for element III.; *i.e.*, in the first 0·08 milligrm. copper would be deposited in the hour, and with the latter 0·09 millgrm. copper.

The dry Daniell elements are to be recommended for another purpose, viz., for charging a quadrant-galvanometer. Zamboni's pile has not proved successful for this purpose; it acts excellently for a time, but then the potential difference of its poles changes suddenly, especially with irregular changes of temperature. Apparently the deposition of moisture on the inside of the glass tube containing the pile produces a partial short-circuiting of the pile. With a water-battery these sudden changes do not occur, but the difference of potentials decreases gradually, if slowly. Errors in measurement cannot be caused thus; but the deflections of the electrometer become smaller and smaller, and, apart from the necessity of renewing the evaporated water from time to time, the whole battery every now and then has to be disconnected and cleaned from deposits of oxide and carbonate. I found the electromotive force of a newly prepared zinc and copper element filled with spring water to be 0·992 volt. After twelve hours, during which the element remained open, it had sunk to 0·934 volt. Three of the elements forming my water battery, which has stood now more than a year, were examined. They showed the following differences of potential:—

0·838 0·678 0·724 volt. ...... Mean 0·743 volt.

The dry Daniell elements may conveniently be combined into a battery which requires no filling, and upon which temperature and moisture are without influence.

Since the resistance of the elements is a matter of indifference, they may be made very small. I have filled glass tubes, 8 centim. long and 5 millim. diameter, half with the copper-sulphate plaster and half with the zinc-sulphate plaster, wires of copper and zinc being placed in the corresponding mixture, which wires were then soldered together. The ends of the tubes are closed with paraffin.

Twelve such elements form a row. Twelve such rows stand one behind the other, each connected with the preceding one by insulated binding-screws, so that each chain of twelve elements hangs between two binding-screws. Any desired number of such series of twelve elements may therefore be taken to produce the charge. The whole battery of 144 elements shows a polar difference of potential of 152 volts; whereas the same difference requires 156 elements of the freshly prepared water-battery and 200 of the enfeebled one. The whole dry battery covers a surface of 16 centimetres square.

Postscript.—In the elements last prepared the zinc wires are amalgamated at the ends and covered elsewhere with shellac, and the concentrated solutions have been diluted with one third of water.

ELECTRIC LIGHTING IN BRUSSELS.

The Grand Place,* Brussels, will shortly be illuminated by the electric light, the temporary installation being all but complete. It comprises the dynamos, &c., established in one of the cellars of the Maison du Roi, intended to supply two large lamps, mounted on masts 20 metres (65ft.) high, each lamp being supplied by its own machine. The two generators are on the Gramme system with flat magnets, greatly resembling the five-light type, from which they only differ in the dimensions and the coil wires. While the five-light machine is intended to generate electricty of high E.M.F. at 1,400 revolutions a minute (these machines give out a current of 13 amperes at 350 volts) the generators put down in the Maison du Roi rather produce electricity in quantity (at one normal speed of 750 revolutions they afford a current of 50 amperes and 65 volts).

This type of machine is used with advantage with incandescent light, in which case they run at 1,100 revolutions, and are capable of maintaining 75 Edison lamps of the **A** or 16-candle type.

The two dynamos are driven by a 12 horse-power Otto gas-engine, making 140 revolutions per minute. It is proposed eventually to modify this motor by providing it with driving pulleys fixed with spiral springs in such a way as to compensate for the irregularities of working, which are not very manifest with arc lighting, but should nevertheless be avoided. It is on this engine that the first and favourable trial was made of an English appliance, the "anti-fluctuator," the object of which is to completely neutralise the influence of the gas engine on gas burners fed from the same pipe.

This lighting of the Grand Place by the Communal Administration of Brussels is not undertaken so much to test the lamps and engines as to give an idea of the effect produced, and on this trial, more or less imperfect, will depend the ultimate decision as to the number and situation of the lamps. A commencement is made with two lamps of 1,000 carcels (say 10,000 candles) each, placed 20 metres (65ft.) high. The later type of Jaspar lamp is used, in which the mechanism for bringing the carbons together is placed above the luminous point. The carbons used are 25 millimetres, or 1in., in diameter; and the construction of the lamp ensures illumination during 7½ hours. The average height of the houses in the Grand Place is 20 metres (65ft.), the cornice of the Maison du Roi being 19 metres (62ft.) above the ground line, and that of the Hôtel de Ville 22 metres (72ft.), so that all the *façades* are illuminated. Moreover, a small slit in each reflector will permit of throwing a pencil of rays over the spire of the Hôtel de Ville, which will therefore be lighted up on three sides. The temporary masts at present erected turn on a pivot at the base for lowering; but the permanent supports will be like the Venetian masts, with large and ornamented bases, which produce so fine an effect in the Piazza San Marco, Venice. The electric current is led from the Maison du Roi to each of the masts by underground conductors, consisting of a single copper wire 5 millimetres (⅕in.) in diameter (about 20 square millimetres sectional area), covered with an insulating substance, then a lead casing, and over that an asphalte coating. The leads which conduct the electricity to the lamps consist of fourteen copper wires of

* Where are situated the fine old Gothic Hôtel de Ville and the ancient houses of the various trade corporations.

Digitized by Google

1½ millimetre diameter; they are laid in a groove made in the masts.

If the lighting should be continued permanently it is intended to double the generating power, and appropriate the new machines to illuminating the Hotel de Ville with incandescent lamps. The installation has been made by the Compagnie Générale d'Electricité, under the direction of M. Wybauw, the city engineer.—*Bulletin de la Société Belge d'Electriciens.*

TREES AND LIGHTNING.

Mr. Francis George Heath writes in the *Daily News* from Underwood, Kew Gardens, under date August 21st:—

"I doubt whether even the cholera intelligence (seeing that the scourge is at present abroad) of to-day's paper will have so much attraction for your readers generally as the able and interesting article you publish on thunderstorms and the dangers of lightning. The great human interest in these atmospheric fireworks centres around the curious attraction which the animal body has for lightning; and I was therefore surprised to read of the remarkable suggestion which you quote of the Swiss electrician, that metal rods should be fastened to the trunks of trees at their bases to divert the lightning from the killing of human beings who might be taking shelter under them, for it is well known that the fluids of an animal body are much better conductors of the electric fluid than any metals. A very striking illustration of this fact was given in the death of Mr. Crosse, the famous electrician, who lived near Taunton. Mr. Crosse had a gigantic electrical apparatus and an enormous Leyden jar set up in his house, and he was wont to tap the clouds by means of long conductors. One day, during a terrific thunderstorm which was passing over his house, he became so deeply absorbed in the great sparks which were going 'click, click,' into the metal knob of his jar, that he approached a little too close to it. Instantly a flash entered his forehead, ran through his body, and burst out through the non-conducting leather of his boot, not only killing him immediately, but hurling his body across the room. We must therefore be content, I think, to trust for the protection of foolish people who might wish to resort to trees for shelter in thunderstorms to the oft-repeated warnings on this subject. But the protection of dwellings is another and very important phase of this subject, for the destruction of a dwelling house may mean the destruction of the whole of its occupants, and if we can make the dwelling safe, then we establish at once an important asylum. At the worst, people in the open country can make themselves perfectly safe by lying flat on the ground well away from any prominent perpendicular conductor, such as metal or wood. Respecting the protection of dwellings, then, I should like to make widely known a suggestion for their protection of an altogether pleasant and inexpensive kind. It is the fact that poplars in general, and especially Lombardy poplars, have been proved to be the best tree conductors of electricity. Lombardy poplars are the best, because with the poplar affinity for lightning, they have tall, pointed, narrow forms and a remarkable uprightness of growth, together with an abundance of small but closely set spray. So soon as the tree has risen beyond the woodwork of the roof, if kept, say not less than twelve feet from the wall of the building, a most perfect conductor will have been established; and if several Lombardy poplars are planted around a house, but away from the paths, so much the better. I have never seen an explanation offered of the reason why poplars are such good conductors of electricity—for mark that when other trees are destroyed the Lombardy poplars will harmlessly take the lightning discharge—but I am of opinion that the extreme moistness of these trees is the reason, combined with the abundance and with the peculiar arrangement of the moist branches. There is no doubt, I think, that lightning when striking a tree does not strike it with one direct and isolated flash, but that the body of the fluid is instantly divided at the moment of striking into almost as many parts as there are branches to receive it. In such trees as the oak and the elm, where in the lower parts there are first the trunk and then large limbs without any covering of twigs or smaller branches, the electric fluid, separated at first by the most topmost twigs, rushes downwards to the channels formed by the drier limbs and trunk. Forced suddenly and accumulated into these confined and congenial passages there is not room for the easy course of the discharge, and disruption ensues. In proof of this theory, it will be remembered that the whole head of a tree is not infrequently broken off by lightning just where the trunk joins the limbs—at the fork—and the trunk and larger limbs always are the sufferers. Now, it will be noticed that the ramification of the Lombardy poplar is, if untouched by the meddling gardener, very peculiar. From base to top the trunk is surrounded by closely-set, densely-clothed branches, or rather branches and twigs, which point upwards. Hence the action of this tree upon a lightning cloud might be likened to that of a sponge. It breaks the force of a discharge by absorbing the fluid, so to speak, at a thousand points, all of which, from their extreme moistness, are excellent conductors. But care must be taken not to plant a Lombardy poplar on one side of a house when there is a pond, a marsh, a stream, or any collection of water immediately on the other side. In such a case a lightning flash might diverge from the tree midway and go through the house to the more attractive water pure and simple; but a pond at the foot of the tree would be an advantage; it would furnish a point of attraction for the electric fluid, and it would make the tree flourish."

THE BRITISH ASSOCIATION MEETING AT MONTREAL.

Section A (Mathematics and Physics) was opened at 11 a.m. on Thursday, Aug. 28, when the President, Sir William Thomson, read the following address:—

The now well-known kinetic theory of gases is a step so important in the way of explaining seemingly static properties of matter by motion, that it is scarcely possible to help anticipating in idea the arrival at a complete theory of matter, in which all its properties will be seen to be merely attributes of motion. If we are to look for the origin of this idea, we must go back to Democritus Epicurus and Lucretius. We may then, I believe, without missing a single step, skip 1,800 years. Early last century we find in Malabranche's "Recherche de la Verité" the statement that "la dureté des corps" depends on "petits tourbillons." These words, embedded in a hopeless mass of unintelligible statements of the physical, metaphysical, and theological philosophies of the day, and unsupported by any explanation, elucidation, or illustration throughout the rest of the three volumes, and only marred by one other single sentence or word to be found in the great book, still do express a distinct conception which forms a most remarkable step towards the kinetic theory of matter. A little later we have Daniel Bernoulli's promulgation of what we now accept as a surest article of scientific faith—the kinetic theory of gases. He, so far as I know, thought only of Boyle's and Marriott's law of the "spring of air," as Boyle called it, without reference to change of temperature or the augmentation of its pressure if not allowed to expand for elevation of temperature, a phenomenon which perhaps he scarcely knew, still less the elevation of temperature produced by compression and the lowering of temperature by dilatation, and the consequent necessity of waiting for a fraction of a second or a few seconds of time (with apparatus of ordinary experimental magnitude), to see a subsidence from a larger change of pressure down to the amount of change that verifies Boyle's law. The consideration of these phenomena 40 years ago by Joule, in connection with Bernoulli's original conception, formed the foundation of the kinetic theory of gases as we now have it. But what a splendid and useful building has been placed on this foundation by Clausius and Maxwell, and what a beautiful ornament we see on the top of it in the radiometer of Crookes, securely attached to it by the happy discovery of Tait and Dewar that the length of the free path of the residual molecules of air in a good modern vacuum may amount to several inches. Clausius' and Maxwell's explanations of the diffusion of gases and thermal conduction in gases, their charmingly intelligible conclusion that in gases the diffusion of heat is just a little more rapid than the diffusion of molecules, because of the interchange of energy in collisions between molecules, while the chief transference of heat is by actual transport of the molecules themselves; and Maxwell's explanation of the viscosity of gases, with the absolute numerical relations which the work of those two great discoverers found among the three properties of diffusion, thermal conduction, and viscosity, have annexed to the domain of science a vast and ever-growing province. Rich as it is in practical results, the kinetic theory of gases as hitherto developed stops absolutely short at the atom or molecule, and gives not even a suggestion towards explaining the properties in virtue of which the atoms or molecules mutually influence one another. For some guidance towards a deeper and more comprehensive theory of matter we may look back with advantage to the end of last century and the beginning of this century, and find Rumford's conclusion regarding the heat generated in boring a brass gun:—"It appears to me to be extremely difficult, if not quite impossible, to form any distinct idea of anything capable of being excited and communicated in the manner the heat was excited and communicated in these experiments, except it be motion;" and Davy's still more suggestive statement, "The phenomena of repulsion are not dependent on a peculiar elastic fluid for their existence. . . ." "Heat may be defined a peculiar motion, probably a vibration, of the corpuscles of bodies, tending to separate them. . . ." "To distinguish this motion from others, and to signify the causes of our sensations of heat, &c., the name 'repulsive' motion has been adopted." Here we have a most important idea. It would be somewhat a bold figure of speech to say the earth and moon are kept apart by a repulsive motion; and yet, after all, what is centrifugal force but a repulsive motion, and may it not be that there is no such thing as repulsion; and that it is solely by inertia that what seems to be repulsion is produced? Two bodies fly together, and, accelerated by mutual attraction, if they do not precisely hit one another, they cannot but separate in virtue of the inertia of their masses. So, after dashing past one another in sharply concave curves round their common centre of gravity, they fly asunder again. A careless onlooker might imagine they had repelled one another, and might not notice the difference between what he actually sees and what he would see if the two bodies had been projected with great velocity towards one another, and either colliding and rebounding, or repelling one another into sharply convex continuous curves, fly asunder again. Joule, Clausius, and Maxwell, and no doubt Daniel Bernoulli himself, and I believe everyone who has hitherto written or done anything very explicit in the kinetic theory of gases, has taken the mutual action of molecules in collision as repulsive. May it not after all be attractive? This idea has never left my mind since I first read Davy's "Repulsive Motion" about thirty-five years ago; but I never made anything of it, at all events have not done so until to-day (June 16, 1884), if

Digitized by Google

this can be said to be making anything of it, when in endeavouring to prepare the present address I notice that Joule's and my own old experiments on the thermal effect of gases expanding from a high pressure vessel through a porous plug, prove the less dense gas to have greater intrinsic potential energy than the denser gas, if we assume the ordinary hypothesis regarding the temperature of a gas, according to which two gases are of equal temperatures when the kinetic energies of their constituent molecules are of equal average amounts per molecule. Think of the thing thus. Imagine a great multitude of particles enclosed by a boundary which may be pushed inwards in any part all round at pleasure. Now station an engineer corps of Maxwell's army of sorting demons all round the enclosure, with orders to push in the boundary diligently everywhere when none of the besieged troops are near, and to do nothing when any of them are seen approaching, and until after they have turned again inwards. The result will be that, with exactly the same sum of kinetic and potential energies of the same enclosed multitude of particles, the throng has been caused to be denser. Now Joule's and my own old experiments on the efflux of air prove that if the crowd be common air, or oxygen, or nitrogen, or carbonic acid, the temperature is a little higher in the denser than in the rarer condition when the energies are the same. By the hypothesis, equality of temperature between two different gases or two portions of the same gas at different densities, means equality of kinetic energies in the same number of molecules of the two. From our observations proving the temperature to be higher it therefore follows that the potential energy is smaller in the condensed crowd. This—always, however, under protest as to the temperature hypothesis—proves some degree of attraction among the molecules, but it does not prove ultimate attraction between two molecules in collision, or at distances much less than the average mutual distance of nearest neighbours in the multitude. The collisional force might be repulsive, as generally supposed hitherto, and yet attraction might predominate in the whole reckoning of difference between the intrinsic potential energies of the more dense and less dense multitudes. It is, however, remarkable that the explanation of the propagation of sound through gases, and even of the positive fluid pressure of a gas against the sides or the containing vessel, according to the kinetic theory of gases, is quite independent of the question whether the ultimate collisional force is attractive or repulsive. Of course it must be understood that if it is attractive the particles must be so small that they hardly ever meet—they would have to be infinitely small to never meet: that, in fact, they meet so seldom, in comparison with the number of times their courses are turned through large angles by attraction, that the influence of these purely attractive collisions is preponderant over that of the comparatively very rare impacts from actual contact. Thus, after all, the train of speculation suggested by Davy's "Repulsive Motion" does not allow us to escape from the idea of true repulsion, does not do more than let us say it is of no consequence, nor even say this with truth, because if there are impacts at all the nature of the force during the impact and the effects of the mutual impacts, however rare, cannot be evaded in any attempt to realise a conception of the kinetic theory of gases. And, in fact, unless we are satisfied to imagine the atoms of a gas as mathematical points endowed with inertia, and as, according to Boscovich, endowed with forces of mutual positive and negative attraction, varying according to some definite function of the distance, we cannot avoid the question of impacts, and of vibrations and rotations of the molecules resulting from impacts, and we must look distinctly on each molecule as being either a little elastic solid or a configuration of motion in a continuous all-pervading liquid. I do not myself see how we can ever permanently rest anywhere short of this last view; but it would be a very pleasant temporary resting-place on the way to it, if we could, as it were, make a mechanical model of a gas out of little pieces of round perfectly elastic solid matter flying about through the space occupied by the gas, and colliding with one another and against the sides of the containing vessel. This is, in fact, all we have of the kinetic theory of gases up to the present time, and this has done for us, in the hands of Clausius and Maxwell, the great things which constitute our first step towards a molecular theory of matter. Of course, from it we should have to go on to find an explanation of the elasticity and all the other properties of the molecules themselves, a subject vastly more complex and difficult than the gaseous properties, for the explanation of which we assume the elastic molecule; but without any explanation of the properties of the molecule itself, with merely the assumption that the molecule has the requisite properties, we might rest happy for a while in the contemplation of the kinetic theory of gases and its explanation of the gaseous properties, which is not only stupendously important as a step towards a more thorough-going theory of matter, but is undoubtedly the expression of a perfectly intelligible and definite set of facts in nature. But alas for our mechanical model consisting of the cloud of little elastic solids flying about among one another. Though each particle have absolutely perfect elasticity the end must be pretty much the same as if it were but imperfectly elastic. The average effect of repeated and repeated mutual collisions must be to gradually convert all the translational energy into energy of shriller and shriller vibrations of the molecule. It seems certain that each collision must have something more of energy in vibrations of very finely divided nodal parts than there was of energy of such vibrations before the impact. The more minute this nodal subdivision, the less must be the tendency to give up part of the vibrational energy into the shape of translational energy in the course of a collision, and I think it is rigorously demonstrable that the whole translational energy must ultimately become transformed into vibrational energy of higher and higher nodal subdivisions if each molecule is a continuous elastic solid. Let us, then, leave the kinetic theory of gases for a time with this difficulty unsolved, in the hope that we or others after us may return to it, armed with more knowledge of the properties of matter, and with sharper mathematical weapons to cut through the barrier which at present hides from us any view of the molecule itself, and of the effects other than mere change of translational motion which it experiences in collision. To explain the elasticity of a gas was the primary object of the kinetic theory of gases. This object is only attainable by the assumption of an elasticity more complex in character, and more difficult of explanation, than the elasticity of gases—the elasticity of a solid. Thus, even if the fatal fault in the theory to which I have alluded did not exist, and if we could be perfectly satisfied with the kinetic theory of gases founded on the collisions of elastic solid molecules, there would still be beyond it a grander theory—which need not be considered a chimerical object of scientific ambition—to explain the elasticity of solids. But we may be stopped when we commence to look in the direction of such a theory with the cynical question, What do you mean by explaining a property of matter? As to being stopped by any such question, all I can say is that if engineering were to be all and to end all physical science, we should perforce be content with merely finding properties of matter by observation, and using them for practical purposes. But I am sure very few, if any, engineers are practically satisfied with so narrow a view of their noble profession. They must and do patiently observe, and discover by observation, properties of matter, and results of material combinations. But deeper questions are always present, and always fraught with interest to the true engineer, and he will be the last to give weight to any other objection to any attempt to see below the surface of things than the practical question, Is it likely to prove wholly futile? But now, instead of imagining the question, What do you mean by explaining a property of matter? to be put cynically, and letting ourselves be irritated by it, suppose we give to the questioner credit for being sympathetic, and condescend to try and answer his question. We find it not very easy to do so. All the properties of matter are so connected that we can scarcely imagine one thoroughly explained without our seeing its relation to all the others, without, in fact, having the explanation of all, and till we have this we cannot tell what we mean by "explaining a property," or "explaining the properties" of matter. But though this consummation may never be reached by man, the progress of science may be—I believe will be—step by step towards it, on many different roads converging towards it from all sides. The kinetic theory of gases is, as I have said, a true step on one of the roads. On the very distinct road of chemical science, St. Clair Deville arrived at his grand theory of dissociation without the slightest aid from the kinetic theory of gases. The fact that he worked it out solely from chemical observation and experiment and expounded it to the world without any hypothesis whatever, and seemingly even without consciousness of the beautiful explanation it has in the kinetic theory of gases, secured for it immediately an independent solidity and importance as a chemical theory when he first promulgated it, to which it might even by this time scarcely have attained if it had first been suggested as a probability indicated by the kinetic theory of gases, and been only afterwards confirmed by observation. Now, however, guided by the views which Clausius and Williamson have given us of the continuous interchange of partners between the compound molecules constituting chemical compounds in the gaseous state, we see in Deville's theory of dissociation a point of contact of the most transcendent interest between the chemical and physical lines of scientific progress. To return to elasticity. If we could make out of matter devoid of elasticity a combined system of relatively moving parts, which, in virtue of motion, has the essential characteristics of an elastic body, this would surely be, if not positively a step in the kinetic theory of matter, at least a finger post pointing a way which we may hope will lead to a kinetic theory of matter. Now this, as I have already shown, we can do in several ways. In the case of the last of the communications referred to, of which only the title has hitherto been published, I showed that, from the mathematical investigation of a gyrostatically dominated combination contained in the passage of Thomson and Tait's "Natural Philosophy," referred to, it follows that any ideal system of material particles, acting on one another mutually through massless connecting springs, may be perfectly imitated in a model consisting of rigid links jointed together, and having rapidly rotating fly-wheels pivoted on some or on all of the links. The imitation is not confined to cases of equilibrium. It holds also for vibration produced by disturbing the system infinitesimally from a position of stable equilibrium and leaving it to itself. Thus we may make a gyrostatic system such that it is in equilibrium under the influence of certain positive forces applied to different points of this system; all the forces being precisely the same as, and the points of application similarly situated to, those of the stable system with springs. Then, provided proper masses (that is to say, proper amounts and distributions of inertia) be attributed to the links, we may remove the external forces from each system, and the consequent vibration of the points of application of the forces will be indentical. Or we may act upon the systems of material points and springs with any given forces for any given time, and leave it to itself, and do the same thing for the gyrostatic system; the consequent motion will be the same in the two cases. If in the one case the springs are made more and more stiff, and in the other case the angular velocities of the fly-wheels are made greater and greater, the periods of the vibrational constituents of the motion will become shorter and shorter, and the amplitudes smaller and smaller, and the motions will approach more and more nearly those of two perfectly rigid groups of material points, moving through space and rotating according to the well known mode of rotation of a rigid body having unequal moments of inertia about its three principal axes. In one case the ideal nearly rigid connections between the particles is produced by massless exceedingly stiff springs; in the other case it is produced by the exceedingly rapid rotation of the fly-wheels in a system which, when the fly-wheels are deprived of their rotation, is perfectly limp. The drawings (Figs. 1 and 2) before you illustrate two such material systems. In Fig. 1 the two hooked rods seen projecting from the sphere are connected by an elastic coach spring. In Fig. 2 the hooked rods are con

nected one to each of two opposite corners of a four-sided jointed frame, each member of which carries a gyrostat, so that the axis of rotation of the fly-wheel is in the axis of the member of the frame which bears it. Each of the hooked rods in Fig. 2 is connected to the framework through a swivel joint, so that the whole gyrostatic framework may be rotated about the axis of the hooked rods in order to annul the moment of momentum of the framework about this axis due to rotation of the fly-wheels in the gyrostats. The directions of rotation of the fly-wheels in the gyrostatic system (Fig. 2) are indicated by directional ellipses, which show in perspective the direction of rotation of the fly-wheel of each gyrostat. The gyrostatic system (Fig. 2) might have been constituted of two gyrostatic members, but four are shown for symmetry. The enclosing circle represents in each case in section an enclosing spherical shell to prevent the interior from being seen. In the inside of one there are fly-wheels, in the inside of the other a massless spring. The projecting hooked rods seem as if they are connected by a spring in each case. If we hang any one of the systems up by the hook on one of its projecting rods, and hang a weight to the hook of the other projecting rod, the weight when first put on will oscillate up and down, and will go on doing so for ever if the system be absolutely unfrictional. If we check the vibration by hand, the weight will hang down at rest, the pin drawn out to a certain degree; and the distance drawn out will be simply proportional to the weight hung on, as in an ordinary spring balance. Here, then, out of matter possessing rigidity, but absolutely devoid of elasticity, we have made a perfect model of a spring in the form of a spring-balance. Connect millions of millions of particles by pairs of rods such as these of this spring balance, and we have a group of particles constituting an elastic solid, exactly fulfilling the mathematical ideal worked out by Navier, Poisson, and Cauchy, and many other mathematicians who, following their example, have endeavoured to found a theory of the elasticity of solids on mutual attraction and repulsion between a group of material particles. All that can possibly be done by this theory, with its assumption of forces acting according to any assumed law of relation to distance, is done by the gyrostatic system. But the gyrostatic system does, besides, what the system of naturally acting material particles cannot do, it constitutes an elastic solid which

FIG. 1

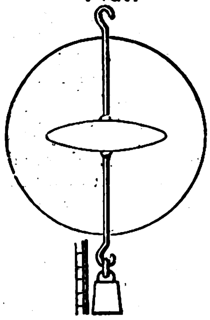

FIG. 2

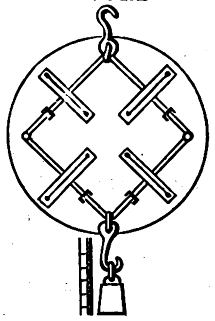

can have the Faraday magneto-optic rotation of the plane of polarisation of light, supposing the application of our solid to be a model of the luminiferous ether for illustrating the undulatory theory of light. The gyrostatic model spring-balance is arranged to have zero moment of momentum as a whole, and therefore to contribute nothing to the Faraday rotation; with this arrangement the model illustrates the luminiferous ether in a field unaffected by magnetic force. But now let there be a different rotational velocity imparted to the jointed square round the axis of the two projecting hooked rods, such as to give a resultant moment of momentum round any given line through the centre of inertia of the system, and let pairs of the hooked rods in the model thus altered, which is no longer a model of a mere spring-balance, be applied as connections between millions of pairs of particles as before—with the lines of resultant moment of momentum all similarly directed. We now have a model elastic solid which will have the property that the direction of vibration in waves of rectilinear vibrations propagated through it shall turn round the line of propagation of the waves; just as Faraday's observation proves to be done by the line of vibration of light in a dense medium between the poles of a powerful magnet. The case of wave front perpendicular to the lines of resultant moment of momentum (that is to say, the direction of propagation being parallel to these lines) corresponds, in our mechanical model, to the case of light travelling in the direction of the lines of force in a magnetic field. In these illustrations and models we have different portions of ideal rigid matter acting upon one another, by normal pressure at mathematical points of contact—of course, no forces of friction are supposed. It is exceedingly interesting to see how thus, with no other postulates than inertia, rigidity, and mutual impenetrability, we can thoroughly model not only an elastic solid, and any combination of elastic solids, but so complex and recondite a phenomenon as the passage of polarised light through a magnetic field. But now, with the view of ultimately discarding the postulate of rigidity from all our materials, let us suppose some to be absolutely destitute of rigidity, and to possess merely inertia and incompressibility, and mutual impenetrability with reference to the still remaining rigid matter. With these postulates we can produce a perfect model of mutual action at a distance between solid particles, fulfilling the condition, so keenly desired by Newton and Faraday, of being explained by continuous action through an intervening medium. The law of the mutual force in our model, however, is not the simple Newtonian law, but the much more complex law of the mutual action between two electro-magnets—with this difference, that in the hydro-kinetic model in every case the force is opposite in direction to the corresponding force in the electro-magnetic analogue. Imagine a solid bored through with a hole and placed in our ideal perfect liquid. For a moment let the hole be stopped by a diaphragm, and let an impulsive pressure be applied for an instant uniformly over the whole membrane, and then instantly let the membrane be dissolved into liquid. This action originates a motion of the liquid relatively to the solid, of a kind to which I have given the name of "irrotational circulation," which remains absolutely constant however the solid be moved through the liquid. Thus, at any time the actual motion of the liquid at any point in the neighbourhood of the solid will be the resultant of the motion it would have in virtue of the circulation alone were the solid at rest, and the motion it would have in virtue of the motion of the solid itself had there been no circulation established through the aperture. It is interesting and important to remark in passing that the whole kinetic energy of the liquid is the sum of the kinetic energies which it would have in the two cases separately. Now, imagine the whole liquid to be enclosed in an infinitely large rigid containing vessel, and in the liquid, at an infinite distance from any part of the containing vessel, let two perforated solids, with irrotational circulation through each, be placed at rest near one another. The resultant fluid motion due to the two circulations will give rise to fluid pressure on the two bodies, which if unbalanced will cause them to move. The force systems—force-and-torques, or pairs of forces—required to prevent them from moving will be mutual and opposite, and will be the same as, but opposite in direction to, the mutual force systems required to hold at rest two electro-magnets fulfilling the following specification. The two electro-magnets are to be of the same shape and size as the two bodies, and to be placed in the same relative positions, and to consist of infinitely thin layers of electric currents in the surfaces of solids possessing extreme diamagnetic quality—in other words, infinitely small permeability. The distribution of electric current on each body may be any whatever which fulfils the condition that the total current across any closed line drawn on the surface once through the aperture is equal to $\frac{1}{4\pi}$ of the circulation through the aperture in the hydro-kinetic analogue. It might be imagined that the action at a distance thus provided for by fluid motion could serve as a foundation for a theory of the equilibrium and the vibrations of elastic solids, and the transmission of waves like those of light through an extended *quasi*-elastic solid medium. But, unfortunately for this idea, the equilibrium is essentially unstable, both in the case of magnets and, notwithstanding the fact that the forces are oppositely directed, in the hydro-kinetic analogue also, when the several movable bodies (two or any greater number) are so placed relatively as to be in equilibrium. If, however, we connect the perforated bodies with circulation through them in the hydro-kinetic system by jointed rigid connecting links we may arrange for configurations of stable equilibrium. Thus without fly-wheels, but with fluid circulations through apertures, we may make a model spring-balance, or a model luminiferous ether, either without or with the rotational quality corresponding to that of the true luminiferous ether in the magnetic fluid—in short, do all by the perforated solids with circulations through them that we saw we could do by means of linked gyrostats. But something that we cannot do by linked gyrostats we can do by the perforated bodies with fluid circulation. We can make a model gas. The mutual action at a distance, repulsive or attractive according to the mutual aspect of the two bodies when passing within collisional distance of one another, suffices to produce the change of direction of motion in collision which essentially constitutes the foundation of the kinetic theory of gases; and which, as we have seen before, may as well be due to attraction as to repulsion, so far as we know from any investigation hitherto made in this theory. There remains, however, as we have seen before, the difficulty of providing for the case of actual impacts between the solids, which must be done by giving them massless spring buffers, or, which amounts to the same thing, attributing to them repulsive forces sufficiently powerful at very short distances to absolutely prevent impacts between solid and solid, unless we adopt the equally repugnant idea of infinitely small perforated solids with infinitely great fluid circulations through them. Were it not for this fundamental difficulty the hydro-kinetic model gas would be exceedingly interesting; and, though we could scarcely adopt it as conceivably a true representation of what gases really are, it might still have some importance as a model configuration of solid and liquid matter, by which without elasticity the elasticity of a true gas might be represented. But, lastly, since the hydro-kinetic model gas with perforated solids and fluid circulations through them fails because of the impacts between the solids, let us annul the solids and leave the liquid performing irrotational circulation round vacancy, in the place of the solid cores which we have hitherto supposed; or let us annul the rigidity of the solid cores of the rings and give them molecular rotation according to Helmholtz's theory of vortex motion. For stability the molecular rotation must be such as to give the same velocity at the boundary of the rotational fluid core as that of the irrotationally circulating liquid in contact with it, because, as I have proved, frictional slip between two portions of liquid in contact is inconsistent with stability. There is a further condition upon which I cannot enter in detail just now, but which may be understood in a general way when I say that it is a condition of either uniform or of increasing molecular rotation from the surface inwards analogous to the condition that the density of a liquid, resting for example under the influence of gravity, must either be uniform or must be greater below than above for stability of equilibrium. All that I have said in favour of the model vortex gas composed of perforated solids with fluid circulations through them holds without modification for the purely hydro-kinetic model composed of either Helmholtz cored vortex rings or of coreless vortices, and we are now troubled

Digitized by Google

with no such difficulty as that of the impacts between solids. Whether, however, when the vortex theory of gases is thoroughly worked out it will or will not be found to fail in a manner analogous to the failure which I have already pointed out in connection with the kinetic theory of gases composed of little elastic solid molecules, I cannot at present undertake to speak with certainty. It seems to me most probable that the vortex theory cannot fail in any such way, because all I have been able to find out hitherto regarding the vibration of vortices, whether cored or coreless, does not seem to imply the liability of translational or impulsive energies of the individual vortices becoming lost in energy of smaller and smaller vibrations. As a step towards kinetic theory of matter it is certainly most interesting to remark that in the quasi-elasticity—elasticity looking like that of an india rubber band which we see in a vibrating smoke-ring launched from an elliptic aperture, or in two smoke-rings which were circular, but which have become deformed from circularity by mutual collision, we have in reality a virtual elasticity in matter devoid of elasticity, and even devoid of rigidity, the virtual elasticity being due to motion and generated by the generation of motion.

Section B (Chemistry) met at noon on Thursday, when Professor Sir Henry Roscoe read the presidential address, which was as follows :—

With the death of Berzelius in 1848 ended a well-marked epoch in the history of our science ; with that of Dumas—and, alas ! that of Wurtz also—in 1884 closes a second. It may not perhaps be unprofitable on the present occasion to glance at some few points in the general progress which chemistry has made during this period, and thus to contrast the position of the science in the "Sturm und Drang" year of 1848 with that in the present perhaps quieter period. The differences between what may properly be termed the Berzelian era and that with which the name of Dumas will for ever be associated show themselves in many ways, but in none more markedly than by the distinct views entertained as to the nature of a chemical compound. According to the older notions the properties of compounds are essentially governed by the qualitative nature of their constituent atoms, which were supposed to be so arranged as to form a binary system. Under the new ideas, on the other hand, it is mainly the number and arrangement of the atoms within the molecule, which regulate the characteristics of the compound, which is to be looked on not as built up of two constituent groups of atoms, but as forming one group. Among those who successfully worked to secure this important change of view on a fundamental question of chemical theory the name of Dumas himself must first be mentioned, and, following upon him, the great chemical twin-brethren, Laurent and Gerhardt, who, using both the arguments of test-tube and of pen in opposition to the prevailing views, gradually succeeded, though scarcely during the lifetime of the first, in convincing chemists that the condition of things could hardly be a healthy one when chemistry was truly defined "as the science of bodies which do not exist." For Berzelius, adhering to his preconceived notions, had been forced by the pressure of new discovery into the adoption of formulæ which gradually became more and more complicated, and led to more and more doubtful hypotheses, until his followers at last could barely succeed in building up the original radical from its numerous supposed component parts. Such a state of things naturally brought about its own cure, and the unitary formulæ of Gerhardt began to be generally adopted. There is another change of view, dating from the commencement of the Dumas epoch, which has exerted an influence equal, if not superior, to those already named on the progress of our science. The relative weights of the ultimate particles, to use Dalton's own words, which up to this time had been generally adopted by chemists, were the equivalent weights of Dalton and Wollaston, representing, in the case of oxygen and hydrogen, the proportions in which these elements combine, viz., as 8 to 1. The great Swedish chemist at this time stood almost alone in supporting another hypothesis ; for, founding his argument on the simple laws of volume-combination enunciated by Gay-Lussac, he asserted that the true atomic weights are to be represented by the relations existing between equal volumes of the two gases, viz., as 16 to 1. Still these views found no favour in the eyes of chemists until Gerhardt, in 1843, proposed to double the equivalent weights of oxygen, sulphur, and carbon, and then the opposition which this suggestion met with was most intense, Berzelius himself not even deigning to mention it in his annual account of the progress of the science, thus proving the truth of his own words : "That to hold an opinion habitually often leads to such an absolute conviction of its truth that its weak points are unregarded, and all proofs against it ignored." Nor were these views generally adopted by chemists until Cannizaro, in 1858, placed the whole subject on its present firm basis by clearly distinguishing between equivalent and molecular weights, showing how the atomic weights of the constituent elements are derived from the molecular weights of their volatile compounds based upon the law of Avogadro and Ampère, or where, as is the case with many metals, no compounds of known vapour-density exist, how the same result may be ascertained by the help of the specific heat of the element itself. Remarkable as it may appear, it is, nevertheless, true that it is in the country of their birth that Gerhardt's atomic weights and the consequent atomic nomenclature have met with most opposition, so much so that within a year or two of the present time there was not a single course of lectures delivered in Paris in which these were used. At the Edinburgh meeting of this Association in 1850, Williamson read a paper on "Results of a Research on Ætherification," which included not only a satisfactory solution of an interesting and hitherto unexplained problem, but was destined to exert a most important influence on the development of our theoretical views. For he proved, contrary to the then prevailing ideas, that ether contains twice as much carbon as alcohol, and that it is not formed from the latter by a mere separation of the elements of water, but by an exchange of hydrogen for ethyl, and this fact being in accordance with Avogadro's law of molecular volumes, could only be represented by regarding the molecule of water as containing two atoms of hydrogen to one of oxygen, one of the former being replaced by one of ethyl to form alcohol, and the two of hydrogen by two of ethyl to form ether. Then Williamson introduced the type of water (subsequently adopted by Gerhardt) into organic chemistry, and extended our views of the analogies between alcohols and acids, by pointing out that these latter are also referable to the water-type, predicting that bodies bearing the same relations to the ordinary acids as the ethers do to the alcohols must exist, a prediction shortly afterwards (1852) verified by Gerhardt's discovery of the anhydrides. Other results followed in rapid succession, all tending to knit together the framework of modern theoretical chemistry. Again, in 1852, we note the first germs of a theory which was destined to play an all-important part in the progress of the science, viz., the doctrine of valency or atomicity, and to Frankland it is that we owe this new departure. Singularly enough, while considering the symmetry of construction visible among the inorganic compounds of nitrogen, phosphorus, arsenic, and antimony, and while putting forward the fact that the combining power of the attracting element is always satisfied by the same number of atoms, he does not point out the characteristic tetrad nature of carbon ; and it was not until 1858 that Couper initiated, and Kekulé in the same year thoroughly established, the doctrine of the linking of the tetrad carbon atoms, a doctrine to which, more than to any other, is due the extraordinary progress which organic chemistry has made during the last 20 years, a progress so vast that it is already found impossible for one individual, even though he devote his whole time and energies to the task, to master all the details, or make himself at home with the increasing mass of new facts which the busy workers in this field are daily bringing forth. The subject of the valency of the elements is one which, since the year above referred to, has given chemists much food for discussion, as well as opportunity for experimental work. But whether we range ourselves with Kekulé, who supports the unalterable character of the valency of each element, or with Frankland, who insists on its variability, it is now clear to most chemists that the hard and fast lines upon which this theory was supposed to stand cannot be held to be secure. For if the progress of investigation has shown that it is impossible in many instances to affix one valency to an element which forms a large number of different compounds, it is also equally impossible to look on the opposite view as tending towards progress, inasmuch as to ascribe to an element as many valencies as it possesses compounds with some other element, is only expressing by circuitous methods what the old Daltonian law of combination in multiple proportions states in simple terms. But, however many doubts have been raised in special instances against a thorough application of the law of valency, it cannot be denied that the general relations of the elements which this question of valency has been the means of bringing to light are of the highest importance, and point to the existence of laws of nature of the widest significance ; I allude to the periodic law of the elements first foreshadowed by Newlands, but fully developed by Mendelejeff and Lothar Meyer. Guided by the principle that the chemical properties of the elements are a periodic function of their atomic weights, or that matter becomes endowed with analogous properties when the atomic weight of an element is increased by the same or nearly the same number, we find ourselves for the first time in possession of a key which enables us to arrange the hitherto *disjecta membra* of our chemical household in something like order, and thus gives us means of indicating the family resemblances by which these elements are characterised. And here we may congratulate ourselves on the fact that, by the recent experiments of Brauner, and of Nilson and Petterson respectively, tellurium and beryllium, two of the hitherto outstanding members, have been induced to join the ranks, so that at the present time osmium is the only important defaulter among the 64 elements, and few persons will doubt that a little careful attention to this case will remove the stigma which yet attaches to its name. But this periodic law makes it possible for us to do more ; for as the astronomer, by the perturbations of known planets, can predict the existence of hitherto unknown ones, so the chemist, though, of course, with much less satisfactory means, has been able to predict with precision the properties, physical and chemical, of certain missing links among the elements, such as ekaluminium and ekaboron, then unborn, but which shortly afterwards became well known to us in the flesh as gallium and scandium. We must, however, take care that success in a few cases does not blind us to the fact that the law of nature which expresses the relation between the properties of the elements and the value of the atomic weights is as yet unknown ; that many of the groupings are not due to any well ascertained analogy of properties of the elements, and that it is only because the values of their atomic weights exhibit certain regularities that such a grouping is rendered possible. Passing from this subject, we arrive, by a process of natural selection, at more complicated cases of chemical orientation—that is, given certain compounds which possess the same composition and molecular formulæ but varying properties, to find the difference in molecular structure by which such variation of properties is determined. Problems of this nature can now be satisfactorily solved, the number of possible isomers foretold, and this prediction confirmed by experiment. The general method adopted in such an experimental inquiry into the molecular arrangement or chemical constitution of a given compound is either to build up the structure from less complicated ones of known constitution, or to resolve it into such component parts. The discovery of the aniline colours by Perkin, their elaboration by Hoffmann, the synthesis of alizarin by Graebe and Liebermann, being the first vegetable colouring matter which has been artificially obtained, the artificial production of indigo by Baeyer, and lastly the preparation by Fischer, of kairine, a febrifuge as potent as quinine, are some of the well-known recent triumphs of modern synthetical chemistry. And these

Digitized by Google

triumphs, let us remember, have not been obtained by any such "random haphazarding" as yielded results in Priestley's time. In the virgin soil of a century ago, the ground only required to be scratched and the seed thrown in to yield a fruitful crop; now the surface soil has long been exhausted, and the successful cultivator can only obtain results by a deep and thorough preparation, and by a systematic and scientific treatment of his material. In no department of our science has the progress made been more important than in that concerned with the accurate determination of the numerical, physical, and chemical constants upon the exactitude of which every quantitative chemical operation depends. For the foundation of an accurate knowledge of the first of these constants—viz., the atomic weights of the elements, science is indebted to the indefatigable labours of Berzelius. But *humanum est errare*, and even Berzelius's accurate hand and delicate conscientiousness did not preserve him from mistakes, since corrected by other workers. In such determinations it is difficult, if not impossible, always to ascertain the limits of error attaching to the number. The errors may be due, in the first place, to manipulative faults; in the second, to inaccuracy of the methods; or, lastly, to mistaken views as to the composition of the material operated upon; and hence the uniformity of any series of similar determinations gives no guarantee of their truth, the only safe guide being the agreement of determinations made by altogether different methods. The work commenced by Berzelius has been worthily continued by many chemists. Since the date of Berzelius's death to the present day no discovery in our science has been so far-reaching, or led to such unforeseen and remarkable conclusions, as the foundation of spectrum analysis by Bunsen and Kirchoff in 1860. Independently altogether of the knowledge which has been gained concerning the distribution of the elementary bodies in terrestrial matter, and of the discovery of half-a-dozen new elements by its means, and putting aside for a moment the revelation of a chemistry not bounded by this world, but limitless as the heavens, we find that over and above all these results spectrum analysis offers the means, not otherwise open to us, of obtaining knowledge concerning the atomic and molecular condition of matter. Let me recall some of the more remarkable conclusions to which the researches of Lockyer, Schuster, Liveing and Dewar, Wülner and others in this direction have led. In the first place it is well to bear in mind that a difference of a very marked kind, first distinctly pointed out by Alex. Mitscherlich, is to be observed between the spectrum of an element and that of its compounds, the latter only being seen in cases in which the compound is not dissociated at temperatures necessary to give rise to a glowing gas. Secondly, that these compound spectra—as, for instance, those of the halogen compounds of the alkaline-earth metals—exhibit a certain family likeness, and show signs of systematic variation in the position of the lines, corresponding to changes in the molecular weight of the vibrating system. Still this important subject of the relation of the spectra of different elements is far from being placed on a satisfactory basis, and in spite of the researches of Lecoq de Boisbaudran, Ditte, Troost and Hautefeuille, Ciamician and others, it cannot be said that as yet definite proof has been given in support of the theory that a casual connection is to be found between the emission spectra of the several elements belonging to allied groups and their atomic weights or other chemical or physical properties. In certain of the single elements, however, the connection between the spectra and the molecular constitution can be traced. In the case of sulphur, for example, three distinct spectra are known. The first of these, a continuous one, is exhibited at temperatures below 500deg., when, as we know from Dumas' experiments, the density of the vapour is three times the normal, showing that at this temperature the molecule consists of six atoms. The second spectrum is seen when the temperature is raised to above 1,000deg., when, as Deville and Troost have shown, the vapour reaches its normal density, and the molecule of sulphur, as with most other gases, contains two atoms, and this is a band spectrum, or one characterised by channelled spaces. Together with this band spectrum, and especially round the negative pole, a spectrum of bright lines is observed. This latter is doubtless due to the vibrations of the single atoms of the dissociated molecule, the existence of traces of a band spectrum demonstrating the fact that in some parts of the discharge the tension of dissociation is insufficient to prevent the reunion of the atoms to form the molecule. To this instance of the light thrown on molecular relations by changes in the spectra others may be added. Thus the low-temperature spectrum of channelled spaces, mapped by Schuster and myself, in the case of potassium, corresponds to the molecule of two atoms and to the vapour-density of seventy-nine, as observed by Dewar and Dittmar. Again, both oxygen and nitrogen exhibit two, if not three, distinct spectra; of these the line spectrum seen at the highest temperatures corresponds to the atom; the band spectrum seen at intermediate temperatures represents the molecule of two atoms; while that observed at a still lower point would, as in the case of sulphur, indicate the existence of a more complicated molecule, known to us in one instance as ozone. That this explanation of the cause of these different spectra of an element is the true one can be verified in a remarkable way. Contrary to the general rule, among those elements which can readily be volatilised, and with which, therefore, low-temperature spectra can be studied, mercury exhibits but one spectrum, and that one of bright lines, or, according to the preceding theory, a spectrum of atoms. So that, judging from spectroscopic evidence, we infer that the atoms of mercury do not unite to form a molecule, and we should predict that the vapour-density of mercury is only half its atomic weight. Such we know, from chemical evidence, is really the case, the molecule of mercury being identical in weight with its atom. The cases of cadmium and iodine require further elucidation. The molecule of gaseous cadmium, like that of mercury, consists of one atom; probably, therefore, the cadmium spectrum is also distinguished by one set of lines. Again, the molecule of iodine at 1,200deg. separates, as we know from Victor Meyer's researches, into single atoms. Here spectrum analysis may come again to our aid; but as Schuster remarks, in his report on the spectra of the non-metallic elements, a more extensive series of experiments than those already made by Ciamician is required before any definite opinion as to the connection of the different iodine spectra with the molecular condition of the gas can be expressed. It is not to be wondered at that these relations are only exhibited in the case of a few elements. For most of the metals the vapour-density remains, and probably will remain, an unknown quantity, and therefore the connection between any observed changes in the spectra and the molecular weights must also remain unknown. The remarkable changes which the emission spectrum of a single element—iron, for instance—exhibits have been the subject of much discussion, experimental and otherwise. Of these, the phenomenon of long and short lines is one of the most striking, and the explanation that the long lines are those of low temperature appears to meet the facts satisfactorily, although the effect of dilution, that is a reduction of the quantity of material undergoing volatilisation, is, remarkably enough, the same as that of diminution of temperature. Thus it is possible, by the examination of a spectrum by Lockyer's method, to predict the changes which it will undergo, either on alteration of temperature or by an increase or decrease of quantity. There appears to be no theoretical difficulty in assuming that the relative intensity of the lines may vary when the temperature is altered, and the molecular theory of gases furnishes us with a plausible explanation of the corresponding change when the relative quantities of the luminous elements in a mixture are altered. Lockyer has proposed a different explanation of the facts. According to him, every change of relative intensity means a corresponding change of molecular complexity, and the lines which we see strong near the poles would bear the same relation to those which are visible throughout the field, as a line spectrum bears to a band spectrum; but then, almost every line must be due to a different molecular grouping, a conclusion which is scarcely capable of being upheld without very cogent proof. The examination of the absorption spectra of salts, saline, and organic liquids, first by Gladstone and afterwards by Bunsen, and by Russell, as well as by Hartley for the ultra-violet, and by Abney and Festing for the infra-red region, have led to interesting results in relation to molecular chemistry. Thus Hartley finds that in some of the more complicated aromatic compounds, definite absorption bands in the more refrangible region are only produced by substances in which three pairs of carbon atoms are doubly linked, as in the benzene ring, and thus the means of ascertaining this double linkage is given. The most remarkable results obtained by Abney and Festing show that the radical of an organic body is always represented by certain well-marked absorption bands, differing, however, in position, according as it is linked with hydrogen, a halogen, or with carbon, oxygen, or nitrogen. Indeed, these experimenters go so far as to say that it is highly probable that by this delicate mode of analysis the hypothetical position of any hydroden which is replaced may be identified, thus pointing out a method of physical orientation, of which, if confirmed by other observers, chemists will not be slow to avail themselves. This result, it is interesting to learn, has been rendered more than probable by the recent important researches of Perkin on the connection between the constitution and the optical properties of chemical compound. One of the noteworthy features of chemical progress is the interest taken by physicists in fundamental questions of our science. We all remember, in the first place, Sir William Thomson's interesting speculations, founded upon physical phenomena, respecting the probable size of the atom—viz., "That if a drop of water were magnified to the size of the earth, the constituent atoms would be larger than small shot, but smaller than cricket balls." Again, Helmholtz in the Faraday lecture, delivered in 1881, discusses the relation of electricity and chemical energy, and points out that Faraday's law of electrolysis, and the modern theory of valency, are both expressions of the fact, that when the same quantity of electricity passes through an electrolyte, it always either sets free, or transfers to other combinations, the same number of units of affinity at both electrodes. Helmholtz further argues, that if we accept the Daltonian atomic hypothesis, we cannot avoid the conclusion that electricity, both positive and negative, is divided into elementary portions, which behave like atoms of electricity. He also shows that these charges of atomic electricity are enormously large as compared, for example, with the attraction of gravitation between the same atoms—in the case of oxygen and hydrogen, 71,000 billion times larger. A further subject of interest to chemists is the theory of the vortex-ring constitution of matter thrown out by Sir William Thomson, and lately worked out from a chemical point of view by J. J. Thomson, of Cambridge. He finds that if one such ring be supposed to constitute the most simple form of matter, say the monad hydrogen atom, then two such rings must, on coming into contact with nearly the same velocity, remain enchained together, constituting what we know as the molecule of free hydrogen. So, in like manner, systems containing two, three, and four such rings constitute the dyad, triad, and tetrad atoms. How far this mathematical expression of chemical theory may prove consistent with fact remains to be seen. In conclusion, while far from proposing even to mention all the important steps by which our science has advanced since the year 1848, I cannot refrain from referring to two more—in the first place, to that discovery, more than foreshadowed by Faraday, of the liquefaction of the so-called permanent gases by Pictet and Cailletet; and, secondly, to that of the laws of dissociation as investigated by Deville. The former, including Andrews's discovery of the critical point, indicates a connection, long unseen, between the liquid and the gaseous states of matter; the latter has opened out entirely fresh fields for research, and has given us new views concerning the stability of chemical compounds of great importance and interest. Turning for a moment to another topic, we feel that, although science knows no nationalities, it is impossible for those who like ourselves exhibit strong national traits to avoid asking whether we Anglo-Saxons hold our own, as compared with other nations, in the part we have played and are playing in the development of our science. With regard to the past, the

Digitized by Google

names of Boyle, Cavendish, Priestley, Dalton, Black, Davy, are sufficient guarantees that the English have, to say the least, occupied a position second to none in the early annals of chemistry. How has it been in the era which I have attempted to describe? What is the present position of English chemistry, and what its look-out for the future? In endeavouring to make this estimate I would take the widest ground, including not only the efforts made to extend the boundaries of our science by new discovery, both in the theoretical and applied branches, but also those which have the no less important aims of spreading the knowledge of the subject among the people, and of establishing industries dependent on chemical principles by which the human race is benefited. Taking this wide view, I think we may, without hesitation, affirm that the progress which chemistry has made through the energies of the Anglo-Saxon race is not less than that made by any other nation. In so far as pure science is concerned, I have already given evidence of the not inconsiderable part which English chemists have played in its progress since 1848. We must, however, acknowledge that the number of original chemical papers now published in our language is much smaller than that appearing in the German tongue, and that the activity and devotion displayed in this direction by the heads of German laboratories may well be laid to heart by some of us in England; yet, on the other hand, it must be remembered that the circumstances of different countries are so different that it is by no means clear that we should follow the same lines. Indeed, our national characteristics forbid us to do so, and it may be that the bent of the German lies in the assiduous collection of facts, while their subsequent elaboration and connection is the natural work of our own race. As regards the publication of so-called original work by students, and speaking now only for myself as the director of an English chemical laboratory, I feel I am doing the best for the young men who, wishing to become either scientific or industrial chemists, are placed under my charge, in giving them as sound and extensive a foundation in the theory and practice of chemical science as their time and abilities will allow, rather than forcing them prematurely into the preparation of a new series of homologous compounds, or the investigation of some special reaction, or of some possible new colouring matter, though such work might doubtless lead to publication. My aim has been to prepare a young man, by a careful and fairly complete general training, to fill with intelligence and success a post either as teacher or industrial chemist, rather than to turn out mere specialists who, placed under other conditions than those to which they have been accustomed, are unable to get out of the narrow groove in which they have been trained. And this seems a reasonable course, for while the market for the pure specialist, as the colour chemist for example, may easily be overstocked, the man of all-round intelligence will always find opportunity for the exercise of his powers. Far, however, from underrating the educational advantages of working at original subjects, I consider this sort of training to be of the highest and best kind, but only useful when founded upon a sound and general basis. The difficulty which the English teacher of chemistry, and in this I may include Canada and the United States, has to contend with is, that while in Germany the value of this high and thorough training is generally admitted, in England a belief in its efficacy is as yet not generally entertained. "The Englishman," to quote from the recent report of the Royal Commission on Technical Instruction, "is accustomed to seek for an immediate return, and has yet to learn that an extended and systematic education, up to and including the methods of original research, is now a necessary preliminary to the fullest development of industry, and it is to the gradual but sure growth of public opinion in this direction that we must look for the means of securing to this country in the future, as in the past, the highest position as an industrial nation." If, in the second place, we consider the influence which Englishmen have exerted on the teaching of our science, we shall feel reason for satisfaction; many of our text-books are translated into every European language and largely used abroad; often to the exclusion of those written by Continental chemists. Again, science teaching, both practical and theoretical, in our elementary and many secondary schools is certainly not inferior to that in schools of similar grade abroad, and the interest in and desire for scientific training are rapidly spreading throughout our working population, and are even now as great as, if not greater than, abroad. The universities and higher colleges are also moving to take their share of the work, which has hitherto been far less completely done in our country than on the Continent of Europe, especially in Germany, where the healthful spirit of competition, fostered by the numerous State-supported institutions, is much more common than with us, and, being of equal value in educational as in professional or commercial matters, has had its due effect. Turning lastly to the practical applications of our science, in what department does England not excel; and in which has she not made the most important new departures? Even in colour chemistry, concerning which we have heard, with truth, much of German supremacy, we must remember that the industry is originally an English one, as the names of Perkin, Maule, Simpson, and Nicholson testify; and if we have hitherto been beaten hollow in the development of this branch, signs are not wanting that this may not always be the case. But take any other branch of applied chemistry, the alkali trade, for instance, what names but English, with the two great exceptions of Leblanc and Solvay, do we find in connection with real discoveries? In the application of chemistry to metallurgical processes, too, the names of Darby, Cort, Neilson, and Bell in iron, of Bessemer, Thomas, Gilchrist, and Snelus in steel, of Elkington and Matthey in the noble metals, show that in these branches the discoveries which have revolutionised processes have been made by Englishmen; while Young, the father of paraffin, Spence the alum maker, and Abel of gun cotton fame are some among many of our countrymen whose names may be honourably mentioned as having founded new chemical industries. Hence, while there is much to stimulate us to action in the energy and zeal shown by our Continental brethren in the pursuit both of pure and applied chemistry, there is nothing to lead us to think that the chemistry of the English speaking nations in the next fifty years will be less worthy than that of the past half century of standing side by side with that of her friendly rivals elsewhere.

TELEPHONY IN SOUTH AUSTRALIA.

A VISIT TO THE ADELAIDE EXCHANGE.

[The following special report from *The South Australian Register* will give a good idea of the manner in which telephony is viewed and is progressing in Australia.—ED. *E.*]

A short time ago a London journalist visited the office of the Indo-European Telegraph Company, which occupies an unpretentious building in Old Broad-street, and made an inspection of the wonderful line between England and Teheran, the capital of Persia, the length of which is 3,800 miles. He says that the clerk in charge informed him that he wires through to Emden, and "with the same ease with which one wires from the city to the West End." He asked a few questions of the telegraphist in the German town. When he had finished he spoke with the same facility to the gentleman on duty at Odessa. This did not satisfy him, and in a few seconds he was through to Teheran. From here he passed to Kurrachee, then to Agra, and from Agra he was switched on to another line, and was "soon talking to a native telegraphist at the Indian Government Cable Station, Calcutta." Thus he had, by means of automatic repeaters, communication without break over 7,000 miles of wire, and he attests that the signals were excellent, and that the speed attained was not less than twelve words per minute. This is a most remarkable feat, and one may well ask, where will the achievements of science end? From the Post Office at Adelaide it is as easy to speak Port Darwin as it is to speak Port Adelaide, although the distance in the former case is about 2,000 miles. And, what is more wonderful still, messages have been received from England in less than an hour. On the occasion of the opening of the Melbourne Exhibition a message to the Queen was through from Melbourne to Windsor in forty minutes, and I am informed that in one instance the result of a Derby race reached this colony from England in twenty minutes. If a direct line throughout the whole of the distance were practicable the time would be reduced to as many seconds. The number of messages despatched by these lines has increased with great rapidity. In 1878 the number forwarded by the colonies was 9,283, and the number received by the colonies 8,161, making a total of 17,444 messages, on which were paid £146,125, the South Australian proportion being £16,421. In 1883 the number of messages forwarded from the colonies was 21,771, and the number received by the colonies 21,563, making a total of 43,334 messages, yielding a revenue of £251,278, of which the proportion accruing to South Australia was £27,510. The rate over which messages to Europe travel may not be generally known. The overland line joins the cables at Port Darwin, and the cables cross to Banjoewangie, the southernmost point of Java. The old cable joins a line which goes through Java to Batavia, and from thence the communication is continued to Singapore, Penang, and eventually to Madras, where the ordinary Indian lines are reached. The new cable goes from Banjoewangie to Singapore direct, avoiding Java, where Dutch operators are employed, with results that are sometimes most harassing to the persons who receive the messages at this end. We cannot boast of lines equal to those of the Indo-European Telegraph Company; but our system is one of which we have good reason to be proud. We have made great progress in this respect, and the day may come when we shall be able to go to some exchange of telegraphy or telephony and converse with our friends "at home" with almost as much freedom as if they were speaking to us across our garden fence. When Volta made his discoveries no one anticipated that we should ever flash messages around the world; and when Wheatstone conveyed the sounds of a musical box from a cellar to an upper room by means of what came to be known as the "Enchanted Lyre," it was not even suggested that the time would come when articulate speech would be transmitted over hundreds of miles. We have long since learnt that there are more things in heaven and earth than are dreamt of in our philosophy, and there are few persons who will be disposed to say that science has yet reached its highest point of development. The telegraph and the telephone are among the greatest triumphs of human skill, and both inventions have been applied in South Australia. The principle and mode of operation of the telegraph are well known, but there is a degree of novelty attaching to the telephone, and it is the latter instrument which is to be the special subject of my sketch.

THE INVENTION AND THE IMPROVEMENT OF THE TELEPHONE.

The original of the telephone now in use was discovered by Professor A. Graham Bell in 1877. This consists of a thin disc of iron placed in front of a permanent magnet surrounded by a coil of insulated copper wire. The sound of the voice speaking causes a vibration of the disc, a current of electricity is generated, which being sent round a similar coil on a distant magnet repeats the vibration on another disc, and reproduces the sound. In short, sound is converted into electricity, and electricity is reconverted into sound. This instrument was employed as both a transmitter and a receiver, and it was found by experience that it was not of any practical value for ordinary purposes, inasmuch as the sounds it gave, although distinct, were weak. Something was required to complete the invention, and this something was supplied by Professor H. E. Hughes in what is known as the microphone. This instrument multiplies sound just as the microscope multiplies the field of sight. It consists of two pieces of carbon attached to a diaphragm, which are made to recede from and approach to each other by the vibration caused by the sound of the voice and to offer a variable

resistance to the electric current which is generated. The current passes through a primary wire of a small induction coil, and produces a corresponding current in the secondary wire by which it is enveloped. This secondary, or "induced," current is transmitted through the line, and reproduces the speech in the receiver at the other end. The microphone is now used as the transmitter and the Bell telephone as the receiver, and in addition to these another instrument is required, which may be described as the "call." This may be either magneto-electric or galvanic. In the former the currents are generated by turning a handle, which revolves an armature containing a coil of very fine copper wire between the poles of permanent magnets, and causes alternating currents by which the bells are rung. In the latter a battery, generally of the Leclanché type, is employed; but there are various objections to this system, and the magneto-electric is the one which is most generally adopted.

THE TELEPHONE IN SOUTH AUSTRALIA.

The Postmaster-General (Mr. Todd) and his able assistant in this department (Mr. C. Unbehaun) have devoted close attention to the study of the telephone ever since its invention by Professor Bell. The improvements have been followed, and numerous experiments conducted with the view of ascertaining which was the best of the various systems brought out. In the first instance imitations of the original instrument were constructed from drawings in the scientific journals, and subsequently a variety of different instruments were obtained from England, including the Gower-Bell, which is the system adopted by the postal authorities in England. Mr. Todd eventually selected the Blake transmitter, which is a modification of the microphone, the Bell receiver in the form known as the "Ponycrown," and the "Swiss" telephone. In the year 1880 Mr. Todd submitted a memorandum to the Minister of Education, in which he recommended the Government to establish a Telephone Exchange; and in 1881 a Bill was introduced in the House of Assembly by the Hon. J. L. Parsons for the purpose of giving effect to the scheme Mr. Todd proposed. The Bill gave the Government the exclusive right to erect and maintain telephone lines in the colony, and it rapidly passed through both Houses of the Legislature, the only objection raised to it being based upon what has since proved to be an erroneous assumption that it would interfere with the success of the telegraphic system, and would not contribute anything to the revenue. The Act was first brought into operation in 1882, when a number of private lines were laid down and leased, and the Telephone Exchange was not opened until May of last year. At that time the number of subscribers was only twenty-five, whereas the number at the present time is 263, of which 217 are connected with the Adelaide Exchange and 46 with the Port Adelaide Exchange. In addition to this there are 156 private lines. This is very satisfactory progress, and, considering its age, the exchange will now bear favourable comparison with the exchanges in the other colonies. The number of subscribers in the other colonies at the commencement of this year was as follows:—Melbourne 650, Ballarat 81, Sandhurst 37, Sydney 260, Dunedin 237, Auckland 151, Christchurch 125, and Wellington 60. In addition to the exchanges at Adelaide and Port Adelaide, the telegraph offices at the exchange (Pirie-street), Rundle-street, Adelaide Railway Station, Unley, Norwood, North Adelaide, and Hindmarsh are connected, and the Semaphore and Largs Bay Railway Station are to be added. Branch exchanges are also to be established at the Semaphore and at Mount Lofty, and if the business increases as it has hitherto done further extensions will soon become necessary. There are about 700 sets of telephones now in use, and the greater proportion of these have been purchased for the Western Electric Telegraph Company of Chicago, whose instruments are considered to be superior to those manufactured in England. The total length of wire erected is 983 miles, and the longest telephone lines are the following:—Government House to Marble Hill; 13 miles; M'Culloch—Goolwa to Port Victor, 11 miles; Cave and Co. (S.A.) to Crafers, 10 miles. Mr. Cave joins his Port wire to the Crafers line, and the length is thus increased to 18 miles. The above does not include the railway telephone lines, the longest of which is from Kapunda to North-West Bend, 56 miles, and from Burra to Petersburg, 55 miles. The charges made to subscribers are lower than those imposed by the postal authorities in England, and some special facilities are afforded, some of which do not pertain elsewhere. For instance, Clause 14 of the regulations provides that chemists situated along any existing line of telegraph or telephone within a distance of five miles from a telephone exchange may be connected with such exchange on payment of a subscription of £14 per annum, on the understanding that persons will be allowed to consult any medical subscriber on payment of 6d. for every five minutes, or free of charge where the medical subscriber pays the additional £9 a year. The telephone must be available for purposes of medical consultation day and night; but a private fee of 2s. may be charged during the night, or between the hours of 10 p.m. and 7 a.m. This is a novel arrangement, and the value of it is obvious.

AT THE EXCHANGE.

The system upon which the Exchange is worked is very simple. All the subscribers' lines are brought to a focus at the centre. If a subscriber desires to speak to another subscriber he rings up the exchange, states with whom he wishes to communicate, and is at once connected. To see how things are done I visited the exchange, which occupies what is known as the check room at the General Post Office. I was taken up stairs through a long room in which a host of telegraphists are at work, and into the *sanctum sanctorum*, in which the young lady attendants sit at the telephonic switchboard and answer the calls of subscribers. There were two operators employed in this work, and they were as busy as they could well be replying to the calls and making the necessary connections. The switchboard consists of a series of enunciators with deep shutters, each of which bears the number of a subscriber. Jack-knife switches, corresponding to the enunciators, are placed below; and at the bottom is a row of clearing-out shutters. On the switchboard are two rows of buttons with contact keys, having flexible cords, with plugs attached, which are used for completing the circuit between any two subscribers. When a subscriber rings the shutter of the enunciators with which he is connected drops, and the attendant at once places one of the plugs in the corresponding switch. Having done this, she gives the reply ring by pressing a key, which causes an electric current to pass along the line. The arrangement adopted is a novel one, and, I was informed, is not in use elsewhere. A small turbine, connected with the water service, drives a small magneto-electric machine, which is kept in the crypt in the basement of the building. This supplies the current which rings the bell, and the necessity which before existed of turning a handle, as is done at the subscribers' end, is obviated. The attendant afterwards presses the speaking key, and asks the subscriber with whom he wishes to speak. He replies, and the attendant takes a second plug, and places it in the proper switch, when the connection is complete, and the parties may carry on their conversation in perfect secrecy. When they have finished a signal is given which throws down the clearing-out shutter, and the attendant draws the plugs in readiness for the next call. The whole operation does not occupy more than a few seconds, and the young ladies are able to reply to the requests of subscribers with remarkable rapidity. The number of communications per diem through this exchange is about 1,000, and there is room for almost unlimited extension, the capabilities of the machinery being dependent only on the number of attendants employed. While I was in the exchange many calls were received and answered without a hitch of any kind, and there was nothing to note except that the work was well and efficiently done.

AN IMPORTANT IMPROVEMENT.

After leaving the young ladies in the exchange, I proceeded to the subterranean regions below, some parts of which resemble the cloisters of an ancient Gothic cathedral. After visiting the various apartments, I was taken into the fitting shop, where a number of men were at work repairing instruments, &c. While here we spoke the Port Adelaide Exchange, and my attention was especially directed to the effects of induction. The telephone is its own enemy owing to its sensitiveness. A current passing along one line induces a current in an opposite direction on a neighbouring line, and supposing the telephones to be connected with this latter line they will repeat what is said. Hence a mysterious second voice, or a peculiar pitter-patter caused by the ringing of a bell is sometimes heard when communications are being exchanged. These interruptions interfere with the distinctness of the sounds transmitted, and make the subscriber think that his friend at the other end is amusing himself at his expense by talking double-Dutch. In the ordinary course of things the wire is run to earth, and the earth is used to complete the circuit. For, unless the circuit is complete there can be no transmission of the electric current. Earth is a great conductor, and it is an accepted theory that a current on going to earth will find its way back to the point from which it first came. To overcome the difficulty it has been found necessary to complete the circuit with the line itself, forming what is called a close metallic circuit. The lines are twisted, without being brought into contact, between each four poles, and this has the effect of preventing any repetition of sound. The close metallic circuit is used on all private lines; and a plan has been devised by which it can be adapted to the requirements of the exchange, more particularly in relation to communications between Adelaide and the Port. This plan consists in connecting the subscriber with his own exchange by a single wire, and causing the current to be repeated by induction on the close wire circuit connecting the two exchanges, and again repeated by induction to the subscriber at the other end. This improvement is being introduced, and a new arrangement is in contemplation with regard to the "ringing-off"—a process which, as at present conducted, sometimes leads to confusion.

A NOVEL CLOCK.

While in the fitting-shop I was shown a number of curious instruments and machines, including a "synchronised clock," made by the Standard Diamond Telephone Company (Limited). This clock has a magneto-electric attachment, by which two small figures on the face of the clock are made to clutch precisely at the hour and to regulate the minute-hand. If the clock gains or loses time the hand will at the hour be brought to the centre, and this operation will be continued every hour as long as the clock is going. I understand the system is to be applied at the Post Office. The magneto-electric attachment is to be fixed to the clock in the tower, and this being connected by wire with all the other clocks in the department they will be regulated in the way described.

UNIVERSITY COLLEGE, BRISTOL.

In the Department of Experimental Physics at this College LECTURES and CLASSES arranged progressively are given throughout the Session, and Instruction is given in the Physical and Electrical Laboratory. In the Engineering Department Special Courses have been arranged for Students studying for the profession of Engineering who wish to include in their professional training some knowledge of Electricity and its technical applications, especially with regard to Electric Lighting and Transmission of Power, Telephones and Telephonic Systems, Telegraphy, Electro Plating, &c.

WANTED.—A SITUATION as FIRST LINEMAN, Foreman of Construction Party, or good Assistant to a Mechanic (Telegraphs and Telephones). Experienced abroad. Good references.—Address, U. E., *The Electrician* Office.

AN ELECTRICAL ENGINEER, of good theoretical and practical knowledge, desires an ENGAGEMENT. Would undertake Electric Light or other installation work, or could take management in a small factory. Moderate salary; good references.—"ENERGY," Office of this Paper.

ELECTRICAL ENGINEER, with considerable experience in Electric Lighting, both arc and incandesce t, requires suitable EMPLOYMENT.—Address, E. E., Office of this Paper.

A PRACTICAL ELECTRICIAN, Patentee of valuable Secondary Battery, cheap, light, and of large surface capacity, wishes to negotiate for SALE or WORKING of SAME.—W. W., *The Electrician* Office.

FOR SALE.—PAIR of GOWER-BELL TELEPHONES and TRANSMITTERS; equal to new. Royalty paid. Or would exchange for Dynamo Machine.—Address, WATSON BELL, Guinea Warehouse, Whitehaven.

FOR SALE.—PATENT RIGHTS of VOLTAIC BATTERY, suitable for Motive Power and Electric Lighting. Also Rights of Improvement on Ship Propellers.—Apply to T. and G. B. McKIM, C.A., 149, St. Vincent-street, Glasgow.

DYNAMO MACHINES and ARC LAMPS (Siemens, Bürgin and Gramme) FOR SALE. Stock of company in liquidation. Little used and offered at half price.—MACKAY and MESS, C.A., Dundee.

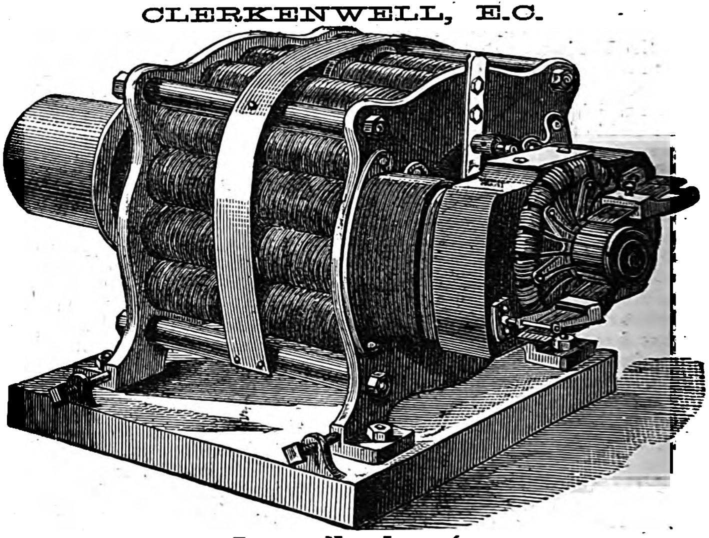
INSULATED ELECTRICAL WIRE, Silk, Cotton, or India Rubber covered. Conductivity guaranteed. German Silver Wires for Resistance. Braided Handle Cord, Silk Cord for Electric Bells, &c.—WILLIAM BICKARD, Derby. London Agent (stock kept), EDWIN HOLLOWAY 2 Gutter-lane E.C.

OPPERMANN BROS.,

Dynamo Machine Makers and Electric Light Engineers.

Works: Brewhouse Yard, 172, St. John Street,

CLERKENWELL, E.C.



TYPE OF NOS. 5 AND 6.

PRICES OF DYNAMOS.

No.	No. of 20-C.P. Lamps.	H.P. Absorbed.	Price.	
1	5	½-H.P.	£10	Shunt or Series-wound Direct Current

7	500	50 ,,	£300	

LEGAL NOTICE.—HORRY v. OPPERMANN.

MESSRS. OPPERMANN BROS. have much pleasure in announcing that the plaintiff has formally withdrawn the proceedings instituted against them to restrain alleged infringement of Letters Patent.

THE

SCHOOL OF TELEGRAPHY & ELECTRICAL ENGINEERING.

ESTABLISHED IN 1868.

12, Princes Street, Corner of Hanover Square, London, W.

(Removed from 4, George Street, Hanover Square.)

MANAGING DIRECTOR: MR. T. J. JONES, M.S.T.E.

The course of Practical and Theoretical Instruction in the higher branches of Overland and Submarine Telegraphy embraces in addition to the manipulation of the various systems of wording in general use, the following subjects:—Mathematics, Mechanics, Chemistry in relation to Telegraphy, Gas and other Motors. Signalling and Testing Instruments. Engineering Formulæ and their application in practice. Electro-Statics. Electro-Dynamics. Magnetism. Methods of Testing the Electrical Condition of a Line during and after its Construction. Testing for and Localising Faults, &c., &c., &c. Telephone and Electric Light Apparatus.

The instruction, both in signalling and testing, is of a thoroughly practical character, as the classes work with the actual instruments used on long lines, through cables of various lengths, from 600 to 3,000 knots, so that the signals of the Eastern, Atlantic, and Brazilian Companies, &c., are exactly reproduced, and the pupils fitted for any line.

A complete practical and theoretical course of instruction on the TELEPHONE and the ELECTRIC LIGHT, and their commercial utilisation, has now been added to, and embodied in, the ordinary curriculum, as the advantages of being associated with any great commercial application of science at an early period of its development is one which has been so often exemplified that it can scarcely fail to be appreciated by those who have in view professional success.

That TELEPHONIC communication and ELECTRIC LIGHTING constitute such applications is sufficiently shown by their rapidly increasing progress; and therefore no pains or expense have been spared to place at the disposal of the pupils the technical and scientific nstruction requisite to qualify candidates for the most important posts in connection with these new branches of electrical engineering. In order that the instruction in the erection, adjustment, testing, and working of TELEPHONE and ELECTRIC LIGHT circuits may also be thoroughly practical, complete working telephone exchanges upon the various systems in use in different countries have been fitted up; every kind of telephone, for both exchange systems and private lines, with all apparatus used therewith, is provided (in duplicate when possible, so that students may be able to dissect and reconstruct the same). The necessary tools and materials are available, and every facility is given for conducting experiments by the pupils desirous of so doing, and a similar course has been pursued with the VARIOUS LAMPS and MACHINES, &c., in the ELECTRIC LIGHT Department, so that Pupils from the School are in a position to enter either of these new fields. Civil and mechanical engineers, sons of professional gentlemen, and others, will now have an opportunity of acquiring a knowledge of all the telegraphic systems of working, of the construction and management of land and submarine telegraphs, of telephone lines, systems and exchange, of the construction, erection, and management of electric light apparatus, testing wires, lines and materials employed, submarine cable testing, localising faults, &c., &c.

Arrangements have been made so that Inventors, Amateurs, and others can now have every facility, with all necessary apparatus provided in private rooms, to compare, test, or perfect any Inventions, Apparatus, &c., connected with Telegraphy, Telephony, and the Electric Light. The highest professional assistance can also be had.

Further particulars may be obtained on application to W. N. TIDDY, *Secretary*.

NOTES.

SAMARCAND.—The telegraph line between Samarcand and Bokhara was opened on September 9th.

ELECTRIC LIGHT AT NAPLES.—It is decided to light by electricity the underground railway to be made in Naples.

GREAT NORTHERN TELEGRAPH COMPANY.—The traffic receipts of this company for the month of August amounted to £26,800.

WEST COAST OF AMERICA TELEGRAPH COMPANY.—The gross earnings of this company for the month ending Aug. 31st were £3,690.

BRAZILIAN SUBMARINE TELEGRAPH COMPANY.—The traffic receipts of this company for the week ended 29th August amounted to £3,251.

KRUPP'S WORKS.—At these well-known works, there are in use some 40 miles of telegraph line, joining 35 stations for the working of 55 Morse instruments.

ELECTRIC LIGHT AT MAYENCE.—Siemens and Halske, of Berlin, have instructions to put up twenty-seven 800-candle arc lamps at the Central Station, Mayence.

EASTERN TELEGRAPH COMPANY.—The traffic receipts of this company for the month of August amounted to £45,329, and to £44,937 in the corresponding period of 1883.

ELECTRIC LIGHT AT LEIPSIG.—The gas company of this town has received a concession from the municipality for a central station to generate electricity for both lighting and power.

ANTWERP EXHIBITION.—The Belgian Government has reduced by 30 fr. per square metre the rent of space, which was originally fixed at 70 fr., so that the actual cost is now 32s. for 10¾ square feet.

ELECTRIC LIGHT FOR LIGHTHOUSES.—A lighthouse, illuminated by electricity, in the Island of Clippy, is approaching completion. Its flashing red light is expected to be visible for a distance of 15 miles.

PARIS EXHIBITION OF 1889.—There is a movement on foot for securing the erection of this exhibition, which seems to be definitely decided upon, in the neighbourhood of Vincennes instead of Boulogne-sur-Seine.

EDISON'S NEW SHIP LIGHTING MACHINE.—This machine we are informed is a great improvement upon earlier types. It gives current for 300 16 candle-power lamps at 110 volts with only 300 revolutions per minute.

THE PHILADELPHIA EXHIBITION.—We understand that Mr. Killingworth Hedges has been invited to act as a member of the Board of Examiners of the Philadelphia Exhibition, of which Prof. M. B. Snyder is chairman.

ROYAL COLLEGE OF SCIENCE, DUBLIN.—The winter session of this college commences on October 4th. There will be a special course of Applied Electricity and Laboratory Work, under the direction of Professor Barrett.

WESTERN AND BRAZILIAN TELEGRAPH COMPANY.—The traffic receipts of this company for the week ending 5th inst. were £2,450, after deducting the "fifth" of the gross receipts payable to the London Platino-Brazilian Telegraph Company.

ELECTRIC LIGHT AT BERLIN.—The central station for the electrical illumination is nearly finished; it will contain four Edison 500-lamp dynamos, with the steam engines and boilers for driving them, capable of maintaining 2,000 16-candle incandescent lamps.

THE TELEPHONE IN THE FRENCH BLACK COUNTRY.—The Lyons journals report that an engineer of the *Société Générale des Téléphones* has lately visited the metallurgical centres of Saint-Etienne, Saint-Chamond, and Rive-de-Gier, with a view to putting them in telephonic communication.

AMBULANCE ELECTRIC LIGHT.—As a result of the recent experiments with the electric light for aiding the search for dead and wounded on the battle field, the Geneva Conference has decided to recommend European Governments to adopt this light in future as part of the ambulance plant.

ELECTRIC LIGHT AT NEW YORK.—It is now proposed to place an automatic electric lamp in the torch of Bartholdi's colossal statue of Liberty Enlightening the World, in New York roads. A current of 60 amperes, with an E.M.F. of 70 volts, will be required for the lamp; and a Mangin reflector will throw the light a distance of 60 miles.

ELECTRIC LIGHT IN THEATRES.—The Ambigu Theatre, Paris, is now added to the gradually lengthening list of theatres illuminated by electricity. The light was used for the first time on the 6th inst., being supplied by the Société d' Eclairage Electrique, the only company that has (says the *Bulletin*) succeeded in completely superseding gas in a Paris theatre.

ELECTRIC HEAD-LIGHT FOR LOCOMOTIVES.—Three companies have been formed in America for working a patent, obtained by Mr. Wooley, for a new head-lamp maintained by a dynamo worked direct by a separate motor, which receives its steam from the locomotive boiler. It appears that the trials on the Chicago, St. Louis, and Pittsburg railway are regarded as satisfactory.

FOOCHOW.—The Great Northern Telegraph Company notify that the steam launch service between Sharp Peak and Foochow having been forcibly interrupted by the Chinese military authorities, telegrams for Foochow can only be accepted for transmission by the Chinese Government land lines from Shanghai, and they must be written in plain English, the use of code words being forbidden.

CHINA.—The Eastern Telegraph Company notifies that, from 1st September until further notice, telegrams for all places in China, with the exception of Shanghai, Amoy, Hong Kong, and Macao, must be written in plain English language. The company also notifies the restoration of the Chinese Government land lines to Tientsin, but owing to pressure of work telegrams will be subject to some delay.

HATCHETT'S HOTEL, PICCADILLY.—Messrs. B. Verity and Sons have fitted this hotel with the electric light. The installation consists of 130 Edison lamps supplied by two of the new 100 light dynamos which are driven by Otto gas engines. Two engines of 12 horse-power each are put down, either of which will supply all the power required. The work has been excellently done by Messrs. Verity and Sons.

ELECTROMOTIVE TRAMCARS IN BRUSSELS.—The working, by electromotive tramcars or electro-locomotives, of the tramway along the Rue de la Loi, Brussels, which should, according to contract made between the Tramway Company and La Société Belge et Hollandaise d'Electricité, have been commenced on 1st July, has been postponed on account of successive improvements introduced into the electrical portion of the vehicles.

THE TELEPHONE IN THE NORTH OF FRANCE.—The journals of this district report that the *Société Générale des Téléphones* has ceded to the French Government the telephone system

Digitized by Google

that they laid down in Lille five years ago. It appears that the inhabitants object to this arrangement, as they fear they will not be so well served by Government management. They even threaten to boycott the telephone if their claims are not attended to.

A YOUNG LADY KILLED BY LIGHTNING.—During a thunderstorm in Orkney, Miss Wilhelmina Leask, residing with her mother at Knockhall, near Stromness, was killed by lightning. Along with some friends, the deceased had been in the harvest field, and when the storm came on they separated. Shortly afterwards, the young woman was found lying on her face quite dead. The lightning struck her on the neck, tearing and burning her clothes, breaking a watch in her pocket, and tearing the boots from her feet.

THE NEW ATLANTIC CABLE.—The cable steamer "Faraday" has arrived at Messrs. Siemens's telegraph works, Charlton, after having successfully laid the first portion of the second Bennet-Mackay Atlantic cable, and is now engaged in taking on board the second portion. It is hoped that both cables will be in working order by the 1st of October. Dr. Muirhead is engaged in duplicating the cable already laid. The work on this side has been done, and Dr. Muirhead is now gone to America to complete the work there.

EGYPT.—It is said to have been decided to erect a light land line by the banks of the Nile for the purposes of the forthcoming expedition. Though the arrangements are not wholly complete, the military authorities contemplate utilising the services of some of the non-commissioned officers and men of the 24th Middlesex Volunteers (Post Office) belonging to the telegraph companies. These men are all skilled manipulators, some of whom have served in Egypt before. The men will be attached to the Royal Engineers, whose scarlet uniform will take the place of the dark grey of the volunteers.

A NON-MAGNETISABLE WATCH.—The editor of the *Centralblat für Electrotecknik* informs his readers that he has got a keyless watch, made by a Nuremburg watchmaker, which is uninfluenced by the electric current. It has gone well for a whole year, although placed near one of the poles of a powerful electro-magnet. We should be glad of details of this useful watch, the possession of one such being better than any of the alternatives supposed to be the only resource with a magnetised watch, viz., subjecting it to alternate currents of decreasing intensity, raising it to a red heat, or throwing it on the scrap heap.

ELECTRIC LIGHT IN THE FURNESS DISTRICT.—Ireleth and Askam are outlying villages within the district of the Dalton Local Board, in that rich iron-bearing promontory known as Furness, in North Lancashire. They are far from gasworks, and laying pipes would be a costly matter. Here, then, is a capital field for the introduction of electric light, especially as the neighbouring Roanhead mines are now lighted on the arc system. The Board has decided, we think unwisely, to adopt the incandescent system, with Menzies' lamps, for the two villages above named, and we look forward with interest to the result of the experiment.

COMPETITION IN TELEPHONES.—The Trinidad papers announce that Mr. Gray, the manager of the American Telephone Exchange in Port of Spain, has been recently superseded by another gentleman, sent out by the parent company in New York. Subsequently Mr. Gray submitted to the mercantile community of Port of Spain a proposal to form a new telephone company with lower rates than the present one, and bound himself to have everything ready to start in January next. Most of the leading merchants present agreed to the proposal, and signed a preliminary arrangement. So it would seem the "grey" mare proved to be the better horse.

COMPARISON OF COST.—The cost of electric light for illumination, as compared with gas, has been computed by Hartford, Conn., where arc lights have been in use for about a year. The report states that each electric light in use displaces six and a half street burners, besides giving at the same time at least ten times as much light. The gas lamp costs 35dols. per burner per annum, kept burning 328 nights in the year, while for the electric lights 65 cents. a night is paid. The electric light being equal to six and a half gas burners, a saving of 15·60dols. per lamp per year is effected by the use of electricity, besides the cost of lighting and extinguishing the gas lamps.

FRENCH SUBMARINE CABLES.—*L'Electricité* gives the following list of submarine cables laid in France since 1878 by the French Minister of Posts and Telegraphs, forming, with the subsidiary submarine communications for completing the coast lines, an increased length of 3,210 kilometres (1,990 miles), or an average of 535 kilometres (330 miles) of new cable yearly:—In 1878, a direct line between France and Corsica; in 1879 and 1880 two new cables between Marseilles and Algiers; in 1881, a cable between La Calle in Algeria and Bizerte in Tunis; in 1882, one between the last-named place and Bône in Algeria; and a series of cables on the east coast of Tunis, between Soussa, Sfax, Gabes, Djebba, and Zarzis.

BICHROMATE OF POTASH.—M. Roemer has found a process for the economical production of bichromate of potash, which consists in melting together 100 parts of chrome ore with 150 parts of potash and 30 parts of soda. The levigation is effected, as usual, with water; and the resulting liquor, which contains chromate of potash and chromate of soda, is treated with sulphuric or hydrochloric acid in suitable proportion to form bichromate of potash and sulphate of soda. By evaporation the bichromate of potash becomes crystallised. An equivalent of neutral bichromate of potash, with an equivalent of neutral chromate of soda, require an equivalent of monohydrated sulphuric acid, and yield an equivalent of bichromate of potash, an equivalent of sulphate of soda, and two equivalents of water.

A DELICATE QUESTION.—The householders at Dundee are in a state of uncertainty with regard to the question how to treat the rent derived from telephone wires. At a meeting the other day of the Finance and Police Committees of the Dundee Police Commission, the question was raised whether house proprietors included in their returns to the Assessor of Taxes the amount received by them as rent for the erection of telephone wires and standards on their properties. Several members said that such payments must be regarded as rent, and that the rental of the burgh would be increased by several hundred pounds if the money paid to house proprietors by the telephone companies was included in the valuation roll. The meeting instructed the treasurer to communicate with the assessor on the subject.

IMPROVED EARTH CONNECTION.—Herr J. Halitz, chief electrician of the Galician railways, has devised a new arrangement of metal plates intended to ensure the earth connection of the ends of telegraph lines. A layer of medium-sized coke is placed in a hole, two metres deep, and having a square metre (10¾ square feet) of surface. On this coke rests a wooden pipe, 38 square centimetres, or nearly six square inches, in sectional

Digitized by Google

area, filled with coke, and surrounded by earth. On the top of this pipe is a block of coke, previously immersed in melted lead; and this block is itself fixed to a copper rod which communicates with the telegraph line. This arrangement permits any gas which may issue from the earth to pass off freely into the air, and thus is counteracted the resistance offered by the gaseous layer which is sometimes formed on the surface of earth plates.

THE EARTH'S MAGNETISM.—The six subterranean chambers at the Paris Observatory, for securing a uniform temperature, in order to study the earth's magnetism, have just been completed. The internal dimensions of each are 60 metres by 16 metres; and the walls, of concrete and millstone grit, are 1·8 metre, or 6ft., thick. Inside the space thus formed come the inner chambers, isolated from the outer by a gallery 2 metres wide, the inner walls, of similar construction to the outer, by 80 centimetres, or nearly 3ft., thick. The height of the chambers is 3·65 metres = 12ft. under the crown of the arch, which is a metre thick, covered with earth to the depth of 2 metres, turfed and planted with shrubs. The observation chambers are destined to receive the following instruments:—Recording apparatus of magnetic variations; Lamont's instruments for direct observation; and Arago's appliances. Strange to say, gas has been adopted for illumination.

TELETHERMOMETER FOR THE BRUSSELS OPERA HOUSE.—A thermometer has been devised for the Théâtre Royal de la Monnaie, Brussels, for recording in a central office the various degrees of temperature at different points of the house. It consists of thermometers placed in any parts of the building the temperature of which it is desirable to be constantly informed of; of a receiver in the central office, indicating the temperatures; and of an electric battery. The action is due to a spiral spring, like that of a Bourdon pressure gauge, expanding and thus closing an electric circuit, by means of which the indication is given, eight Leclanché cells affording the current. The expansion and contraction of the spiral spring cause an indicator hand to move along a graduated arc; and the point, as it reaches the successive degrees, closes corresponding circuits which communicate with the receiver. The first idea of the instrument is due to M. Bordiau, architect, who got out the arrangements for warming and ventilation; and it is made by M. Emile Closset, electrical engineer, Brussels.

NEW CABLE BETWEEN SENEGAL AND THE CANARIES.—The *Bulletin Mensuel des Postes et Télégraphes* has just published the text of two conventions concluded by France, one with the Spanish National Submarine Telegraph Company, and the other with Spain, settling the conditions of the laying and working of the submarine cable for connecting Senegal with the Canary Isles, and communicating with that already laid between the Canaries and Cadiz. The concession is for 25 years, after which the cable is to become the property of the French Government, who grant the company a subvention of 1,700,000fr. (£68,000), payable by instalments. After the fifth year of working the Government has the option of buying up the rights of the company. The cable will be subject to the provisions of the international convention, the official messages of the Government being transmitted at half rates. The receipts are to be shared by the French Government and the company in the proportion of one-third for the former and two-thirds for the latter, after deducting 10 centimes (1d.) for the transit tax due to the Spanish Government.

THE WRONG ORDER.—Once a year great amusement is obtained from the Postmaster-General's report, in which it is stated that letters are posted without addresses, and addresses without letters, and so on, and our comic papers and our novelists can always utilise the idea of the change of letters into the wrong envelopes. A laughable case has just occurred in which the wrong letter has evidently been sent to Messrs. Crompton and Co., the well known manufacturers of dynamos:

"High-street, ——

"Dear Sir:

Please send to —— Station, Great Eastern Rail,

3 pair each women's elastic side boots,
3-4-5-6 size, 4s. 6d.
2 pair each women's Memal top, button,
4-5-6 size, 5s. 6d.; or
2 pair each women's kid top, button,
3-4-5 size, 6s.,

And oblige

Yours, &c.,

——."

AMERICAN INSTITUTE OF ELECTRICAL ENGINEERS.—The following has been issued by the Secretary of the Institute:—Inquiries have been made as to the present standing of enrolled members. According to rules, certain qualifications are necessary for both members and associate members. The Council has defined the rules by resolution as follows:—Qualifications for a member: "He shall have practised on his own account, or in the service of some individual, organised institution, or company engaged in electrical work, in the capacity of electrical engineer, or electrician, for at least two years; or he shall be so intimately associated with the science of electricity, or the progress of the art, that the Council consider his admission to membership would conduce to the interests of the institute." Qualifications for an associate member: "Any person of good standing in the community, properly endorsed, who is in any way interested in electrical matters or studies." At present all enrolled members, of whom there are nearly three hundred, stand upon the same footing—that of associate members. Those now enrolled, who possess the necessary qualifications, and who desire to become members, may do so by applying to the Council for its action on the matter, as provided by the rules. The proper blanks will be furnished by the secretary.—*Electrical World.*

THE BRITISH ASSOCIATION IN 1854.—It has been our custom to compare notes of the current meeting with that of twenty years ago. The period is not a long one, but comparison always brings sadness in that we recognise how many able workers and earnest supporters of the Association have passed from among us. In 1854 the meeting was held at Liverpool, in the month of September. Among the names of those who submitted reports we miss at our meetings now Mallet, Chesney, Powell, Sabine, Rosse, Daubeny, &c. The purely electrical papers at this meeting were of a very insignificant character, scientifically considered, though historically Mr. J. W. Brett advanced the claims of himself and his brother, Mr. Jacob Brett, to the invention and perfection of submarine telegraphs. Mr. E. B. Bright read a paper on "Magneto-Electricity and Underground Wires;" Sir John Ross one on the "Deviation of the Magnetic Needle" peculiar to Liverpool; Mr. Archibald Smith on a "Graphic Method of Correcting the Deviations of a Ship's Compass;" Prof. W. Thomson (now Sir W. Thomson) discussed "Experiments in Thermo-Electricity;" Professor Tyndall discoursed on "The Diamagnetic Force;" Mr. C. F. Varley on "Improvements in Submarine and Subterranean Telegraphy;" and Captain Ward on "The Application of Voltaic Electricity to the Firing of Gunpowder."

MECHANICAL DEPOLARISATION OF BATTERIES.—Under this head, M. V. Bablon makes a few judicious reflections in our contemporary, *L'Electricien.* Although, when great intensity is required, an electrical generator of some type or other would naturally be preferred to a battery, still there are occasions where special circumstances may render the use of large batteries advisable. In such a case some mechanical means for depolarising the positive electrode may be adopted with advantage, as the circular form of plate revolving in the liquid is inconvenient. The writer advises that the positive electrode consist of a supple metallic band passing over two rollers, the lower immersed in the liquid, and the upper caused to revolve. The portion of band not immersed in the liquid is of sufficient area for each successive point to become completely depolarised by contact with the air before being again immersed. The effect may also be increased by means of brushes rubbing against the band, and causing the liquid drawn up with it to fall down more quickly, thus effecting a more perfect contact of the surface with the oxygen of the air. The zinc pole is placed between the two sides, ascending and descending, of the positive electrode; and two other zincs may also be placed opposite the two other faces of the band, so as to increase as much as possible the active surface of the battery. The direction of the band, both in the liquid and out of it, may be varied according to the arrangement of the battery.

ELECTRIC LIGHTING AT BRIGHTON.—An offer has been made to the Corporation of Brighton by the Hammond Electric Light Company, and was laid before the Town Council this week, with the view of putting into operation the provisional order obtained by the Corporation for the lighting of a district including part of the King's-road and the centre of the town. It was calculated that the expense would amount to something like £60,000, and when the matter came before the Council they decided to let it rest for six months pending further improvements or more definite knowledge of house-to-house lighting. The result has not been considered satisfactory, and the committee with whom the matter was left have not stirred in it, though the Council have, on the other hand, laid down a system of electric lighting at the Royal Pavilion, where both in the rooms and in the grounds on the occasion of outdoor fêtes in the evening it has proved effective. Otherwise the supply of electricity for illuminating purposes in the town generally has been left to the Hammond Company, who have a station at an iron foundry near the railway. The company now propose to take over the powers of the Corporation under their provisional order, which they suggest should be varied so as to abolish the area of compulsory supply, leaving them to supply electricity only where it could be done at a profit, to nearly double the maximum price, and to make other considerable variations, regarding which they expressed the opinion that the Board of Trade would be happy to vary the terms of the order, so that one Corporation in England at least should put into force in a modified form the provisional order of the Electric Lighting Act, 1882, "which unfortunately and to their great disappointment has up to the present been practically a dead letter." As to the profits, the company proposed that the first 10 per cent. should go to them, and any surplus be divided between them and the Corporation, the latter having power to purchase the undertaking at six months' notice. The committee, however, do not consider it would be advantageous to the town to agree to the offer and consequently recommended the Council to refuse it.

MUSIC BY TELEPHONE.—The transmitting by telephone of musical sounds, and even a whole concert or operatic performance, is no longer new; but intelligence reaches us from Brussels of a novel phase of this combination in connection with the long-distance telephoning along telegraph wires by the Van Rysselberghe system. The Committee of the Antwerp International Exhibition, to be held next year, and in which electricity will take a prominent part, are providing an additional attraction—magnetic it turns out to be as well as in the showman's sense—in a concert room, where visitors may hear music from Brussels, and other places, transmitted by telephone through the existing telegraph wires. A trial—not rehearsal—of the arrangements was made a few days ago, and we are informed surpassed the most sanguine expectations. The orchestra of the Brussels Opera, playing in the Wauxhall concert kiosque of the Parc at Brussels, was distinctly heard at Antwerp, a distance of about thirty miles. And, not only was the orchestral performance distinctly reproduced, but a violin solo, Gounod's "Meditation," was heard in its minutest details, although the ordinary telegraph service was not suspended. Six microphones had been fixed to two small columns of the Wauxhall orchestra, on a level with the musical instruments; and carbon transmitters, of the model devised by M. Van Rysselberghe, mounted in quantity and actuated by a small Faure accumulator, were put in connection with the central office of the Compagnie des Téléphones. From this spot the circuit was continued by a double wire, so as to avoid telephonic induction, as far as the directors' office of the Central Telegraph Station at the Northern Terminus, Brussels. Here ten Bell receivers were intercalated in the circuit, so as to allow of the music being heard (while being transmitted to Antwerp) by the Minister of Railways, Posts, and Telegraphs, and the principal officials of the Government Telegraph Department, who warmly congratulated M. Van Rysselberghe on this additional application of his invention. At Antwerp were assembled Professor Rousseau, President of the Electrical Committee of the Antwerp Exhibition, some members of the Commission, several directors of the Bell Telephone Company, Lieutenant Lemière, of the Military Telegraphic Department, Antwerp; M. Charles Mourlon, manager of the works where M. Van Rysselberghe's apparatus is made, and M. Berlin, superintendent of the arrangements for adapting the Belgian telegraph wires for telephoning, under whose direction this interesting trial took place.

DEATH FROM INTENSE CURRENTS.—In conjunction with Professor Brouardel, M. C.-M. Gariel has drawn up a report (reproduced in full by *L'Eléctricien*) on the circumstances attending the death of two young men, Martin and Kenarec, through contact with the conductors for furnishing the current to electric lights at the *Fête de la Presse*, held recently in Paris. On leaping the ha-ha, which separates the Tuileries Gardens from the reserved portion, they became entangled in the wires. A Garde de Paris, who noticed the incident, but did not see them re-appear, went to the spot and found them lying at the bottom of the trench, one dead and the other dying. Although the sloping side of the trench had not been watered on the day of the accident, it could not have been quite dry, owing to the rainy weather. There were two conducting wires extending from a raised frame in the central alley of the Tuileries Gardens to a tree, where they were attached by insulators, and then continuing to another post. The wires, covered with insulating material, descended to the ground, and were then laid horizontally along the face of the wall, under the coping, being held in place by small cords attached at intervals to the iron balustrade surmounting the wall. At the spot where the accident occurred one of the wires was insulated for its whole length; but the other was uncovered

Digitized by Google

for a portion of its length, being held by porcelain insulators attached by iron wires. This wire was stretched so tightly that it could not be made to touch any metal near which it passed. One of the unfortunate young men must have fallen and so touched the naked wire, while the other is supposed to have seized it in order to draw himself up the perpendicular wall. In the circuit were twelve Siemens arc lamps, maintained by an alternate-current machine placed in the Court of the Tuileries. Therefore the mean difference (although constantly varying from the maximum to the minimum) between the potential of the two wires must have been about 500 volts, while the difference of tension may be put approximately at 250 volts. After examining several hypotheses as to the manner in which the fatal accident occurred, M. Gariel concludes that death ensued, in both cases, through the passage of a portion of the current through the body, which came in contact with the naked wire at two different points, and thus formed a shunt circuit. Although the portion of current thus passing through the body can only have been a slight fraction of the whole—because the resistance of the human body is enormous compared with that of a 6mm., say ¼in., copper wire, of the slight length represented by the distance between the two points where contact was established—it is far from being proved that the intensity, that is to say the quantity, of the current is a measure of the effect produced. Perhaps, suggests the writer, it is the energy which determines the intensity of the action—that is to say, the product of the quantity of electricity by the fall of the potential. And he believes that the electricity operated indirectly by suspending the action of the nervous system, and thus bringing about a fatal result, because there was no material injury caused by the electricity capable of directly causing death. Professor Brouardel is of opinion that death was instantaneous in the case of Martin, the immediate cause being cessation of the heart's action; and Dr. Bourrot concluded, from a detailed examination, that stoppage of the heart's action, though not so sudden, was also the immediate cause of Kenarec's decease. In the installation generally all the wires were covered, except those placed above the reach of the public, who were excluded by a wire fence from the ha-ha, in which were laid the two conductors, one covered and the other uncovered.

Influence of Heat and Magnetism on the Electrical Resistance of Bismuth.—In a paper on the above subject, by M. A. Righi, published by the *Journal de Physique*, the author, after giving an account of his experiments, arrives at the following conclusions:—"1. The resistance of the bismuth of commerce increases on its being heated between certain temperatures, and dimishes between others. As a rule, the resistance diminishes at temperatures near the ordinary temperature. In constructing the curve of resistance, with the temperatures as abscissæ and the specific resistances as ordinates, a curve in the form of the letter M is generally obtained. There is a maximum at a low temperature, then a minimum, then a second maximum a little before the temperature of fusion is reached, and lastly a second minimum after the changes of condition. When the metal is liquid, its resistance increases regularly with the temperature. 2. The diminution of resistance during fusion (that is to say, its passage from the second maximum to the second minimum), reduces the resistance by almost one-half. 3. The temperatures of the two maximums and of the first minimum vary with the conditions of solidification and cooling of the bismuth. 4. If bars of bismuth be taken, the temperature of which, after fusion, has sunk with progressive rapidity, it will be observed that the two maximums approach one another, the temperature of the first increasing and that of the second diminishing. The first minimum, comprised between the two maximums, gradually disappears; and the resistance curve shows two deflections in its place. Lastly, with a still more rapid cooling, the deflections disappear; the two maximums become merged in one, and the curve of resistance begins to resemble a parabola. The variations of resistance then present only two phases, the first of increased resistance commensurate with the temperature, and the second of diminution, which continues until fusion ensues. For instance, bismuth, when cooled slowly, has shown the first maximum at −40° Cent., the first minimum at 115° Cent., and the second maximum at about 240° Cent. Bismuth cooled very rapidly has given a single maximum at about 50° Cent. To these changes in the resistance curve corresponds a variation of physical characteristics similar to those connected with the hardening and tempering of steel. Moreover, hardened wires melt at a temperature a few degrees above that for annealed wires. 5. Wires obtained by pressure, hot, show curves of the same forms, but higher. 6. In the case of wires obtained by pressure, cold, similar but still higher curves are obtained. 7. The resistance offered by the bismuth of commerce varies, therefore, not only with the temperature, but also with the manner in which the piece is prepared and with the temper (degree of hardness). Thus, the resistance of 0° C., by comparison with mercury, has varied, according to the degree of temper, from 2·4 to 3·5 for the metal when cast, from 3·3 to 4·2 in the case of wires obtained by pressure, at a temperature near that of fusion, and from 3·9 to 6·3 in the case of wires made by pressure, cold. For the metal in a state of fusion, 1·3 has been observed. 8. Bismuth chemically pure behaves like the other metals; it cannot be hardened to any appreciable extent; and its resistance at zero Centigrade has been found to be 1·15. 9. The difference between pure bismuth and that of commerce depends upon the traces of tin which communicate to it properties similar to those owing to which steel differs from iron. 10. By adding to bismuth tin in gradually increasing quantity, the specific resistance increases considerably until the maximum is attained, and then diminishes rapidly. The resistance at zero Centigrade for bismuth, which contains 0·1, 0·23, 0·56, 2, and 10 per cent. of tin, has been found to be respectively:—2·47, 3·47, 4·24, 3·65, and 1·84. These values correspond to the metal cooled slowly. 11. The presence of tin in gradually increasing quantity modifies the resistance curve, in the same manner as a gradually increasing degree of hardness. 12. The resistance of bismuth, whether pure or not, increases when it is placed in a magnetic field. 13. This increase of resistance takes place either when the bar or band traversed by the current in the direction of its length is placed in the direction of the lines of magnetic force, or when it cuts them at right angles; but in the latter case it is much stronger. In the author's experiments the increase of resistance has attained one-eighth of its value. 14. Hardened bismuth is less influenced by magnetism than that unhardened, in so far that the ratio between the variation of resistance and the initial resistance is smaller. In the same way, compressed bismuth is less affected than that which has been cast, and the bismuth of commerce a little less than the pure metal. 15. The variation of resistance is proportional to the magnetic force, except for slight values, for in that case it increases a little more rapidly than the intensity of the magnetic field. 16. The variations of resistance due to magnetism diminish on raising the temperature of the bismuth, at least up to about 100° C.; but M. Righi has not continued his experiments in this direction to higher temperatures.

AN EXTRAORDINARY EXPERIMENT IN SYNCHRONOUS-MULTIPLEX TELEGRAPHY.*

BY PROFESSOR EDWIN J. HOUSTON.

A most extraordinary experiment, which is not devoid of practical bearings, has quite recently been made by Mr. Patrick B. Delany with his synchronous-multiplex telegraphic system, which is now in operation between Boston and Providence, a distance of about fifty miles.

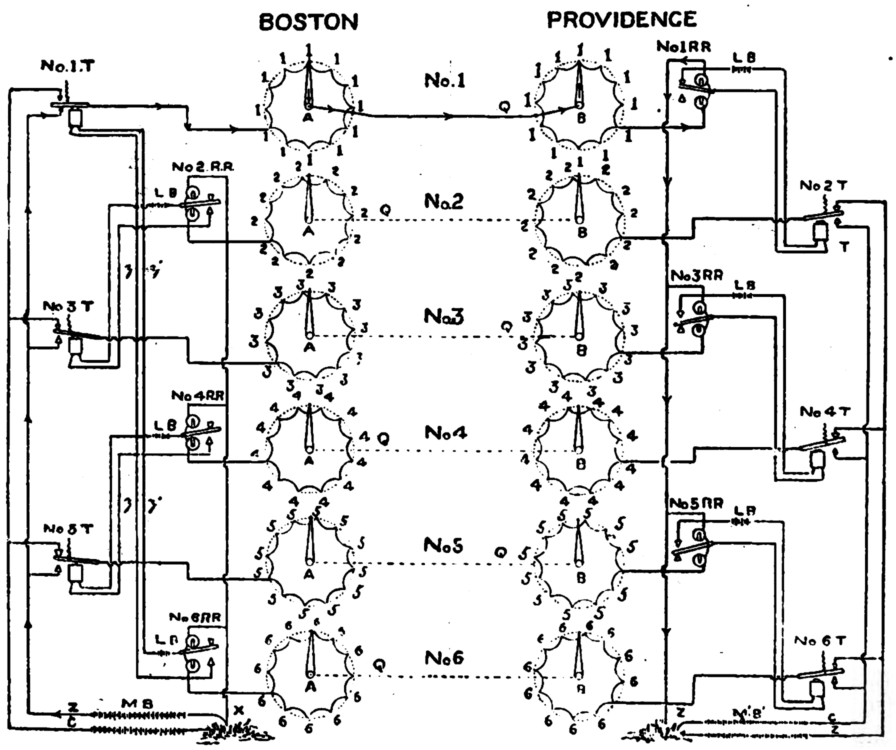
As the experiment about to be described almost challenges belief in its possibility, I desire to state that I have seen it myself, and can vouch for the accuracy of the facts herein stated.

Wishing to try the adaptability to the synchronous system of the automatic repeaters employed by other telegraphic systems, whereby great distances are overcome, Mr. Delany, on three different occasions during the past two weeks, successfully employed such repeaters with his system, the last trial, viz., that on Monday, the 14th of July, being witnessed by myself.

One of the two wires erected by the Multiplex Company between Boston and Providence was divided into six separate and distinct Morse circuits. The first of these circuits, which we will call No. 1, was operated to Providence, at which place the receiving relay on that circuit was connected to the transmitting instrument on No. 2 circuit. In Boston the receiving relay of No. 2 circuit was connected to the transmitting instrument of No. 3 circuit. In Providence the receiving relay of No. 3 circuit was connected to the transmitting instrument of No. 4 circuit. In Boston the receiving instrument of No. 4 circuit was connected to the transmitting instrument of No. 5 circuit. Finally, in Providence the receiving relay or instrument of No. 5 circuit was connected to the transmitting instrument of No. 6 circuit. Under these arrangements, the transmitting instruments at both stations were operated by the receiving relays on the other circuit the same as if worked or operated by an operator; in other words, the six separate and distinct circuits established by the synchronising apparatus between Boston and Providence were arranged so as to form in reality a continuous wire stretched six times between Boston and Providence, with both of its free ends in Boston.

Mr. Delany then transmitted a message on the No. 1 circuit, from Boston to Providence, which was automatically retransmitted from Providence to Boston on No. 2 circuit; again automatically retransmitted from Boston to Providence on No. 3 circuit; again automatically retransmitted from Providence to Boston on No. 4 circuit; again automatically retransmitted from Boston to Providence on No. 5 circuit; and finally automatically transmitted from Providence to Boston on No. 6 circuit. Or, in other words, the message sent from Boston on the first circuit went to Providence, came back to Boston, again went to Providence and came back to Boston, when it again went to Providence and came back to Boston, at which final station it was clearly read by an operator without the loss of a single character, or the slightest impairing of its original clearness, and without the aid of any person except the transmitting operator on the No. 1 circuit in Boston and the receiving operator on the No. 6 circuit in Boston. All this was done over one and the same wire, so that the message travelled in its back and forth journeys between the two cities about three hundred miles, or six times the distance between the two cities.

A reference to the drawing will render the preceding explanation clearer. The synchronised distributing instruments A and B, situated at Boston and Providence respectively, are connected by the single main line Q Q. The line is divided into six circuits, which we will call respectively No. 1, 2, 3, 4, 5, and 6. For the purpose of rendering the connections clearer, these six circuits have been separately represented with the sychronised distributing instruments connected therewith. It will of course be understood that but a single main line, Q Q, furnished with but two distributing instruments, viz., one, A, at Boston, and the other, B, at Providence, exists between the two cities.



This being premised, an inspection of the drawing will show that the main battery, M B, at Boston, split and grounded at X, is connected with the No. 1, No. 3, and No. 5 transmitters, which are respectively connected with the No. 1, No. 3, and No. 5 sextuplex circuits of the single main line Q Q. At Providence the main battery M[1] B[1], split and grounded at Z, is connected with the No. 2, No. 4, and No. 6 transmitters, which are respectively connected with the No. 2, No. 4, and No. 6 sextuplex circuits of the single main line Q Q.

At Providence, the No. 1 receiver is connected with the transmitter of No. 2 circuit, so that a message sent from Boston by No. 1 transmitter would be received by the No. 1 receiving relay in Providence, which, by means of the local battery L B, would have its message repeated by No. 2 trans-

mitter, and sent to Boston over the No. 2 sextuplex circuit of the main line Q Q. This message would be received in Boston by the No. 2 receiving relay, which by means of the local battery L B, connected with No. 2 receiving relay, would have its message automatically repeated by the No. 3 transmitting instrument at Boston, over the No. 3 sextuplex circuit of the main line circuit Q Q, to Providence, at which place it would be received by the No. 3 receiving relay. This relay, in its turn, through the aid of the local battery connected with it, automatically transmits the message through the No. 4 transmitter, over the No. 4 sextuplex circuit of the main line Q Q, to Boston, at which place it is received by the No. 4 receiving relay. This relay, in its turn, through the local battery L B, connected therewith, automatically repeats the message to the No. 5 transmitting instrument, over the No. 5 sextuplex circuit of the main line Q Q, to Providence, where it is received by the No. 5 receiving relay. Finally, this relay, in its turn, through the intervention of the local battery L B, connected therewith, automatically repeats the message to No. 6 transmitter, over the No. 6 circuit to Boston, at which place it is received by the No. 6 receiving relay, by the operator stationed at the Morse instrument connected with that relay. This receiving relay is, in reality, shown in the drawing as connected with No. 1 transmitting instrument at Boston.

The purposes secured by means of this connection will be hereafter explained.

Briefly, the course taken by the message in its journeys to and from the two cities is as follows, viz.:

From Boston, by No. 1 transmitter over main line to No. 1 receiving relay at Providence.

From Providence, automatically repeated to No. 2 transmitter, and sent over main line through No. 2 sextuplex circuit to No. 2 receiving relay at Boston.

From Boston, automatically repeated to No. 3 transmitter, and sent over main line through No. 3 sextuplex circuit to No. 3 receiving relay at Providence.

From Providence, automatically repeated to No. 4 transmitter, and sent over main line through No. 4 sextuplex circuit to No. 4 receiving relay at Boston.

From Boston, automatically repeated to No. 5 transmitter, and sent over main line through No. 5 sextuplex circuit to No. 5 receiving relay at Providence.

Finally, from Providence, automatically repeated to No. 6 transmitter over the main line through No. 6 sextuplex circuit, to the No. 6 receiving instrument at Boston, where it is received by the operator.

It is not necessary, as might be supposed from the drawing, that the characters received on the group of segments comprising No. 1 circuit must necessarily begin to return on the next adjoining segment of No. 2 circuit. Suppose, for example, that a character concluded on the segments of No. 1 circuit, where the trailing contact indicates on the drawing. By the time the armature of the relay has moved in response to this character, and has placed No. 2 circuit in connection with the battery for return transmission, the trailing contact may be on the second or third contact of the No. 2 circuit. This, however, will make no difference, since both the distributing arms are synchronous, so long as the rotating arms pass over two or three of the No. 2 segments, while the armature of the transmitting magnet is in contact with either of the poles of the battery.

When we consider that a message made up of many words, each word containing numerous letters, each letter consisting of numerous separate and distinct characters, and each character, under the synchronous multiplex system, consisting of numerous impulses, was transmitted with certainty over a single wire, back and forth, this number of times, without the slightest interruption the one with the other, the fact almost challenges belief.

While these results may appear almost incredible, what I am about to describe may at first thought seem impossible. I will endeavour, however, to give such a description of this experiment as I saw it actually made, as will persuade the reader that so far from being impossible, its possibility must necessarily follow as a natural result of the exquisitely maintained synchronism secured by Mr. Delany's ingenious inventions.

After having successfully established by actual trial the possibility of the use of repeaters in his synchronous system, Mr. Delany connected the relay of the sixth circuit in Boston, where the message was received, with the transmitting instrument on No. 1 circuit. Now under these conditions, on making one dot on No. 1 instrument, this dot started on its zigzag way, to and from Providence, in the manner already described, only, instead of terminating on the sixth circuit in Boston, as in the previous experiment, the same dot was automatically retransmitted into the first circuit, and again sent on its journeying between the two cities, only on its arrival at the sixth circuit, in Boston, to be again automatically retransmitted over this same winding route.

An inspection of the drawing will render this connection clearer. Instead of the message being received by an operator stationed at the No. 6 receiving relay at Boston, this instrument is furnished with a local battery, L B, and connected by means of the conducting wire $z\,z$, and $z^1 z^1$, with the No. 1 transmitting instrument at Boston. By this means, therefore, the operator at the No. 6 receiving relay is dispensed with, since this receiving relay again automatically sends the signal by means of the No. 1 transmitting instrument on its zig-zag way between the two cities, until the No. 6 transmitter at Providence again sends it to the No. 6 receiving relay at Boston, which again automatically repeats it by the No. 1 transmitter over the six circuits between the two cities, and so on indefinitely.

In this manner, then, the original signal kept passing from city to city, over the different circuits, in perfect rotation, without the intervention of any operator, save the one who first started the signal on its ceaseless journeyings.

Timing the intervals of the returns of the original signal between the two cities over the sextuplex circuits, it was observed that it travelled between Boston and Providence over these six circuits 300 times; or covered the distance between Boston and Providence 1,800 times in each minute, thus making an entire distance of 1,500 miles a second, or 90,000 miles a minute; or for five minutes that a dot was kept going, the original signal in that short time travelled no less than 450,000 miles, or 18 times as far as the entire distance around the world at the equator.

Of course it will be understood that most of this time was taken up by the automatic movements of the armatures of the receiving relays, and the levers of the transmitting instruments. The experimental figures so obtained, however, furnish interesting data as to the rapidity, precision, and certainty with which these masses of matter may be influenced by the electric current.

An observer, noticing the progress of this experiment, and reflecting on the numerous complex conditions requisite for its successful accomplishment, cannot but be singularly impressed by its extreme weirdness. Bearing in mind the exceeding complexity of structure of the synchronous multiplex message, and the necessity for maintaining practically absolute synchronism between the distributing and receiving instruments at each end of the main line, a feeling of incredulity almost unconsciously arises in the listener's mind. Surely this weird traveller must miss some of his numerous connections, and once missed, his journeys are at an end for ever. But when the signals are heard recurring with their automatic regularity, as though tossed to and fro between the cities by a mighty juggler; when they are heard as mysterious whisperings in the air, that follow too rapidly on one another to permit more than a part to be intelligently received, we almost lose sight of the actual conditions of the experiment, and begin to vaguely doubt whether Mr. Delany has not received a visit from Puck, who is bewildered by the rapidity with which he is forced to travel; and when the strange repetitions of the original signal follow one another with such rapidity and regularity as to produce a kind of a prolonged but mysterious murmur, we are almost disposed to believe that these sounds are the plaints of the Wandering Jew, as he ceaselessly speeds on his never-ending journey.

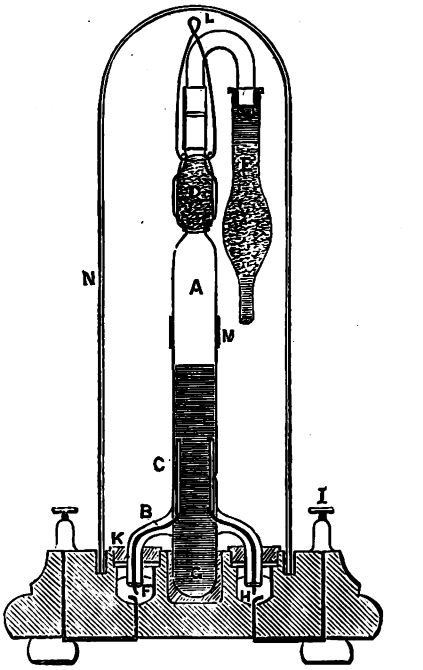
CORRESPONDENCE.

WEIGHT VOLTAMETER, FOR MEASURING ELECTRIC CURRENTS.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: While experimenting with apparatus for measuring electric currents, the idea of doing so by means of a weight voltameter suggested itself as being a method which, at all events, would have the advantage of being constant and unaffected by external agents, as temperature, pressure, magnetism, &c. The following is a brief description of one of the forms which I constructed and experimented with:—

Description.—It consists, as will be seen from the drawing, of a glass tube, A, provided with two arms, B B, containing the platinum wires, which are welded to and support the electrodes C C. The ball D is filled conveniently with pieces of thin glass tube. These serve to keep sparks of water from being mechanically carried over into the drying tube E, containing chloride of calcium. The stand has three circular cavities, F G and H. G holds the bottom of the voltameter, and F H accommodate its arms, B B. G and H contain



mercury, and are connected by copper wires to I. They are fitted on the top with round pieces of sheet rubber, which are fastened to and kept in their places by means of small portable wooden rings K; these rubbers being slit nearly across form valves, which permit of the apparatus being shifted about without loss of mercury, at the same time freely admitting the arms B B. These mercury pools form a cool and reliable connection, and to a great extent do away with the inconveniences and risks attending the direct connecting of the terminals with the platinum wires, as notably the heating of the junctions, and the cracking of that part of the glass into which the wires supporting the electrodes C C are fixed. N N represents a 9in. glass shade.

Taking a Measurement.—The terminals of the wires through which the current to be measured flows are fixed in the binding screws I, and the voltameter freed from air by allowing the electrolysis to proceed for a minute or so. It is now suspended from a balance by the wire L and weighed, then placed in the spring clip M; at a noted time the circuit is completed by pressing the arms B B into the mercury pools F and H. The electrolysis is continued for some minutes, when, at a noted second, the current is broken by raising B B out of the mercury. The voltameter is again weighed; the difference gives the exact quantity of water electrolysed. Now, referring to the known fact that "the amount of water electrolysed in a given time is exactly in proportion to the current strength, and a unit current decomposes ·0000945 of a grain of water in one second."

The current strength, then, in amperes is got by dividing the weight of water electrolysed by the constant ·0000945, multiplied by the time taken, reduced to seconds, thus:

$$C \times t \times \cdot 0000945 = \text{wt. water decomposed},$$

$$\therefore C = \frac{\text{wt. water decomposed}}{\cdot 0000945 \times t}.$$

Let W_1 = original wt. of voltameter,
W_2 = wt. after passage of currents,
T = time in seconds,
C = current in amperes.

Then $W_1 - W_2$ = wt. of water electrolysed,

$$C = \frac{W_1 - W_2}{\cdot 0000945 \times T}.$$

Example.

$W_1 = 52 \cdot 3215$ grams,
$W_2 = 52 \cdot 2199$ „
$T = 600 \cdot$ seconds,

$$\therefore C = \frac{52 \cdot 3215 - 52 \cdot 2199}{\cdot 0000945 \times 600 \cdot} = 1 \cdot 791 \text{ amperes.}$$

NOTE.—This form of voltameter is not adapted for the measurement of very strong currents, but more for laboratory and experimental work, where accuracy and constancy are of first importance. When the water acidulated with sulphuric acid requires renewing the apparatus is held by A in the warm hand, by which means some of the gases or air will be expelled. If now a little water (free from acid) be dropped into D, it will, on removal of the hand, be sucked into A.—Yours, &c.,

Govan. LAURENCE N. LEDINGHAM.

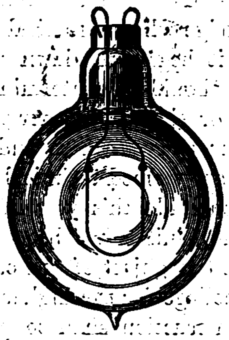
HEALTH EXHIBITION.—VIII.

One of the most enterprising and, as far as we can see, one of the most successful of electrical firms is that of Messrs. WOODHOUSE and RAWSON. This firm not only have about 2,000 of their incandescent lamps illuminating different parts of the Exhibition, but also a stand whereat the apparatus made by the firm is shown in action. Taking the apparatus pertaining to lighting first, or, at any rate, a portion of it, we notice that specimens of the various incandescent lamps made by the firm are exhibited. We know a literary confrère who is generally deputed to report shows for a certain paper. This gentleman maintains that it is impossible to say anything new about many of the exhibits at these shows, and so he takes his previous report, transposes a few words or sentences, it may be adds or subtracts words, and lo! the new report is done. Would that he had to write about incandescent lamps, for what can be said about them that has not been said before? Shall we say that Messrs. Woodhouse and Rawson will supply lamps of all kinds—for medical purposes, for microscopical, telescopical, for ordinary lighting, and for extraordinary lighting? They will supply the ballet girls with star lamps and batteries, or the gentlemen with an incandescent lamp for a scarf pin.

Those who have tested these lamps state that they are economical users of electrical energy, leaving for more extended experience the value of their lasting powers. Figs. 1, 2, and 3 show types of these lamps. The lamps intended for surgical purposes can be had with flexible stems, or stems containing water, so that great coolness can be obtained. One feature of the small lamps is noticeable. The efficiency is so high that the current they take is very small; the bulbs, therefore, unlike those of most small lamps now made, keep so cool that they can be allowed to touch the flesh while surgical operations are being performed. The method adopted for obtaining a variable resistance, so that the intensity of light may be altered at will, is worthy of notice. Two coils of German

Digitized by Google

silver wire are wound spirally around the stem of the lamp; the coils are insulated from each other. A split ring which slides up and down these wires at will forms the contact maker. If the ring is raised to the top there is practically none of the wire in circuit; as it slides down more and more wire is brought into the circuit, till when at the lower end all the wire is in the circuit. One of the great hindrances to the extensive application of incandescent lamps for surgical and dental purposes has been the unwillingness of the members of the pro-



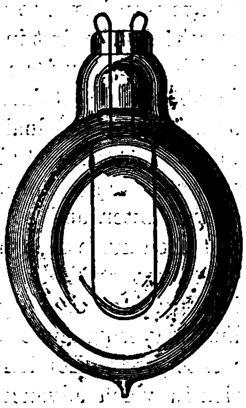


Fig. 1. Fig. 2. Fig. 3.

fessions to have anything to do with a battery which is at all "troublesome." This objection has, we believe, now been met by the introduction of a special arrangement of Leclanché battery, which will serve without recharging for about seven months. The recharging of this type of battery is, as every one knows, of a very simple nature. While this battery is being used for the purpose of every now and again enabling

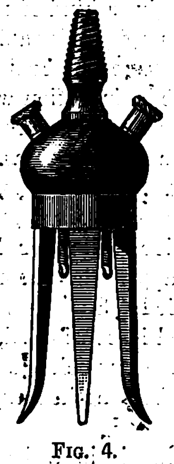

Fig. 4.

the dentist to examine the interior of the patient's mouth, it can at the same time be utilised for ringing the electric bells through a house, the lamps only requiring three cells.

The holder used with ordinary lamps is shown in Fig. 4, and it is claimed that a reliable contact is always made with this holder. It will be seen to be capable of being adapted to ordinary gas fittings, and even when the lamp vibrates a good

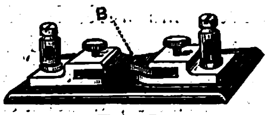

Fig. 5.

deal, as on board ship, the contact is still maintained. Writing just now of lamps for medical purposes reminds us that some excellent medical coils, complete with batteries (chloride of silver) are exhibited. Of wire the samples are numerous; whether the object is electric lighting, telegraphy, telephony, or modest electric bell work, something suitable will be found.

Fig. 5 shows one form of safety fuse used in incandescent lighting. A thin strip of foil, B, is placed upon a piece of vulcanised fibre, the fuse being inserted between the brass clips, as shown. Too large a current fuses a portion of the foil, and thus stops the current to the branch. Fig. 6 shows a safety plug, with box as it appears in practice. Another safety appliance which seems to act with extraordinary accuracy will be illustrated and described separately. Meanwhile we can say its action depends upon the attraction of an electromagnet upon its armature, the armature carrying two arms, which usually dip into mercury cups. When the armature is attracted by the magnet the motion breaks the contact of these arms with the mercury, and hence breaks the circuit. We watched one of these over and over again, acting with a current 4 per cent. greater than the normal current, and we believe they can be set much more delicately than this.

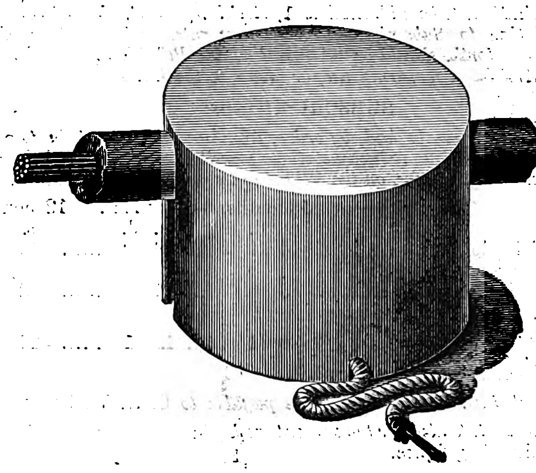

Fig. 6.

Among the minor requisites of electric lighting we may name "terminals," and of these a large variety are shown. The "locking" split terminal is perhaps the newest in design. In this terminal the arrangement is such that when the wire is clamped down the terminal is locked. The arrangement will be better understood by reference to Fig. 7. Messrs. Woodhouse and Rawson also exhibit a new make of cored carbon rods recently introduced. They are said to be superior to those which have hitherto been used, and by a special arrangement in manufacture are made more economically. There are also shown in action voltmeters and ammeters patented by Messrs. Cunyngham, Woodhouse, and Rawson. These have no permanent magnet, but measure the current by the attraction of

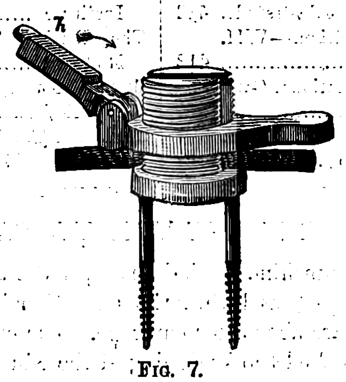

Fig. 7.

an electro-magnet on an armature. They are simple, and the only variable part being a spring similar to that used in Messrs. Siemens' instruments, are not likely to need re-calibration. They seem carefully made and tested.

One of the greatest wants—so say electric light engineers—is a good electric energy meter. Messrs. Woodhouse and Rawson exhibit a very taking meter, invented by M. J. Cauderay, of Lausanne, which will be fully illustrated and described in our next.

There are also various other exhibits shown by their Supply Department, which supplies all kinds of electrical goods not made by the firm.

THE COMING EDUCATIONAL CAMPAIGN.

The waning sunshine reminds us that the time of recuperation is almost past, and that the educational labours of the winter session are about to commence. The end of September might well be called the beginning of the educational year, for it is then that many classes commence anew the various courses held to be necessary for preparation for various examinations. Before touching upon the purely electrical work, it may be well to inquire why so much trouble is taken over the teaching of science. The knowledge obtained is valuable in various ways. With it the imagination yields an inexhaustible fund of gratification, and affords a perpetual source of enjoyment, while the mere acquisition of knowledge is a reward in itself satisfying the innate principle of curiosity which all possess more or less; but the direct aim is to obtain knowledge that we may have power—power which rightly put forth leads to success. Such at least is the direct aim of those who have reached the age of discretion, while those still younger are having a course marked out for them which parents or guardians trust will lead to knowledge, power, and ultimate success. The text of to-day is—How to make money? The leading principle is money, and not that *Qui non recti instituunt atque erudiunt liberos, non solum liberis sed et reipublicæ faciunt injuriam.* (They who do not train and instruct aright their children as greatly injure the State as their offspring.) Twenty years or so ago men began to realise that two parts of a life were spent at school—the first in attending to those time-honoured studies which even now form the basis of our system; and secondly, in obtaining that knowledge which practical life required for application. Gradually it began to dawn upon the public mind that these studies should be conterminous and be completed during school life, or that the former should give place to the latter, and so year by year more and more provision has been made for what are termed technical studies.

A great stride has been made this year in that the central institution of the City and Guilds has been opened. A preliminary programme says the object of the central institution "is to give to London a college for the higher technical education in which advanced instruction shall be provided in those kinds of knowledge which bear upon the different branches of industry, whether manufactures or arts." The teaching at this institute is to be of a different kind to that in the Universities, inasmuch as it is understood more especially "to point out the application of different branches of science to various manufacturing industries." The students who enter the institution are supposed to have already obtained the knowledge of "principles" required, and so far as we can gather, the institution proposes to give a kind of two years' apprenticeship, during which time the pupil, under able and capable professors and demonstrators, will be directed how "theory is to be applied in practice." The intention we fear cannot be carried out in its entirety, and will degenerate more or less into preparation for certain examinations. We do not object to this, for we hold that a brave attempt, even at the impossible, will meet with a fair amount of success. The pupil, after his career at the institution, will enter business with more fully developed powers to apply the theoretic knowledge he has gleaned up to that period. So far as the special subject with which we are concerned is considered, it will be in the hands of Professor W. E. Ayrton, which is a sufficient guarantee that whatever is possible to be done in carrying out the programme will be done.

The electrical student is in a better position than other students in that the subject of electrical engineering is comparatively new, and the literature not very comprehensive. For some time the laboratory at the institution will run fairly with the factory, while this can hardly be the case in other branches of engineering. It must be remembered that Cambridge has for some years had the Cavendish laboratory, originally under the control of Clerk-Maxwell, now under that of Lord Rayleigh. Here, however, the work is of a more theoretical character than at the London Central Institution. The older establishments—King's College and University College, London—have their special classes, under Professor W. G. Adams and Professor Carey Forster respectively, where, perhaps, the studies take a mean between those at Cambridge and Kensington. But not only in London and in the older Universities do facilities for technical studies exist—the country is becoming dotted with younger colleges, which have, under the ablest professors obtainable, to carve out for themselves a niche in the educational system of the country. Newcastle-on-Tyne has Professor Herschel; Durham has Professor Garnett; Leeds, Professor Rucker; Manchester, Professor Balfour Stuart;

Digitized by Google

Liverpool, Professor Lodge; Nottingham, Professor Heaton; Birmingham, Professor Poynting; Bristol, Professor Silvanus P. Thompson; and Cooper's Hill, Professor M'Leod. Then across the border we have the Universities of Glasgow and Edinburgh, with Professor Thomson and Professor Tait respectively; in addition to whom there are Professor Ewing, Dundee; Professor J. Blyth, and Principal Jamieson at Glasgow. Across St. George's Channel we come to Professor Barrett at Dublin, and so on. We should, perhaps, have added the School of Telegraphy, Hanover-square; the Crystal Palace Engineering School, the Hammond Company's School, although these are schools or colleges of a somewhat different character. To these must also be added the hundreds of schools in connection with the Science Department and the City and Guilds Institute. Consider, then, the vast amount of teaching power that is about to commence work for the session, and it will be understood that we ought to obtain indications that good work is being done. Never before has the science crusade been so complete. Not only the pupil but the world at large should benefit from such an array of talent. We hold that it is as much the duty of the professor and the teacher to contribute to the literature of his subject as it is to give certain lectures or lessons. A few sentences written by the late Dr. Todhunter may not be inappropriate here. He says, "Not only may we complain that those who possess such eminent endowments do not employ them, but we have the additional mortification of finding that those who could perform the required work well, though somewhat inferior to the great masters, are discouraged from attempting it by the conviction that at last their performance may be thrown into the shade by utterances from the oracles which have so long been dumb. I wish that those who occupy the highest places in professional science and learning would sometimes reflect on the fact that their eminence may be really an obstacle to the progress of knowledge if they communicate little or nothing themselves, for their reputation naturally deters others from attempting to produce works on the appropriated subjects."

OLD CABLE STORIES RETOLD.—V.

BY F. C. WEBB.

THE CAGLIARI, MALTA, AND CORFU CABLES.

(*Continued from page 366.*)

On 1st November, 1857, therefore, I found myself at Cagliari, and before I proceed further let me point out to those who may have to refer to this town by name for the first time that it is by Englishmen often erroneously pronounced Cagliâri. The French quite as erroneously call it Cagliarî, whereas the Italians—and I suppose they ought to know—call it Câgliari. I was there with Mr. Newall for several days before we started and once or twice afterwards, and I have a kindly—I might say a "lively"—remembrance of the place, in spite of many of the "petites misères de la vie," which abound there. In the first place I never knew any town where church bells kept up such a ringing and clashing. As fast as you thought you had heard the end of a tolling in one quarter a fresh peal would burst out in another. I believe half an hour in Cagliari would drive even a Salvation "Captain" mad. And then the mosquitoes, with no curtains to your bed. But, oh, the chamois! I mean the chamois mentioned by Mark Twain in his "Tramp Abroad." I don't think even Mark Twain could have found such a quarry for chamois as Cagliari. Ladies in Cagliari, so I was credibly informed, at an evening reception, think nothing of taking a "chamois" off another lady's white dress, with a graceful bow and a "scusate," and giving it a pinch, and throwing it aside. The chamois abound all over the floor in the chinks of the red tile pavement. But then this is scarcely to be wondered at. The wash-hand basins are of the smallest possible dimensions, and even this small item it was difficult to get emptied and replenished. After stamping, and fuming, and bawling, a waiter would at last appear, and, sulkily taking the small basin in one hand, would sprinkle the dirty contents over the floor, evidently to feed the chamois. When these small but lively animals are deliberately fed in this manner, how can you expect them not to appear at evening parties? It is these "chamois" that gave me a lively remembrance of Cagliari.

The Cagliarites, I learnt, are very proud of their town, which runs up the side of a hill, bearing a resemblance to Algiers, though I do not know that there is much to boast of in that. I can recollect, however, some mountains on the opposite side of the bay, which at times in the evening presented such lovely tints of purple and blue as would delight the eye of an artist, and puzzle him to reproduce.

Cagliari, I found, was the birth-place of Mario, and I felt infinitely more pleasure in gaining information about that idol of my early days than I am afraid I shall ever feel about the antecedents of any telegraphic or electrical knight or baronet past or present. But this is not the journal in which to write what I gleaned, and I must pass on to the dry and threadworn subject of cable laying.

H.M.S. "Desperate," a screw corvette, was at Cagliari waiting for us. She was told off by the Admiralty to assist us, as the Cagliari, Malta, and Corfu cables were to be laid for the Mediterranean Extension Telegraph Company, which company had a guarantee (as long as the cables were in working order) from our Government. In those days submarine cable expeditions frequently had the assistance of Her Majesty's ships. Lieutenant Watson, who was first lieutenant of the "Royal Albert" flag-ship at Malta, was in temporary command of the "Desperate," and a very nice fellow he, Lieutenant Watson, was. We went round on November 1 in his gig to look at the landing-place for the cable near Cape St. Elias, a few miles from Cagliari.

The "Elba" did not arrive until the 10th, and during the interval of ten days the "Desperate" went out and took soundings, and we made two trips in the "Blazer" to Chia to take tests of the Bona cable. The English Consul at Cagliari, who was a Scotchman, dined with us once or twice, and I recollect that he spoke Italian with a strong Scotch accent, which was very peculiar. Yet he had been Consul there for many years, and the Italians could never make out why he had that peculiar pronunciation. The "Elba" had had a fearful passage across the Bay. She had lost three boats and the carpenter, and part of her bulwarks. There were no Plimsoll marks in those days, and the ship was very deeply laden—in fact too deeply, for when she arrived after burning all her coal she had only fifteen inches free board. The chief officer described to me that the covered passage on each side of the deck house was at times completely filled with green sea. Had a hatch-cover given way she must have gone down like a stone. The crew had at one time begged of the captain to turn back, but the old man stuck to his orders and came on. We did not consider it safe to go to sea and have the hatch covers off without taking first thirty miles of deep sea cable out of her aftermost hold to lighten her. We got the brake off the "Blazer" by means of the "Desperate," and then the "Elba" went alongside the "Desperate," and took it in. The coils in the "Elba" were all circular wooden structures, with cones and rings. The coils were as follow:—

	D.S.	S.E.
Fore	388	—
Main	492	—
After	10	9·5
	—	7·5
Aftermost	70·	—
	960·	17·0
	17	
Total	977	

The deep sea weighed nearly a ton to the mile, but I forget

Digitized by Google

what the shore end weighed, probably about five tons to the mile. There was no picking up gear or bow sheave, but there was a dynamometer, which answered fairly well. A rough sketch of this is given in the report of what I said at the discussion of one of the papers on submarine cables at the Telegraph Engineers, but I forget the date. We anchored close to landing place on the 13th. When we were placing the buoy down a few days before, I had constantly urged its being placed further out than even where Lieutenant Watson thought safe—and this was further out than Mr. Newall wanted it—so as to provide for the wind coming on the land and the ship tailing in, and I shook my head when Lieutenant Watson at last said, "Well, Webb, surely here will do," and down went the buoy. Events proved I was right. It was not far enough out. We got 500 yards of shore end into boats, and commenced landing end, but ran short and got some slack from ship, and at last got end ashore at 8 p.m. in the dark, and *joined it on to land wires*—a horrible thing to do, but no hut had been provided. This was a sin we had never perpetrated on any of the work I did for the Electric Telegraph Company. We laid at anchor all night, with our head in towards land, the wind being off the land. At daylight we under-run cable to shore to see there were no kinks and found all right. Weather then looked bad, and we determined to wait a bit, and Mr. Newall and Mr. Liddell went to Cagliari. They had not gone long before the wind came on the land, and the ship tailed round and struck on the rocks. The "Blazer" saw what had occurred and came down to us, and we got a hawser out to her. The ship hung fast for twenty minutes and then started off. We paid out a bit of slack we had on the forecastle, but ran short, and as bight went over got some kinks in. Got them on board and cut cable. Tested to shore and found dead earth. Disconnected land lines. Still dead earth. Under-run off and found ship had grounded on the cable and smashed it flat. Cut cable and hauled end from ship and made splice in boat. All this trouble and a narrow squeak of losing the ship through anchoring too close in order to save the trouble of landing a few fathoms more cable in boats.

(TO BE CONTINUED.)

LITERATURE.

Dynamo-Electric Machinery: A Manual for Students of Electrotechnics. By SILVANUS P. THOMPSON, B.A., D.Sc., &c. [London: E. and F. N. SPON, 1884.]

FIRST NOTICE.

The steam engine has a distinct literature of its own. It seems that a new implement of torture to rack the brains of the scientific world has been found in the shape of dynamo-electric machinery, demanding and, we may say, deserving a literature of its own. Professor Thompson is the first to contribute a text book to this literature, and probably never in the whole history of the applied sciences has a more satisfactory first step been made. The author has long been known as a careful and conscientious electrical student. His Cantor lectures upon this subject proved that clearness of statement and breadth of grasp of the subject were combined in the author, indicating his fitness for such work as he has now completed. This work is based upon the Cantor lectures, and the author's aim in adding and rearranging "has been to make the work a manual for students of electro-technics, for whom no text book of this branch of science has hitherto been available" (preface). Acknowledgment is made to those who have assisted the author in any way, and then, still in the preface, he points out the recent growth of this branch of knowledge, and the consequent liability to err, asking for further information from those who are in a position to give it. Of the mathematical work of Clausius concerning the theory of the dynamo, we read "This mathematical *tour de force* is, however, fatal. The new constants have no physical significance whatever, and simplicity is gained by sacrificing their utility. The mathematical triumph remains a Pyrrhic victory."

The true mathematical theory is the work of the future, for its true basis is as yet wanting. The field for practice is as open and extensive as the field for theory, and "as with the steam engine so also with the dynamo machine, there will probably be a constant and progressive evolution, finally settling down upon two or three typical forms, which will survive the many comparative crude machines which as yet have taken shape and come into active service."

In this our first and preliminary notice of a work opening up an entirely new field we shall content ourselves with merely describing what the book contains without entering at all into the value of the methods adopted or the correctness of the statements. In fact, we want simply to tell readers what they may expect to find in the work, though, at the same time, we may go so far in criticism as to say that our examination of it has led us to the conclusion that it is well worth reading, and so far as electrical literature is concerned will be *the* work of the season. Physical, Algebraical, Geometrical: the dynamo machine has been viewed from these three points of view. We have firstly brought before us the methods employed in exciting the field magnets, then the action of induction, with a classification of dynamos based upon inductive action. The armature is described, from the ideally simple to those used in practice, and their connection with the "collector." The physics of armatures and field magnets are considered, in which might really be included the chapter on the government of dynamos. Chapters VII.—IX. inclusive are almost wholly devoted to the description of *typical* dynamos. We have italicised the word typical, because the author has exercised a wise descretion in leaving out descriptions of historical and obsolete dynamos and others that really possess no individuality except to the inventors and patent agents.

Chapters X.—XVI. deal with the algebraic theory of the dynamo, then follow eight chapters discussing the geometrical theory of the dynamo. So far as we know, this is the first time any systematic attempt has been made to deal with geometrical matters in connection with dynamos. Of course, the method has been frequently adopted in isolated papers, but here we have it considered more as applicable to a whole theory than to mere parts. We must again mention that we are not now dealing critically with the text, and in passing over without comment the notation adopted and the introduction "gauss," to express unit of field intensity, it must not be taken that we agree with either notation or nomenclature. The remainder of the book deals with the testing of dynamos, together with various appendices referring to special points. A capital index is furnished, and the book is admirably illustrated and printed. One feature which calls for our thanks is that the author has had no hesitation in repeating illustrations when the repetition of the illustrations would save the reader trouble in referring back.

TELEGRAPH AND TELEPHONE WIRES IN NEW SOUTH WALES.—Mr. E. C. Cracknell, Superintendent of Telegraphs, has designed an improved plan for carrying telegraph and telephone wires overhead, and the Government have approved of the design, and accepted a tender from Messrs. D. and W. Robertson for the supply of the ironwork necessary for testing the value of the design in Sydney. As the wires on the telegraph posts in Sydney are very numerous, and the necessity to adopt some other method of carrying the wires is very urgent, Mr. Cracknell has devised a scheme by which the wires will be bunched together in cables. The plan consists of erecting an ornamental frieze on cast-iron standards, cable racks being fixed at the rear of the frieze as places in which the cable may rest. Each cable will contain 50 wires, and in the design for which a tender has been accepted racks are provided for 400 wires. The number of racks, however, may be increased indefinitely. When, in the erection of the frieze and standards, the intersection of a street is met with the cables will be carried through underground pipes below the gas, water, and sewerage, and a plan will be adopted by means of an endless wire to enable the officials of the Telegraph Department, at any time that it is necessary, to have new cables drawn into the underground pipes at the intersection of streets.—*Colonies and India.*

REPORT OF COMMITTEE ON GAUGE FOR THE MANUFACTURE OF SMALL SCREWS.*

BRITISH ASSOCIATION, MONTREAL, 1884.

1. Since the presentation of its first report on a gauge for small screws at the meeting of the Association held in 1882 at Southampton, this committee has further examined into the recommendations there made, with the result that they now have to propose some important modifications, the general effect of which will, it is felt, be to materially facilitate the introduction of the system.

2. The want of unanimity on the part of the committee referred to in paragraph 7 of that report arose mainly on the question as to whether the inch or millimetre should be taken as a unit of measurement. It is evident that if either is rigidly adhered to, and in any way employed in the nomenclature of the screws, as, for example, in specifying the diameter, pitch, or threads per inch or per mm., the same dimensions could not be expressed in whole numbers in the other unit, and thus a material obstacle would be at once introduced to its general adoption.

PROPOSED SMALL SCREW GAUGE.

Number.	Nominal Dimensions in Thousandths of an Inch.			Absolute Dimensions in Millimetres.	
	Diameter.	Pitch.	Threads per inch.	Diameter.	Pitch.
I.	II.	III.	IV.	V.	VI.
25	10	2·8	353	0·25	0·072
24	11	3·1	317	0·29	0·080
23	13	3·5	285	0·33	0·089
22	15	3·9	259	0·37	0·098
21	17	4·3	231	0·42	0·11
20	19	4·7	212	0·48	0·12
19	21	5·5	181	0·54	0·14
18	24	5·9	169	0·62	0·15
17	27	6·7	149	0·70	0·17
16	31	7·5	134	0·79	0·19
15	35	8·3	121	0·90	0·21
14	39	9·1	110	1·0	0·23
13	44	9·8	101	1·2	0·25
12	51	11·0	90·7	1·3	0·28
11	59	12·2	81·9	1·5	0·31
10	67	13·8	72·6	1·7	0·35
9	75	15·4	65·1	1·9	0·39
8	86	16·9	59·1	2·2	0·43
7	98	18·9	52·9	2·5	0·48
6	110	20·9	47·9	2·8	0·53
5	126	23·2	43·0	3·2	0·59
4	142	26·0	38·5	3·6	0·66
3	161	28·7	34·8	4·1	0·73
2	185	31·9	31·4	4·7	0·81
1	209	35·4	28·2	5·3	0·90
0	236	39·4	25·4	6·0	1·00

3. It should be pointed out, however, that it has hitherto been the common practice to designate such small screws as the committee alone is considering, not by any specific dimension, but by a number, which as a rule is arbitrarily chosen and does not of itself form a guide to the size of the screw. Considering, then, that the unit of measurement is only indirectly connected with the subject of a screw gauge, the committee has felt that the two units might be reconciled so far as relates to such a subject, and that thus one important difficulty would be removed.

4. The manner in which the series of screws adopted lately by Swiss manufacturers is correlated has been well explained in the previous Report, and full explanations are given in the two original pamphlets to which reference is there made.* The diameter D is related to the pitch P by the formula $D = 6 P^{\frac{6}{5}}$, (1) all measurements being in millimetres, and P having successively the values 1 (or $0·9^0$) mm., $0·9^1$ mm., $0·9^2$ mm., $0·9^3$ mm. . . . $0·9^n$ mm.

Thus *n*, the index, becomes a convenient designating number for the screw, and the formula (1) may be expressed $D = 6 (0·9^n)^{\frac{6}{5}}$, where $P = 0·9^n$.

5. The pitch of any screw can be at once ascertained from its designating number by raising 0·9 to the power indicated by that number, and from this pitch the diameter is directly deducible by the formula (1), so that the number (*n*) given in the first column of the table, by which a screw is known, is intimately related to all its dimensions.

6. It is evident that, by taking the exact successive powers of 0·9 for the pitch, complex numbers would soon be arrived at. Such dimensions would, however, involve a degree of accuracy which is hardly attainable in practice, and it may be shown that, with two significant figures employed throughout to express the pitch, the degree of accuracy likely to be attained in screws of the kind under consideration is reached. Relying on this fact, the series of pitches given in Column VI.† is arrived at for screws ranging from ·236in. to the smallest in use, 0·01in. in diameter, in place of the mathematically exact series obtained by raising 0·9 to successively higher powers.‡ And this is the series which the committee recommends for adoption.

7. Viewing the numbers thus obtained in the first place merely as a graduated series of pitches, and ignoring the unit of measurement, it may be admitted that the series of powers of 0·9 from which they are deduced is perhaps as good a one as can be suggested for the purpose, and it is found to very closely correspond with experience. Thus Column VI., which gives the nearest approximation to this series that is practically required, is well adapted for such a system of screws. It is to be observed that in selecting a series of pitches there are three simple alternatives to choose from:—(1) to have a constant arithmetical difference between successive pitches, in which case either the pitches of small screws would differ by too great an amount, or those of the larger screws by too small an amount; or (2) to divide the entire range into sets, in each of which the differences are constant. The third alternative is to take successive powers of some other simple fraction, for example 0·8, but such a series would not so well correspond with the screws most generally employed.

8. Accepting this series, it may, however, be urged that it should be based on some aliquot part of an inch rather than on the millimetre. But any advantages to be gained by such a modification are inappreciable, for an examination of the numbers at once shows that they are for the most part awkward fractions of a millimetre, and the metric system of measurement thus enjoys no advantage in this respect over that based on the inch. From the point of view of interchangeability, however, of screws to be manufactured in this country and on the Continent, it is essential that the same basis of measurement of the pitch be everywhere adopted;

* Second Report of the Committee, consisting of Sir Joseph Whitworth, Sir W. Thomson, Sir F. J. Bramwell, Mr. A. Stroh, Mr. Beck, Mr. W. H. Preece, Mr. E. Crompton, Mr. E. Rigg (secretary), Mr. A. Le Neve Foster, Mr. Latimer Clark, Mr. H. Trueman Wood, and Mr. Buckney, appointed for the purpose of determining a gauge for the manufacture of the various small screws used in telegraphic and electrical apparatus, in clockwork, and for other analogous purposes.

* *Systématique des vis Horlogères*, by Professor M. Thury, Geneva, 1878. *Notice sur le Système des vis de la Filière Suisse*, Geneva, 1880, by the same author.

† It may be incidentally pointed out here that this series comprises two screws, with pitches of 1 mm. and 0·25 mm., which would be serviceable for micrometers.

‡ Sir Joseph Whitworth's gauge, in general use, ends at ¼in., where this commences.

Digitized by Google

because, having agreed upon only two significant figures on one basis, terminal decimals are obtained, but such terminable decimals could not be accurately expressed by two significant figures on the other basis of measurement.

9. Again, it is to be remembered that the use of metric measurement to designate the pitch need not inconvenience English manufacturers who are desirous of cutting the screws in their lathes. For, as has recently been pointed out by Mr. Bosanquet,* it is easy to cut a thread whose pitch differs from one millimetre by an amount which may for all ordinary purposes be neglected ($\frac{1}{55,300}$th), with a guide screw based on the inch by the addition of a wheel of 127 teeth, and thus the series here recommended could, on the rare occasions that it became necessary, be originated on any screw cutting lathe provided with the requisite wheels. But the committee do not consider it needful to specially contemplate facility in the originating of the threads, as the screws under consideration are made in a plate or by the aid of dies, and manufacturers on a large scale would be provided with a special lathe for the purpose.

10. Whether the inch or millimetre is adopted as a unit of measurement the series of pitches for these small screws becomes an ideal rarely attained in practice, for with screws tapped in a plate, or even with dies, the exact pitch aimed at will often not be attained; neither is it safe to assume that two screws, tapped in corresponding holes in different plates, will have precisely the same number of threads per inch. This is especially the case with the smaller screws, as may be proved by accurately measuring the pitches of several tapped in holes that are nominally alike.

11. The fact here stated affords a reason against extending the practice of designating screws by their number of threads per inch, already sometimes resorted to in the case of large screws, to the screws now under discussion. It is found that screws, nominally alike, frequently differ in this respect by as much as five or even ten threads in the inch, nor need this occasion surprise when it is remembered that the screw-plates employed must expand to varying extents in the hardening, that the hole is often not more than three or four threads deep, and that the pressure applied by hand must vary considerably. Such a nomenclature would thus involve the use of inconveniently high numbers to express a minute degree of accuracy but seldom attained, while they convey but little real information, since mere examination would not enable any one to distinguish between, say, a screw of 169 and 181 threads per inch.

12. The series of diameters must next be considered. Before the formula $D = 6\,P^{\frac{6}{5}}$ was adopted, it was ascertained by the minute examination of about 140 small screws that the series very closely corresponds with those recognised as good in the trade, and the screws made in the new plates, known as *filières Suisses*, which the committee have had an opportunity of examining, appear to them to be well proportioned in this respect. The series of diameters, like the pitches, are expressed by two significant figures in each case, as the values for D deduced from the formula (1) are necessarily indeterminate in most cases. These diameters are given in millimetres in Column V., and their nearest equivalent in thousandths of an inch in Column II. As the committee considers that these screws are well proportioned as regards pitch and diameter, and approves the formula (1) being take as a basis, it is led to recommend this series of diameters being adopted in conjunction with the pitches already discussed. It has been suggested to the committee that the introduction of such a system into general use in this country might be facilitated by punching against each hole in the screw-plate, side by side with the designating number, as given in Column I., the approximate diameter of the screw made in it, as expressed in thousandths of an inch (Column II.), as these numbers would convey a meaning to English workmen more definite than the numbers in Column I. or V. The committee sees no serious objection to such a course; but it should be remembered that screws have hitherto always been recognised by a number seldom higher than 25, and it may be questioned whether any substantial advantage is gained by substituting such high figures as are involved in the expression of the diameters.

13. It will be seen that the series here recommended gives 26 screws for the range from $\frac{1}{4}$-inch to the smallest in use. Comparing this number with those of two of the best systems commonly met with—namely, the Latard (Perrelet et Martin) and Bourgeaux plates, we find that—

For a range of 21 sizes of watch screws on the Latard plate, this gives 15
For a range of 23 sizes of watch screws on the Bourgeaux plate, this gives.. 17
For a range of 36 sizes of clock screws on the Latard plate, this gives 23

The entire series is thus less than that of well-established plates, and cannot, therefore, be considered greater than the requirements of practice demand; while the fact that the watchmakers (who probably require the most extensive assortment of screws) in Switzerland have accepted it, confirms the committee in its opinion that the series is not deficient in this respect.

14. It remains to consider the form of thread. There are so many practical points to be taken into consideration in discussing such a question that it becomes specially useless to rely much on theory for guidance, and the divergence observable among the forms adopted by different manufacturers is thus very great.

The most important points to be borne in mind in its selection are:—

(1) The threads must be easily cut with the class of screw-cutting tackle ordinarily met with in workshops.

(2) The strength of the threads on the male and female screws must be so correlated that the liability of either to strip is a minimum.

(3) The resistance of the core to torsional stress when force is applied in rotating the screw must be a maximum.

(4) The friction should be as small as possible, in order to reduce wear.

15. In regard to the first of the above conditions it is to be observed that very many of the screws considered by the committee are usually made by means of a plate, in which are round, tapped holes. Such a hole forms a thread by causing the metal to "flow" from a space towards a thread, and its action is obviously of quite a different character from the cutting action of dies or of a chasing tool. In the case of plates with notched holes the cutting and squeezing actions are combined.

16. As bearing on the second condition, it is evident that, as the strength of the threads depends so essentially on the materials of which the screw and nut are made, and these are very varied, no precise and invariable rule is attainable. If strength were the only point to be considered, a purely triangular form without any rounding would be best, contact being assumed to take place over the entire surface. But in practice it is impossible to secure such perfect contact, and it becomes needful to round off the crests from all the threads; and this rounding is the more necessary as the screws are smaller and irregularities in the manufacture become relatively more marked. This modification is also necessary in view of condition (1) already considered.

17. The third point—namely, the resistance of the core to torsional stress—is determined primarily by the depth of thread. If the sectional area of the ring cut away is less than that of the core, the probability of the latter breaking across may be regarded as approximately equal to that of the threads stripping; but it is impossible to maintain a constant ratio, as such a condition would require the thread to be so fine in the case of small screws that there would be no sufficient hold in the nut. Thus in the very smallest screws (those below ·030in. in diameter) the ratio $\frac{\text{area of core}}{\text{sectional area of thread}}$ is less than 1, and it gradually increases till a proportion of between 2 and 3 is attained.

* *Phil. Mag.* (Fifth Series), Vol. XV., pp. 217, 438.

Digitized by Google

18. Condition (4) is evidently best satisfied by a square thread. Such a form is, however, impracticable in the case of the small screws under consideration, but it is obviously approximated to according as the angle of a triangular thread is made less and the rounding greater.

19. The angles that have been adopted in practice show, as might be expected, considerable variation. On the one hand, an angle of 60° is rarely exceeded, the thread being thus derived from the equilateral triangle, and, on the other hand, 45° may be taken as the lower limit.

20. The depth of a thread is evidently a function both of its angle and of the amount of rounding at the top and bottom. It may conveniently be expressed as a fraction of the pitch (taken as unity). In the case of the small screws in general use the mean value of the depth thus expressed is found to be 0·563, the maximum being 0·771, and the minimum 0·311. It is evident that any increase in the depth beyond what is essential will materially and needlessly increase the difficulty of manufacture when a screw-plate is used; at the same time the depth must not be too much reduced on account of the greater tendency of the thread to strip. It is further important that the additional torsion involved in cutting a deep thread, which materially increases the risk of tearing the metal across, should not be lost sight of.

21. The committee, after comparing together a large number of different forms of thread, some of which are in actual use, while others have only been suggested, were much tempted to recommend the Whitworth thread for adoption by the British Association, because it is so well known in this country, and experience has proved indisputably that it is excellent when employed for engineers' bolts, &c. But, as appears from sections 16 and 18, in the case of small screws the tendency should rather be to increase the rounding on account of the difficulties of manufacture, and the depth of the Whitworth thread is 0·64 of the pitch, which is considerably in excess of 0·563, the average adopted in practice. The Whitworth thread is, moreover, characterised by a greater angle than is usual in small screws.

22. The advisability of modifying the form of thread of small screws as compared with those of greater diameter is fully recognised by the Swiss Committee, their thread for the former having an angle of 47½°, while that for the latter is 53°, nearly the same as that of the Whitworth thread. In the case of small screws made in the *filière Suisse* the crest of each thread is rounded off with a radius equal to $\frac{1}{6}$th the pitch, and the hollow with $\frac{1}{5}$th the pitch. The actual depth is 0·60 the pitch, somewhat less than in the Whitworth thread.

23. While approving the general form of thread here described, this committee could not but feel that the difference in the roundings ($\frac{1}{6}$th at the top and $\frac{1}{5}$th at the bottom) was unnecessary. Looking, moreover, to the fact that very many of the screws of the sizes now under consideration are for electrical and telegraphic instruments, and, therefore, may be of brass, and that, with threads of such dimensions, it is impossible for the eye to ascertain whether a given screw satisfies the required conditions in regard to such small differences between the crest and hollow of the thread, the committee feels that an equal rounding ($\frac{2}{11}$ths of the pitch) at the top and bottom would be preferable. This would maintain the angle of thread and the depth the same—namely, 47½° and $\frac{3}{5}$ths of the pitch respectively.

24. Having now discussed the three main points that require to be considered in any system of screws—namely, the pitches, diameters, and form of thread, it seems desirable to enumerate briefly the recommendations at which the committee has arrived. These are :—

(1) That the series of diameters for screws from $\frac{1}{100}$th inch to $\frac{1}{4}$th inch be that given in millimetres in Column V., the nearest thousandths of an inch being given in Column II.; these diameters being the series calculated by making P, in the formula $D = 6 P^{\frac{6}{5}}$, have in succession the following values :—

1 (or $0·9^0$) mm.; $0·9^1$ mm.; $0·9^2$ mm.; $0·9^3$ mm.; . . . $0·9^n$ mm.

Only two significant figures are taken to represent the diameters.

(2) That the pitches of these screws be the above gradually decreasing series, each pitch being $\frac{9}{10}$ths of its predecessor, but that only two significant figures be used in their expression. The series thus obtained is given in Column VI.

(3) That in view of the desirability of securing a system of small screws, international in its character, English manufacturers of screws, screw-plates, &c., adopt the exact pitches given in millimetres in Column VI., which, as explained in par. 9, can, if required, be originated on an English lathe. Further, in view of the fact that small screws and screw-plates, while nominally alike, will not unfrequently differ considerably as regards their number of threads per inch, the practice of designating such screws by their number of threads per inch should not be adopted. For reference, however, the approximate number of threads per inch, as calculated from the pitch given in Column VI., are given in Column IV.

(4) That the designating numbers given in Column I., being the indices of the powers to which 0·9 is raised to obtain the pitch, be punched against each hole in the screw-plate, and that, if thought desirable, its diameter in thousandths of an inch (Column II.) might be punched side by side with this number.

25. In his "Systématique des vis Horlogères," Professor Thury has done for the small screws used by watch, clock, and scientific instrument makers what was done forty years ago by Sir J. Whitworth for the larger screws used by engineers; and, like the admirable system introduced by the latter, the scheme here advocated is based on the data obtained by measuring the several dimensions of many screws accepted by practical men as being well proportioned.

26. The committee has had an opportunity of examining both screws and screw-plates (for the smaller screws) made on this system, which, it is convinced, will satisfy all the demands of practice. The committee can therefore confidently recommend its adoption by the British Association, subject to the slight modification discussed in paragraph 23; and it feels that an important incidental advantage would be the support it would at once receive on the Continent, and the consequent increased rapidity with which it might be expected to come into general use; for it cannot be doubted that its recognition by so important a body as the British Association would have considerable influence in establishing the system abroad.*

THE CITY AND GUILDS OF LONDON INSTITUTE.

Preliminary Programme of the Central Institution.

The object of the Central Institution is to give to London a college for the higher technical education, in which advanced instruction shall be provided in those kinds of knowledge which bear upon the different branches of industry, whether manufactures or arts. The institution is intended to afford practical scientific and artistic instruction which shall qualify persons to become (1) technical teachers; (2) mechanical, civil, electrical, chemical, and sanitary engineers, architects, builders, and decorative artists; (3) principals, superintendents, and managers of manufacturing works.

The main purpose of the instruction to be given in this institution will be to point out the application of different branches of science to various manufacturing industries; and in this respect the teaching will differ from that given in the universities and in other institutions in which science is taught rather for its own sake than with the view to its industrial application. In order that this instruction may be efficiently carried out, the institution, in addition to the lecture theatres and class rooms, is fitted with laboratories, drawing offices and workshops; and opportunities will be afforded for the prosecution of original research, with the object of the more thorough training of the students, and for the elucidation of the theory of industrial processes. The courses of

* The recommendation for the appointment of this committee having failed to reach the Committee of Recommendations at Southport in time to allow of its sanction by the General Committee, the Council at their meeting on November 6th, 1883, requested the committee to continue their labours, and undertook to recommend to the General Committee at Montreal that this report be printed among the reports.

Digitized by Google

instruction will be arranged to suit the requirements of—1. Persons who are training to become technical teachers. 2. Persons who are preparing to enter some industrial or professional career. 3. Persons who desire to attend special courses, with the view of acquainting themselves with the scientific principles underlying their work.

Students intending to go through the complete course of technical instruction with the view of subsequently obtaining a diploma, will be required to pass an entrance or matriculation examination, which will include mathematics, pure and applied, chemistry, physics, drawing and French or German. The fees for the complete course of instruction to be pursued by a matriculated student will be £30 per annum, payable in advance. The fees for separate courses, including laboratory work, will be from £10 to £30. Students wishing to attend separate courses will be required to satisfy the professors that they possess sufficient knowledge to follow such courses.

The hours of attendance at the institution will be from 9:30 a.m. to 5 p.m. on five days a week, with a short interval for luncheon. The first session of the institution will commence on Monday, January 12th, 1885, and the fee for students then admitted will be £20 till the close of the session.

The entrance examination will be held on Tuesday, December 16th, and on the three following days, and will be open to all persons who are not less than 16 years of age at the date of the examination. On the results of the examination, the following scholarships will be awarded to students who are prepared to attend the complete course of instruction in any one department, provided that the merits and circumstances of the candidate justify the committee in making the award.

(1.) The Clothworkers' Scholarship of £60 a year, tenable for two years and renewable for a third year, entitling the successful candidate to free education.

(2.) The Siemens Scholarship of £50 a year for three years founded by Lady Siemens in memory of her husband, the late Sir William Siemens, LL.D., F.R.S. This scholarship will be competed for in October, 1885.

(3.) The Royal Albany Scholarship of £50 a year, for three years, founded by by the Corporation of London in memory of the late Prince Leopold, Duke of Albany.

(4.) Two Mitchell Scholarships of £30 a year, for two years, one with, and one without, free education, to be awarded to candidates who have attended a public elementary school within the City of London, or whose parents are, or have been, resident or engaged in some trade or occupation within the City of London.

Further particulars of the conditions of the tenure of these scholarships may be had on application.

Arrangements will be made for special courses of lectures and laboratory work to commence in June, 1885, and to continue for six weeks, adapted to the requirements of teachers of classes in technology registered by the institute. The instruction to be given in these courses will comprise laboratory work under the direction of the professors of the institution, and special lectures on the technology of particular industries to be given by the professors, or by the institute's examiners, or by other qualified persons. Registered teachers of the institute will be admitted, on the recommendation of the director, to these summer courses, without payment of any fee.

These courses will be open to a limited number of other persons who can satisfy the professors that they are qualified to profit by the instruction. The fee for persons other than registered teachers admitted to these courses will be £2 for a course of 20 lectures and £5 for the corresponding laboratory course.

Persons wishing to become students of the Central Institution must send in, not later than December 1st, 1884, a written application, accompanied by a certificate of birth and a short account of their previous training. Candidates for the entrance examination will be required to pay a fee of £1, which in the case of those who succeed in passing will be deducted from the amount of fees payable on entrance; in the case of candidates who fail to pass, the fee will be retained, but the candidate will be admitted to any one subsequent examination without payment of an additional fee. In the case of candidates obtaining a scholarship with free education the fee will be returned. A diploma stating the industry or branch of engineering in which he is qualified will be awarded to the student who shall have gone through a complete course of instruction as laid down in the programme, and shall have satisfactorily passed the several examinations. This diploma, which will be given, on the recommendation of the professors, will entitle the student to the associateship of the institute. The fellowship will be conferred upon those who, having obtained the associateship, shall have spent some time in actual practice, and shall produce evidence of having done some original and valuable research work, or of having otherwise contributed to the advancement of the industry in which they are engaged. The Siemens Medal, founded by Lady Siemens in memory or her husband, the late Sir William Siemens, LL.D., F.R.S., will be annually awarded to the student of greatest merit in the department of electrical engineering.

The professors in charge of the several departments are :—Chemistry : Professor H. E. Armstrong, Ph.D., F.R.S. ; Engineering: Professor W. C. Unwin, B.Sc., M. Inst. C.E. ; Mechanics and Mathematics : Professor O. Henrici, Ph.D., F.R.S. ; Physics: Professor W. E. Ayrton, F.R.S., A.M. Inst. C.E.

The following are the particulars of the entrance or matriculation examination which candidates who desire to qualify for the diploma will be required to pass :—

1. Mathematics and Mechanics.—*Arithmetic* : The ordinary rules of arithmetic, decimal fractions and calculations with them ; extraction of square root ; use of logarithmic tables. Special value will be attached to exact calculations with decimals, especially by abridged methods. —*Algebra* : The ordinary rules of algebra; determination of common factors. Simple equations, with one or more unknown quantities. The elements of permutations and combinations ; quadratic equations ; arithmetical and geometrical progression ; notation and use of indices and logarithms.—*Geometry*: The first four books of Euclid's "Elements" or the subjects thereof; the theory of similar figures (Eucl., bk. VI.) ; planes and lines in space, their intersection and the angles they form with one another. —*Trigonometry* : The measurement of angles ; the definitions of trigonometrical ratios and their relations ; the elementary formulæ connecting the trigonometrical ratios of two or more angles ; the solutions of plane triangles, including the determination of their areas. Determination of heights and distances. *Mechanics* : Motion of a point ; velocity and acceleration, their units ; their composition, their moments. Quantity of matter and quantity of motion ; inertia, momentum. Mass, force, weight ; their measures. Moment of force and of momentum. Rectilinear motion under the action of gravity. Work and energy ; their units. Composition and resolution of forces at a point and in a plane ; equilibrium of forces at a point and in a plane. Special importance will be attached to clearness in the conception of mechanical quantities.

2. Mechanical Drawing.—*Plane Geometry* : Construction of scales. Reduction of polygons to triangles. Drawing circular arcs to satisfy given conditions. Drawing of geometrical patterns and figures consisting of circular arcs. *Descriptive Geometry* : Problems on the representation of lines in space by projections on given rectangular planes. Representation of simple solids in orthographic projection. Developments of the cone and cylinder. Drawing a helix on a cylinder. Sections of simple solids. Simple problems in isometric projection. *Machine Drawing* : Drawing portions of a machine to scale, in plan and elevation, from rough partly dimensioned sketches.

3. Physics.—The examination, which will consist partly of a paper of questions and partly of experimental work, will comprise the following subjects :—1. Density and its measurement ; 2. Modes of measuring the pressure of liquids and gases ; 3. The change of volume of a gas with changes of pressure and temperature ; 4. Boiling points and their measurement ; 5. Latent heat and specific heat ; 6. Mechanical equivalent of heat ; 7. Electric units ; 8. The modes of measuring electric currents ; 9. Galvanometric method of measuring the electromotive forces of batteries ; 10. Various methods of measuring the resistances of wires and batteries ; 11. The simpler laws of electrolysis ; 12. The magnetic moment of a magnet and some mode of measuring it ; 13. The laws of reflection, refraction, and dispersion of light ; 14. The focal length of mirrors and lenses ; 15. Formation of images. The practical examination will be held in subjects 1, 5, 6, 9, 10, 11, and 14.

4. Chemistry.—The composition of air, how it is determined qualitatively ; the properties of the constituents of air. The composition of water, how it is determined qualitatively and quantitatively ; the properties of water as contrasted with that of its components. The nature of elements and compounds. The use of symbols in expressing chemical change. The chief properties of the commoner elements. The oxides of the commoner elements ; the compounds which they form with water (acids and alkalies), and with one another (salts) ; positive and negative simple and compound radicles. The changes in volume in reactions in which gases take part. The nature of the phenomena of combustion ; the heat of combustion of carbon and of the combustible gases. The practical examination will comprise very simple exercises in quantitative analysis, such as the determination by volumetric methods of alkali or acid, of silver, of iron, or of iodine, and by gravimetric methods of silver, of calcium, of chlorine, or of carbon dioxide ; in the preparation of crystalline salts, and in the fitting up of apparatus for preparing gases, &c.

5. French or German.—Ability to translate at sight an easy passage from French or German into English. At the first examination, to be held in December, 1884, candidates who show special merit, but who may not be qualified in all the above subjects, will be recommended for admission.

THE BRITISH ASSOCIATION MEETING AT MONTREAL.

Sir Frederick Bramwell, F.R.S., delivered the following presidential address to the Mechanical Section of the British Association:—

At our Jubilee meeting at York, I called the attention of the section to the fact that in 1831, when the Association first met in that city, they arrived there laboriously by the stage coach, and that practically the Manchester and Liverpool, the Stockton and Darlington, and some few others, were the only railways then in existence. I also called their attention to the fact that in 1831 there were but very few steamers. I find the total number registered in the United Kingdom in that year was only 447. If under this condition of things the proposition had been made in 1832 at Oxford, as it was made in 1882 at Southampton, that the next meeting but one of the Association should take place in Montreal, the extreme probability is that the proposer would have been safely lodged in a lunatic asylum, for suggesting that that which might have involved a six weeks' voyage out, and a four weeks' voyage back, could ever be seriously entertained. Further, to give once more the hackneyed quotation, some few years after this, *i.e.*, in 1836, Dr. Lardner established to his own satisfaction conclusively that no vessel could ever steam across the Atlantic the whole way. A striking instance of the mistakes made by scientific speculation; a branch of science widely differing in the value of its results from those branches which deal with absolute demonstration. Undeterred, however, by such adverse opinion, the engineers "kept on pegging away," experimenting, improving, and progressing, until the scientific speculation was met with the hard fact of the Atlantic voyage steamed the whole way by the "Sirius" and by the "Great Western" in 1838. The impossible was proved to be the possible, and from that day to this the advancement of steam ocean navigation has continued. The six weeks' voyage, sailing westward, of the year 1831, has become converted into but little over six days. And thus it is that that which would have been a mad proposition in the year 1832, became a perfectly rational one in 1882; and the deliberations of the general committee on the proposition were not directed as to whether it would be possible to convey the members with certainty, expedition, and economy across the Atlantic, but as to whether it was expedient or not on general grounds to hold for the first time a meeting of the British Association elsewhere than in some city of the United Kingdom. I say again that the possibility of such a meeting is absolutely due to the engineer, and that therefore, on this ground, the present is an appropriate occasion to magnify G, the Mechanical Section of this Association. It is true that the man who looks only at that which is on the surface may say, "You arrogate too much to yourselves. You ignore—to which I say Heaven forbid!—the skill and daring of your sailors. You ignore commercial enterprise. You ignore the development of iron and steel manufacture, which have enabled you to build the steamers of the present day. You ignore the increased output of the best steam coal in the world, and you attribute the whole result to the engineer." Such an objector would be in the condition of that man who, in answer to George Stephenson's question, "What is causing that railway train to move?" said, "Why, I suppose the coal that is burning in the locomotive;" and who was met by that grand and comprehensive answer, that it was the "Sun," for the coals were a consequence, and not a first cause. Similarly I venture to say that the mechanical engineer may lay claim to be the central source which has vivified and given rise to the improvements in the manufacture of iron and steel, in the construction of engines, and in the development of our collieries. There are those I know who object that Section G deals too little with pure science, too much with its applications. It may be, as the members of Section G might retort, that it is possible to attend so much to pure science as to get into the unchecked region of scientific speculation, and that had the members of Section G been debarred from the application of science, the speculation of Dr. Lardner might to the present day have been accepted as fact. I have quoted it before, but it has so important a bearing on this point, and comes from a man of such high authority, that I cannot refrain from once more giving you Dr. Tyndall's views on this question. "The knowledge of nature, and the progressive mastery over the powers of nature, imply the interaction of two things—namely, thought conceived and thought executed; the conceptions of the brain, and the realisation of those conceptions by the hand. The history of the human intellect hardly furnishes a more striking illustration of this interaction of thought and fact than that furnished by the Association of Physics and Engineering. Take, for instance, the case of steam. Without knowing its properties, the thought of applying steam could not have arisen, hence the first step was physical examination. But that examination suggested practice, and the steam engine at last saw the light; thus experimental physics was the seedling from which the steam engine sprang. But the matter did not end here. The positions of debtor and creditor were soon reversed, for the stupendous operations of the steam engine forced men of thoughtful philosophic minds to inquire into the origin of the power of steam. Guess succeeded guess, inspiration succeeded inspiration; the ever present fact of our railways, and our power looms, and our steamships gave the mind no rest until it had answered the question, How are heat and steam, its instruments, related to mechanical power? Had the works of the engineer not preceded the work of the natural philosopher, this question would never have been asked with the emphasis, nor pursued with the vigour, nor answered with the success which have attended it. It was the intellectual activity excited by the work which the civil engineers of England had accomplished that gave to philosophy the theory of the conservation of energy, including the dynamical theory of heat. . . . . The engineering genius of the future is certain to derive from this theory strength and guidance. Thus necessarily has thought originated fact, and fact originated thought. In the development of science these two powers are co-equal; each in turn ceasing to be a consequence, and becoming a creative cause. The Atlantic cable also had its small beginnings in the laboratory of the physical inquirer. Here, as before, experimental physics led the way to engineering facts of astounding magnitude and skill. But here also the positions of debtor and creditor have been reversed, for the work of the engineer has caused the physical inquirer to pursue his investigations with a thoroughness and vigour, and has given to those investigations a scope and magnitude which, without the practical stimulus, would have been impossible. The consequence is that the practical realisation of sending electric messages along the bottom of the Atlantic has been an immense augmentation of our knowledge regarding electricity itself. Thus does the human intelligence oscillate between sound theory and sound practice, gaining by every contact with each an accession of strength. These two things are the soul and body of science. Sever sound theory from sound practice, and both die of atrophy. The one becomes a ghost and the other becomes a corpse." I think all men, even although they be followers of science in its purest and most abstact form, must agree that these words are words of sound sense, well worthy of being borne in mind and of being acted on, and will therefore concur in the propriety of Section G dealing with engineering subjects generally as well as with abstract mechanical science.

Section A: Mathematical and Physical Science.—The connection between this section and Section G is most intimate. With any ordinary man I should have referred, in proof of this intimate connection, to the fact that the president of A this year is a member of the Council of the Institution of Civil Engineers; but when I remind you that it is Sir William Thomson who fills this double office, you will see that no deduction such as I have hinted at can be drawn from his dual functions, because the remarkable extent and versatility of his attainments qualify him for so many offices, that the mere fact of his holding some one double position is no certain evidence of the intimate connection between the two. But setting aside this fact of the occupancy of the chair of A by a civil engineer, let us remember that the accomplished engineer of the present day must be one well grounded in thermal science, in electrical science, and for some branches of the profession in the sciences relating to the production of light, in optical science and in acoustics; while, in the other branches, meteorological science, photometrical science, and tidal laws are all important. Without a knowledge of thermal laws, the engineer engaged in the construction of heat motors, whether they be the steam engine, the gas engine, or the hot air engine, or engines depending upon the expansion and contraction under changes of temperature of fluids or of solids, will find himself groping in the dark; he will not even understand the value of his own experiments, and therefore will be unable to deduce laws from them; and if he make any progress at all, it will not guide him with certainty to further development, and it may be that he will waste time and money in the endeavour to obtain results which a knowledge of thermal science would have shown him were impossible. Furnished, however, with this knowledge, the engineer starting with the mechanical equivalent of heat, knowing the utmost that is to be attained, and starting with the knowledge of the calorific effect of different fuels, is enabled to compare the results that he obtains with the maximum, and to ascertain how far the one falls short of the other. He sees even at the present day that the difference is deplorably large, but he further sees in the case of the steam engine that which the pure scientist would not so readily appreciate, and that is how a great part of this loss is due to the inability of materials to resist temperature and pressure beyond certain comparatively low limits; and he thus perceives that unless some hitherto wholly unsuspected, and apparently impossible, improvement in these respects should be made, practically speaking, the maximum of useful effect must be far below that which pure science would say was possible. Nevertheless, he knows that within the practical limits great improvements can be made; he can draw up a debtor and creditor account, as Dr. Russell and myself have done, and as has been done by Mr. William Anderson, the engineer, in the admirable lecture he gave at the Institution of Civil Engineers in December last, "On the Generation of Steam and the Thermo-dynamic Principles Involved." Furnished with such an account, the engineer is able to say, in the language of commerce, I am debtor to the fuel for so many heat units; how, on the credit side of my account, do I discharge that debt? Usefully I have done so much work, converted that much heat into energy. Uselessly I have raised the air needed for combustion from the temperature of the atmosphere to that of the gases escaping by the chimney; and he sets himself to consider whether some portion of the heat cannot be abstracted from these gases and be transmitted to the incoming air. As was first pointed out by Mr. Anderson, he will have to say a portion of the heat has been converted into energy in displacing the atmosphere, and that, so far as the gaseous products of the coal are concerned, must, I fear, be put up with. He will say, I have allowed more air than was needed for combustion to pass through the fuel, and I did it to prevent another source of loss—the waste which occurs when the combustion is imperfect; and he will begin to direct his attention to the use of gaseous or of liquid fuel, or of solid fuel reduced to fine dust, as by Crampton's process, as in these conditions the supply may be made continuous and uniform, and the introduction of air may be easily regulated with the greatest nicety. He will say, I am obliged to put among my credits—loss of heat by convection and radiation, loss by carrying particles of water over with the steam, loss by condensation within the cylinder, loss by strangulation in valves and passages, loss by excessive friction or by leakage; and he will as steadily apply himself to the extinction or the diminution of all such causes of loss, as a prudent Chancellor of the Exchequer would watch and cut down every unproductive and unnecessary expenditure. It is due to the guidance of such considerations as these that the scientific engineer has been enabled to bring down the consumption of fuel in the steam

Digitized by Google

engine, even in marine engines such as those which propelled the ship that brought us here, to less than one-half of that which it was but a few years back. It is true that the daily consumption may not have been reduced, that it may be even greater; but if so it arises from this, that the travelling public will have high speed, and at present the engineer, in his capacity of naval architect, has not seen how—notwithstanding the great improvements that have been made in the forms of vessels—to obtain high speed without a large expenditure of power. I anticipate from the application of thermal science to practical engineering that great results are before us in those heat motors, such as the gas engine, where the heat is developed in the engine itself. Passing away from heat motors, and considering heat as applied to metallurgy, from the time of the hot blast to the regenerative furnace, it is due to the application of science by the engineer that the economy of the hot blast was originated, and that it has been developed by the labours of Lothian Bell, Cowper, and Cochrane. Equally due to this application are the results obtained in the regenerative furnace, in the dust furnace of Crampton, and in the employment of liquid fuel, and also in operations connected with the rarer metals, the oxygen furnace and the atmospheric gas furnace, and, in its incipient stage, the electrical furnace. To a right knowledge of the laws of heat, and to their application by the engineer, must be attributed the success that has attended the air refrigerating machines, by the aid of which fresh meat is at the end of a long voyage delivered in a perfect condition; and to this application we owe the economic distillation of sea water by repeated ebullitions and condensations at successively decreasing temperatures, thus converting the brine that caused the Ancient Mariner to exclaim, "Water, water everywhere, nor any drop to drink," into the purest of potable waters, and thereby rendering the sailor independent of fresh water storage. With respect to the application by the engineer of electrical science, it is within the present generation that electricity has passed from the state of a somewhat neglected scientific abstraction into practical use:—First, by the establishment of the land telegraph, then by the development into the submarine cable, by means of which any one of us visitors here in Canada may be in instant communication with his own country, and may be so without a selfish exclusive occupation of the cable, for once more the application of science has solved that apparently impossible problem of employing a single wire to be at one and the same time the transmitter of multiple electric massages, and messages in opposite directions. Then, thanks to the application of Faraday's great discovery of induced electricity, there has been, during the last quarter of a century, the progressive development of the dynamo machine, whereby the energy of ordinary motors, such as steam engines, is converted into electrical energy, competent to deposit metals, to—as has already been said—fuse them, to light not only isolated buildings, but extensive areas of towns and cities, and to transmit power to a distance, whether for manufacturing purposes or for the railway or tramcar; and thus the miracle is performed of converting a waterfall into a source of light, as at Sir William Armstrong's house, or into the origin of power for a railway, as at the Giant's Causeway. To the application of electrical science is due the self-exciting of the dynamos and the construction of secondary batteries, enabling a development of electricity to be continued for many hours. In the United Kingdom, general electric lighting—that is to say, the lighting of large sections of a town from a central station—has been stopped by the most unwise, because most unjust, conditions imposed by the Government General Electric Lighting Act of 1882. A new and meritorious industry, which should have been granted the same privileges as are accorded to other industrial undertakings needing parliamentary powers, was subjected to this most unjust condition: that at the end of twenty-one years the public authority of the town or place lighted should have the option of buying the undertaking for the then value of the mere materials, and that if the authority did not choose to purchase—for it was not bound to buy—at every subsequent five-year period this option should re-arise; that is to say, that a new undertaking, which would require years for its general acceptance—for the public is slow to take up a novelty—was, after the experimental and non-paying stage had been passed, to be practically forthwith taken away for a mere fraction of the capital that had been outlaid if the undertaking paid, but was not to be taken away if it did not pay. Such, in spite of the teaching of Section F, is the condition to which our Government has arrived in respect of economic science. The next electrical matter I have to touch upon, that of the telephone and microphone, with which will for ever be associated the names of Graham-Bell, Edison, and Hughes, has, as regards the public use of the telephone, been all but similarly treated in the United Kingdom. It has been declared to be within the telegraphic monopoly given by Parliament to the Post Office nine years before the telephone was invented, and the power to use it depends entirely upon the grace and favour of the Post Office, a grace and favour not always accorded; and even when accorded, coupled with limitations as to distance, and coupled with a condition of payment of 10 per cent. of the gross receipts by the companies to the Post Office as a royalty; and all this because Government has become a trader in electrical intelligence, and fears the competition of the telephone with its telegraphs. No one in the ship-loving countries of England, Canada, and the United States can refrain from feeling the warmest interest in all connected with navigation, and we know how frequently, alas! the prosperous voyage across the wide and fathomless ocean ends in shipwreck and disaster when the wished-for shore is approached, and when the sea is comparatively shallow. Except for the chance of collision, there is, in a staunch ship, little danger in the open ocean, but on nearing the shore, not only is the liability to collision increased, but shoals and sunken rocks render navigation perilous, and it is on the excellence of the lighthouses and lightships that—coupled with soundings—the sailor relies. These structures and appliances are confided to the engineer, and to be efficient they require him to be able to apply the teachings of Section A in optical science, and in the case of fogs, or as regards buoys at night time, the science of sound. I parenthetically alluded to soundings as one—indeed, a principal one—of the safeguards of ships when approaching shore. It is important in these days of high speeds that these should be made with ease and without the necessity of stopping the ship, or even of diminishing its velocity. Sir William Thomson, by the application of the science of pneumatics, has enabled this to be done. Again, most important is it that the compass, midst all the difficulties attendant upon its being situated on an iron or steel structure, should be trustworthy. And here Sir William has applied the science of magnetism in his improved compass to the practical purposes of navigation. To go to another important branch of engineering—water supply. The engineer dealing with a district to be fed from the surface will find himself very deficient if he have not the power of applying the science of meteorology to the work that he has in hand; he must know, not the average rainfall, for that is of but little use to him, but the maximum, and most important of all, the minimum rainfall over a consecutive period of years; the maximum so that he may provide sufficient channels and by-washes for floods; the minimum so as to provide sufficient storage. He must know what are the losses by evaporation, what are the chances of frost interfering with his filters and with his distributive plant. Coming to the mathematical side of Section A—whether we consider the naval architect preparing his design of a vessel to cleave the waves with the least resistance at the highest speed, or whether we consider the unparalleled series of experiments of that most able Associate of Naval Architects, the late William Froude, carried out as they were by means of models which were admirable in their material, their mode of manufacture with absolute accuracy to the desired shape, and their mode of traction and of record, we must see that both architect and experimenter should be able to apply mathematical science to their work, and that it is in the highest degree desirable that they should possess, as Froude did, those most excellent gifts, science and practical knowledge. Again, the mathematical side of Section A has to be applied by engineers when considering the strength and proportion of boilers, ships, bridges, girders, viaducts, retaining walls, and in short the whole of the work with which an engineer is entrusted. Notable instances of great bridges will occur to all our minds, especially meeting as we are in this continent of grand streams, Eads' St. Louis Bridge, Roebling's Niagara Bridge, and his and his sons' East River Bridge, Gzowski's International Bridge, and going back to our own land, Fowler and Baker's Bridge over the Forth.

Passing from Section A to Section B, there is evidently so much overlapping of these sections that a good deal that I have said in reference to Section A might properly have been reserved for Section B. The preparation from the ore of the various metals is in truth a branch of engineering; but to enable this to be accomplished with certainty, with economy, involving the not throwing away of that which is called the waste product, but which is frequently a valuable material, it is essential that the engineer and the chemist should either be combined in one and the same person, or should go hand in hand. In the manufacture of pig iron it is absolutely necessary that the chemical constituents of the ore, the fuel, and the flux should be thoroughly understood, and that the excellence of the process followed should be tested by an analysis of the slag. For want of this chemical knowledge thousands upon thousands of tons of bad pig iron have been made, and thousands upon thousands of tons were formerly left in the issuing slag. Similar remarks apply to the production of lead and of copper from the ores, and still more do they apply to that great metallurgical manufacture of the last few years—steel. In the outset steel was distrusted because of the uncertainty of its behaviour, but the application of chemical science now enables the manufacturer to produce with precision the material required to fulfil the physical tests imposed by the engineer. Reverting to the water engineer, the chemist, and the microscopist have their sciences applied to ascertain the purity of the intended source, and as in the case of Clark's beautiful process, by the application of chemistry, water, owing its hardness to that common cause, carbonate of lime, is rendered as soft as the water from the mountain lake. Taking that other branch of engineering commonly coupled with water, viz., the supply of gas, the engineer is helpless without the appplication of chemistry. From the examination of the coal to be used to the testing of the gas to be supplied there is not one stage where chemical science is not necessary. The consumer requires gas which shall be as nearly as possible a pure hydro-carbon of high illuminating power, and it might well have been that a person to whom was delivered the crude gas as it issued from the retort would have said, "Certain things may be separated out more or less, but to practice on the wholesale scale the delicate operations which will be needed to cleanse the illuminating gas from its multifarious accompanying impurities is a hopeless undertaking, and must be so if for no other reason than this—the excessive cost that would be entailed." But what are the facts? Although I for one do not like to sit in a room where gas is burnt, unless special provision is made for taking away the products of combustion, the engineer of the present day, thanks to the application of chemical science, delivers gas to the consumer in a state of comparative purity—although it may have been made from impure coal—which but a few years ago would have been deemed impossible; and so far is this improvement from being attended with extra cost, that the residual products not now uncommonly all but pay the whole cost of the coal, and in some rare instances even leave a slight profit to go towards the charge for labour. Again, it is by the application of chemical science in the dynamite and gun-cotton of the present day that the engineer is enabled to prepare submarine foundations, to blast away shoals, and to drive tunnels through rock of a character that cannot be dealt with by mere cutting machines. Equally to the application of chemistry is it due that there are hopes, by the employment of lime cartridges, of breaking down coal without that risk of igniting fire-damp which is attendant upon the use of gunpowder. I need hardly observe that much more might most pertinently be said on the way in which

Digitized by Google

the engineer applies chemical science. In fact, those ways are so multifarious, that a volume might be written upon them, but I must pass on and ask you to consider how the engineer applies geological science, the science treated by Section C. I have already spoken of the engineer supplying towns by water collected from the surface; even he, however, must have a knowledge of geology, for without it he will not know what places are apt for the huge reservoirs he constructs, nor where he can in safety make his enormous embankments. In this continent of vast lakes one feels it must excite a sensation of the ridiculous when a Welsh lake is spoken of, but I must ask you to believe you are in Lilliput, and to imagine that the "Bala Pond" of eleven hundred acres in extent is really "Bala Lake," as it is called. Within a few miles of that, our friends at the other end of the Atlantic steam ferry, the inhabitants of Liverpool, are now constructing, under the engineering and advice of Mr. Hawksley, a waterworks which will involve the formation, I believe one may safely say the reformation of a lake practically the same area as that of Bala, of some 80ft. in depth, and containing between the overflow and the point of lowest discharge nearly twelve thousand million gallons. This lake will be made by the throwing from side to side of the valley of a solid stone bank, 100ft. above the ground, 140ft. above the deepest part of the foundations, and 113ft. thick at its thickest part. Contrasted with Lake Superior this new lake will be small, a thing demanding a microscope even, but the bursting of the wall would liberate a body of water sufficient to carry death and ruin throughout a considerable district. It is therefore in the highest degree important that whether he be constructing the solid stone wall, or the more common earthen embankment with a puddle trench, the engineer should so apply geological science as to ensure the safety of his work. But in those cases where the waterworks engineer has to derive the supply from underground sources the application of this science is still more necessary; he must know whether he is likely to find a water-bearing stratification at all—if so, where it receives the rain from heaven, and the extent of the area which receives it; in what direction the water travels through it, what is the varying height of water in the different parts of the stratification giving the "head" to produce that travel; how far this height is likely to be affected by the pumping of the desired quantity; whether, if near the outflow into the sea, the pumping is likely to reverse the direction of the current, and to bring back brackish water, and whether the rocks are of such a character as to be liable to yield a water impregnated with iron or with lime, and whether these water-bearing rocks are accessible from the surface without the execution of costly and laborious work in passing through over-lying stratifications of an unfit or it may be even of a dangerous character. It need hardly be said that the engineer when engaged in metalliferous mining, or in the extraction of coal or of petroleum, unless he applies the science of Section C, is but a haphazard explorer whose work is more likely to end in disaster than in success. Again, the engineer when laying out a railway, has to consider the geological features of the country in determining the angles of his cuttings, and to determine where it becomes more economical to tunnel than to cut. Indeed, without the application of that science to engineering there are some enterprises on the feasibility of which the engineer would not be able to pronounce an opinion—a notable instance, the Channel Tunnel. The engineers, of whom I am one, said there is a material, the compact non-water-bearing grey chalk, which we have at a convenient depth on the English side, and is of all materials the most suitable; if that exist the whole way across success is certain. Then came geological science, and that told the engineer that in France the same material existed; that it existed in the same position in relation to other stratifications as it existed in England; that the line of outcrop of the gault lying below it had been checked across; and that taken together, these indications enabled a confident opinion to be expressed that it was all but certain this grey chalk stratification did prevail from side to side. The engineer believed it, an intelligent section of the public believed it, and came forward with their money; large sums were expended in England and in France on the faith of the repeated declaration of the English Government—of both sides of politics—that so long as the nation was not called on to contribute towards the cost of the work, it would hail with satisfaction the improved means of communication between England and the Continent; the experimental works were carried on from both sides with the happiest results, and then, when success appeared certain, the whole work was stopped by the incredible suggestion that in the event of a war the soldiers of England, and the science of England, could not defend a couple of rat-holes—holes 14ft. in diameter and 20 miles long, situated far below the surface of the sea, having a rapid dip from the shore to a low point, gradually rising from there to the centre of the length of the tunnel, so that the English end could be flooded with sea-water in twenty-five minutes up to the soffit of the arch at the dip; and in consequence of this incredible and most-to-be-ashamed-of scare it is due that one of the finest instances of civil engineering work in connection with the science of geology, and, as I believe, one of the most useful works that has ever been proposed, has been put a stop to. To come to Section D, the botanical side of it is interesting to the engineer as instructing him in the locality and quality of the various woods that he occasionally uses in his work. With regard to that most important part of the work of D which relates to "germs" and their influence upon health, the engineer deals with it thus far; he bears in mind that the water supply must be pure, and that the building must be ventilated, and that excreta must be removed without causing contamination; thus the waterworks engineer, the warming and ventilating engineer, the sewage engineer can—and do—all of them profit by the labours of Section D, and can by their works assist in giving practical value to the pure science of that section.

Section E, Geography.—Probably in these days, when our kingdom at home and the old countries near us are all but full of the works of the engineer, there are few who take a greater interest in geography than he does, and I am quite sure there are none who make a more useful application of geographical knowledge for the benefit of mankind at large than does the engineer. Almost at the outset of this address I claimed to magnify Section G, on the ground that without the aid of its members we should not have had that practical lesson in geography which we have received by our visit here, a lesson that no doubt will be continued and amplified by many of us before we return to our homes. Whether it be by the ocean steamer or by the railway train, the enterprising geographical explorer is carried to or through countries which now, thanks to the engineer, are well known and settled, up to the beginning of the unknown and not settled; and thus his labours are lightened, he consumes his energies only upon his true work, brings back his report, which is, as I have said, studied by the engineer, with a view to still further development, and thus turn by turn the geographer and the engineer carry civilisation over the face of the world. Now to come to Section F, which treats of Economic Science. The matters with which this section deals—birth-rate, death-rate, the increase or diminution of populations, the development of particular industries in different localities, the varying rates of wages, the extent and nature of taxation, the cost of production, the cost of transport, the statistics of railway and marine disasters, the consumption of fuel, and many matters which come within the purview of F, are of importance to the engineer. Guided by the information given him by the labours of this section, he comes to the conclusion that a work having a particular object in view should or should not be undertaken. With the information derived from the past he judges of the future; he sees what provision should be made for prospective increase of population or of industries; he sees the chances of the commercial success of an undertaking or of its failure, and he advises accordingly. I do not propose to say anything about Section H, for I have dealt with it as being still included within D. I trust I have now established the proposition with which I set out, viz., that not only is Section G the section of Mechanical Science, but it is emphatically the section of all others that applies in engineering to the uses of man the several sciences appertaining to the other sections, an application most important in the progress of the world, and an application not to be lightly regarded, even by the strictest votaries of pure science, for it would be in vain to hope that pure science would continue to be pursued if from time to time its discoveries were not brought into practical use.

SELECTED CORRESPONDENCE.

ELECTRIC LIGHTING

The following letter appeared in *The Times* of Sept. 10th, and is a continuation of the Correspondence which had previously appeared, and which we have reprinted:—

"SIR: Referring to the letters of your correspondents 'A. S.' and 'G.' on this subject, it will be opportune, now that so many of the provisional orders have been revoked, to endeavour to ascertain why the legislation which was ostensibly designed to facilitate and regulate the supply of electricity has so completely failed in its purpose, and, with the knowledge now possessed, to see whether the delay in the application of electricity to house-to-house lighting has been due to legislation or to causes attributable to the companies.

"The march of events in regard to every new matter of general and public importance has shown that hitherto any innovation has had in its initial stages to push its way as best it could, and it has only been gradually, as the demand has exceeded the means of supply, or the opposition of vested interests has proved too strong, that the Legislature has interfered to mediate between the opposed interests. But for electric lighting the extraordinary destiny has been reserved of being smothered by kindness in its infancy. So long as the industry was free and untrammelled and until the demand for legislation in electrical matters arose it prospered, and, although the advance was not comparable with that made in America, yet by working in harmony with local authorities good and steady progress was being made in different parts of the country, and there was every prospect of electricity as a lighting power being generally adopted in the course of a few years; but, as stated by Sir Frederick Bramwell at the meeting of the British Association last week, 'the lighting of large sections of a town from a central station has been stopped by the most unwise, because most unjust, conditions imposed by the General Electric Lighting Act, 1882.' I do not mean that this effect was produced at once, perhaps it would have been better if it had been, for the evil of the repressive conditions in the Act would then have been better appreciated, much money would have been saved, and the Act no doubt would have been speedily amended.

"Earnest and legitimate attempts, however, were made to work in accordance with its provisions, but with the exception of a few notable and creditable instances they have all practically failed, and it has now become evident to the companies who boldly and enthusiastically undertook to develop this new industry that there is but little to be done against such severe odds.

"A consideration of the following points will, I think, make it manifest that if the object of the Legislature had been not to facilitate and encourage the development of a new industry, but to dishearten and throttle it as an unwelcome intruder, this object could not have been better accomplished than by the onerous conditions imposed upon the undertakers by the Act and by the spirit in which the Board of Trade have framed the provisional orders.

"There is one clause which in itself is quite sufficient to condemn the Act as unjust and unbusinesslike—viz., the one by which local authorities can within six months after the expiration of 21 years, or such shorter period as may be specified in the provisional order, require the contractors to hand over to them their business, upon terms of paying the then value

Digitized by Google

of all lands, buildings, works, material, and plant, 'without any addition in respect of compulsory purchase, or of goodwill, or of any profits which may or might have been or be made from the undertakings, or of any similar considerations.'

"The local authorities are not even deprived of this extraordinary privilege if at the end of 21 years they see no advantage in taking over the undertaking, but they have the opportunity to exercise this right to appropriate the successful results of private enterprise after the expiration of every subsequent period of seven years; and this consequently makes it incumbent upon the contractors to earn sufficient profits during the limited term of their proprietorship to compensate for all the initial losses which are inseperable from a new enterprise, including the not inconsiderable cost of obtaining the order, and to provide for the difference (a very uncertain factor) between the original cost of the properties and their fair market price at the time of purchase by the local authorities, 'due regard being paid to the state of repair thereof and the suitability of the same to the purposes of the undertaking.' The undertakers are allowed no option in the matter but to cover their expenses as quickly as they can, and are thus precluded from taking a broad view of the business by charging low rates in order to compete with the gas companies, but are constrained to charge the maximum rates allowed by the order, for if they failed to accomplish the return of their money with interest within the time stated, they must inevitably suffer enormous pecuniary loss, because, however remunerative the concern may have become by the end of 21 years, they can be required to hand it over to the community on terms which can only be described as confiscatory, just as if they had been actuated in the work solely and simply by philanthropic motives.

"The Act assumes that two years are required to carry out the necessary works of development, so that even if the extreme period is specified, there are only 19 years in which the undertakers have a chance of recouping themselves; but in some of the provisional orders which have been granted, and subsequently abandoned in spite of the large sums spent in obtaining them, the tenure of the undertakers is limited to 15 years. Could it reasonably be expected that any body of shareholders would assent to the sinking of their capital for the purpose of supplying the electric light under the Act when once the full purport of this section was recognised? While there is no inducement for capitalists to invest money in such an enterprise at the outset, there is far less reason for expecting them to do so as the period of compulsory sale draws nearer, as the only security which the undertakers would be able to offer, should they require additional funds for the legitimate extension of a profitable business, would be a mortgage on the purchase money, payable by the local authorities in the event of their taking over the undertaking.

"The Board of Trade seem to have recognised this, for the provisional orders provide that sufficient capital shall be set aside for the purposes of the undertaking before any work can be commenced, and that one-half of such amount shall be deposited or secured to their satisfaction. These conditions are supplemented by several stringent regulations as to time, &c., the neglect of which may involve the revocation of the order 'on such terms as the Board of Trade may think just.'

"The Act was a panic Act, and was carried through by representations that the public would be left at the mercy of an enormous monopoly, similar to, if not greater than, those possessed by the gas and water companies. It should be remembered, however, that these monopolies were only granted as inducements to capitalists to embark money in enterprises to supply the public largely and cheaply with the commodities required. In the opinion of many the same results would have been obtained at greater advantages to the public had free trade been allowed, and all that electric lighting contractors ask is to work on the principle of free trade, subject to a maximum charge and to reasonable control by local authorities in consideration of the use of the streets and pavements; and it should be remembered that the disturbance to the streets in the case of the supply of electric light and power is infinitely less than that rendered necessary by the supply of gas and water.

"This leads up to the argument which is sometimes advanced that the section by which the proprietary rights of the initiating company are limited to a term of years has a precedent in the Tramways Act, and it is argued that because that Act has not frustrated the progress of tramway enterprise, the later Act is not likely to obstruct the advance of electric lighting. Bnt in drawing this analogy the fact is evidently lost sight of that the Tramways Act specially stipulates that local authorities shall not themselves work the tramways after they have acquired them, but shall entrust the administration of the same to contractors. This salutary provision is altogether omitted from the Electric Lighting Act, and it should further be remembered that the promoters of tramways are granted the right to use, free of rent, and to the exclusion of all tramway competitors, about two acres of public land for every mile of double tramway. This is a concession which compensates for a great deal, and is worth paying for, seeing that it renders unnecessary the purchase of land, which in railway and other undertakings forms the main item of capital expenditure; but the provisional orders under the Electric Lighting Act grant no such monopoly, and confer no rights except those of forming conduits under the pavements of the public streets.

"It will be seen, therefore, that the electric lighting companies have been treated with the most exceptional severity. They are too much at the mercy of both the Board of Trade and the local authorities, and many of the conditions imposed upon them are violations of those commercial and economical principles which lie at the root of all enterprise and progress. For instance, although the contractors are bound to supply, within a given area, electricity to any inhabitant who may demand it, there is no provision enabling them to acquire compulsorily the land which they require to carry out their engagements. Although the Lands Clauses Acts are to a certain extent embodied in the Electric Lighting Act, the enactments with respect to the purchase and taking of lands otherwise than by agreement are carefully eliminated, and yet without these rights electric lighting companies, any more than railway companies, are unable to carry out their undertakings.

"Many of the other clauses are either inoperative or mischievous. No one is likely to deny that the Board of Trade is right in taking due precautions for the public safety, similar, say, to the restrictions it imposes upon railway companies in regard to level crossings, to the speed of trains round curves, and the condition of the rolling stock and permanent way; but to limit the electromotive force or pressure of electricity in well insulated and protected leads in or under the streets to below what would, under any conditions, be unsafe, is as absurd as to limit the speed of trains along a well laid and protected line of railway to 15 miles an hour. Many of the other rules laid down by the Board of Trade are of such a character as to render economical house-to-house lighting on an extensive scale almost impossible.

"Nevertheless, there are companies who will be able, it is hoped, to persevere in their earnest endeavours to supply the public with electricity from central stations at a reasonable price, in the hope that by demonstrating the enormous advantages of the electric light over all other illuminants public opinion may be aroused on the subject, and that the Act may be amended and the Board of Trade convinced that the best way to facilitate and regulate the supply of electricity is to allow the electric lighting companies to make a start, and to ascertain by practical experience what the needed conditions are for securing alike the welfare of the public and the interests of the undertakers. This is a question more for the public than for the companies, for the latter have for some time to come a very wide field in providing electric lighting plant for theatres, factories, ships, railway stations and trains, and for those occupiers of dwelling houses who are prepared to find their own motive power rather than be deprived of the advantages of the new light; while those who, appreciating the evidences of these isolated installations as to the purity, safety, and cleanliness of electricity, are waiting to be supplied with the electric light, but not the plant, will, I trust, find in this letter a sufficient reply to the very reasonable inquiry—'Why does not electric lighting go ahead?'—I am, Sir, your obedient servant, "E. G."

NOTES.

CARRE'S CARBONS.—We hear that Messrs. Thompson, Dowsing, and Rew have been appointed sole agents for Carré's improved carbons, manufactured by M. Lévy, of Paris.

ELECTRIC LIGHT AT HARROGATE.—The Corporation have made an arrangement with a firm of electricians at Leeds, who are lighting the Spa, to illuminate the town for three months at a cost of £50, by way of experiment.

FOUNDER OF THE "SCIENTIFIC AMERICAN."—Rufus Porter, who brought out the *Scientific American* in 1845, died recently at the age of 92 years. He was a man of fertile invention and great versatility of genius.

NEW CABLE SHIP.—The steamer "Mackay Bennett" was launched on Thursday from Messrs. Elders' yard. The vessel is intended for the Commercial Cable Company for holding cables, her capacity for which is 27,000 cubic feet.

CHANGE OF ADDRESS.—Messrs. F. Young and Co., telephone, telegraph, and bell-case makers, have removed their offices to 11 and 10, Dean-street, Holborn, W.C., but are still carrying on their steam works at 11, Clerkenwell-green, E.C., as heretofore.

ELECTRIC LIGHT AT CHICAGO.—A local company has constructed a large central station on the west side, for illuminating the business houses in the vicinity of Madison and Halstead streets. The Van Depoele system is used, and 150 lights are probably now shown.

ELECTRIC LIGHT AT CARDIFF.—At a recent meeting of the Lighting Committee of the Cardiff Corporation, the offer made by the Great Western Electric Light and Power Company to illuminate St. Mary-street with a number of incandescent lamps for £167 a year was accepted.

ELECTRICITY AND SEWING MACHINES.—The American Electric and Illuminating Company proposes to fit up a building with improved sewing machines, each running with a Stockwell electric motor, to be let to women at the nominal price of 20 to 25 cents (1s. or less) a day.

ELECTRIC LIGHT AT NEW ALBANY.—The proprietors of the large woollen mills have contracted with the Cleveland, U.S., Brush Company to supply 275 incandescent lamps of 20 candle-power, to be run from a Brush dynamo direct. The De Pauw Glass Works are using Brush arc lights.

ELECTRIC LIGHT AT BRADFORD.—At a recent meeting of the Bradford Town Council the Gas Supply Committee's minutes were adopted, with the exception of that part relating to the electric lighting of a portion of Allerton, which was referred back to the committee for further consideration.

BELLATI'S AUTOMATIC REGULATOR.—At the Turin Exhibition is shown the automatic electrical regulator devised by Bellati, of Padua, in which a mechanical thermometer, interrupting and concentrating the circuit, causes the intensity of the flame to vary, so that the temperature can never exceed, or fall below, certain limits.

TELEPHONE RATES IN BELGIUM.—As soon as the arrangements are complete the fee for telephoning between Brussels and the provinces over the telegraph wires by the Van Rysselberghe system will be 1fr. for five and 1½fr. for ten minutes' conversation. The subscribers will be able to telephone directly after getting put in communication with the central office, the *employés* of which will collect the fees.

CABLE BETWEEN BRISBANE AND SAN FRANCISCO.—The proposal of an Australasian syndicate to lay an ocean cable from Brisbane to San Francisco has been favourably received by the Hawaiian Legislature, and a report in favour of granting a subsidy of 20,000dols. (£4,000) per annum for fifteen years promptly passed the third reading. This syndicate also proposes to lay a cable between California and Queensland.

WIGAN COAL AND IRON COMPANY.—An order for the lighting of the Wigan Coal and Iron Company's works has just been given to Mr. F. D'A. Goold, electrical engineer and contractor, Arcade Chambers, St. Mary's Gate, Manchester. This order is the outcome of a successful installation which our readers will remember we drew their attention to some months back. Mr. Goold is also to supply the apparatus required for lighting Westfield, Coventry.

BOOKS RECEIVED.—"Illustrations and Descriptions of Telegraphic Apparatus," by A. C. Terry and W. Finn, published by A. C. Terry, Buffalo, New York; "*Transactions* of the Institution of Civil Engineers of Ireland, forty-seventh and forty-eighth Sessions to June, 1883," Vol. XIV. This volume contains a paper by Mr. T. B. Grierson on Electric Lighting by Water Power, and a paper by Mr. J. Angelo Fahie on Magneto and Dynamo Electric Machinery.

THE EASTERN TELEGRAPH COMPANY AT THE TURIN EXHIBITION.—In a notice inserted in a publication bearing the title of *Esposizione Italiana del* 1884 *in Torino*, the ingeniere R. Sartorio expresses pleasure at welcoming this company, "the most powerful that exists," at the national show of electricity, so well represented by "Cavaliere Alfredo Eggington." He recounts the early struggles of the company, as well as its surmounting of all difficulties "with British perseverance," and by aid of the siphon recorder, which he translates *sifone annotatore*.

LOCOMOTIVE HEAD-LIGHT.—In our last issue we referred to Mr. Wooley's electric head lamp, maintained by a dynamo, worked by a separate motor with steam from the locomotive boiler. We now learn that it is intended not only to place the electric head-light in its usual position on the locomotive, but also to put another in the rear of the cab for throwing a light over the whole train, and so arranged that it can be turned to the right or left, and be made to illuminate stations and their approaches when the train is standing.

BELGIAN ARMY TELEGRAPH CORPS.—The corps of telegraphists in the Belgian Army is divided into two companies, the first of which is intended for the telegraphic service of the army in time of war, while the second, named the Compagnie des Télégraphistes de Place et d'Artificers, is intended for service in fortified places. In time of peace each company consists of a captain with an effective of 80 men, for the most part non-commissioned officers; but in time of war each company consists of 200 men, furnished by the military engineer corps and trained for telegraph service.

ELECTRIC LIGHT IN NEW YORK.—It is rumoured that the New York Steam Company intends to undertake electric lighting as well as the supply of steam for heat and power. Mr. W. C. Andrews, the president, has stated that his company hoped within a year to have every house in Fifth Avenue, from Washington-square to the Park, heated by its steam and

Digitized by Google

lighted by Sawyer-Mann lamps, obtaining current from their dynamos. He expressed the belief that the electric light will come cheaper than gas. The company is laying down an ordinary gas pipe, which may be used for an electric wire cable, and also a steam pipe, along Fifth Avenue, from the square to the Central Park.

ELECTRIC RAILWAYS AND LIGHTING.—Plans were duly deposited with the Board seeking to confer powers on two different companies for the construction of electric railways beneath the carriage way of High Holborn. One of these schemes did not reach the stage of committee; but the London Central Electric Railway was before a Committee of the House of Commons for the greater part of a week, when, after evidence had been taken both for and against the measure, the preamble was declared not proved. As regards electric lighting, two companies obtained provisional orders, conferring parliamentary powers for public electric lighting in the district, but neither of them put those powers in force.

ELECTRIC EXHIBITION AT BOSTON.—It is proposed to hold an electrical exhibition in the building of the Massachusetts Mechanics' Association, Huntingdon-avenue, Boston, from 24th November next to 3rd January, 1885. Its object is to show the rapid advancement that has been made in electricity, its methods and appliances, and all its possibilities and probabilities. Exhibitors will have to pay an entrance fee of 10 dollars (£2 2s.) each, to cover space and power. They will be permitted to sell, but not deliver goods, during the exhibition, except by special permission. Application for space must be made by 1st November. There is an influential "advisory board." P. H. Alexander is general manager, W. S. Hill superintendent, and B. F. Porter chief clerk.

SENEGAL CABLE.—We are informed that the Silvertown Company's ss. "International" arrived at Santa Cruz de Tenerife on Monday, the 15th inst., and that on the following day she landed the Tenerife shore end of the Senegal cable in Tejita Bay. This vessel leaves Tenerife for St. Vincent and St. Jago, Cape de Verde Islands, to survey landing places on these two islands, and to sound the route between them. After completing her work between these islands she will proceed to a point off Dakar, Senegal, whence she will sound towards Tenerife. On her arrival there she will meet the ss. "Silvertown," with the deep-sea portion of the Senegal section. The "Silvertown" arrived at the India Rubber Company's moorings on Tuesday, the 16th inst., and commenced shipping Senegal cable on Thursday, the 18th.

ELECTRIC LIGHT IN CHINA.—A special correspondent at Foochow thus describes the effect produced on the natives by an electric search light from the French flagship:—"I happened to be going down to the anchorage last night in a steam launch, and just as Pagoda anchorage hove in sight the 'Volta,' the French flagship, lit her electric search lamp and threw a blinding ray on each Chinese gunboat in turn to see if they were slily slipping their anchors or rigging torpedoes. I steamed through the Chinese fleet while the search light was on them, and the effect was most ludicrous—the cries and antics of the men on board who seemed to think there was something very awful in a light so strong that their eyes could not bear to look at it. It was a curious sight seen from a little distance; the night was slightly hazy, and the ray from the lamp seemed like a gigantic wedge-shaped arm thrown out by the vessel. The 'Volta' had two torpedo boats alongside, with steam up, and all on board were moving about in an excited, restless manner."

STATISTICS OF THE BRITISH EMPIRE.—Sir R. Temple in his presidential address to the Economic Science Section of the British Association at Montreal, among other things touched upon telegraphy. He said, regarding electric telegraphs on land, that there are 86,000 miles in the British Empire, or nearly one-fifth of the sum total for the world. It is remarked that the telegraphs in Australia—26,000 miles—are exactly equal to those in the United Kingdom. But in illustration of the difference between an old and a new country there are 31,000,000 of messages yearly in the United Kingdom, and only 5,000,000 in Australia. In other words, the telegraph does six times as much in the old country as in the new. Similarly in the United States, the length of telegraph—121,000 miles—is amazing; but the messages are only 34,000,000, just in excess of those in the United Kingdom. In other words, the work is more than four times as heavy in the United Kingdom as in the United States. Besides the land telegraphs, there are submarine cables in the world with the surprising length of 105,000 miles. Of these the greater part belong to the British Empire.

ELECTRIC FILTER.—Dr. Dobell lately advised that noxious germs should be destroyed by passing an electric current through the water that contains them. A similar idea appears to have occurred to Dr. Stephen Emmens, who has devised an electric filter, consisting of a glass vessel in which are placed porous vases. These latter contain coal or spongy iron, and also carbon plates connected with the positive pole of a Leclanché battery, being kept apart by other carbon plates communicating with the negative pole. The water to be filtered flows into the porous vases, passes through the coal or spongy iron, and runs out of the containing vessel. Like Dr. Dobell, Dr. Emmens supposes that the oxygen set free destroys all the germs which might render water injurious to health. The invention is also applicable to the purification of sewage waters, in which case the filter takes the form of a conduit, divided by partitions into a series of elements, traversed in succession by the water. The electrodes are wooden cages, alternately filled with pieces of iron and coke. With this arrangement a primary battery is not necessary, for the conduit itself forms a powerful battery, the current of which is more than sufficient.—*L'Electricien.*

THE TELEPHONE AT ABERDEEN.—At a *conversazione* given by the Corporation of Aberdeen to the delegates attending the Trades Union Congress, the corridor was lighted by a Pilsen 2,000-candle lamp; and the square room was set aside for telegraphic and telephonic instruments. The latter department was in charge of Mr. John D. Millar, district manager of the National Telephone Company, Limited, who had arranged a miniature switch room, showing the whole working of a telephone exchange, and permitting the visitors to hear pianoforte music played at Ferryhill and band music from Oldmill. There was also a fire alarm which, when the temperature rises beyond a certain point, gives warning at the Post Office, and also at the owner's house. So sensitive is this appliance, that any excess of heating in a grain merchant's store is exactly indicated, and the bell continues to ring until the normal degree of temperature is restored. In a burglar alarm, direct communication is made with the police station on a door being opened after being once closed for the night, and that without the knowledge of the person opening it. Mr. Millar also showed Gower-Bell telephones of the original type, with a number of the recent improvements for the rapid transmission of telephonic messages, and also his own patented switch connection with complete telephonic apparatus.

Digitized by Google

ELECTRIC LIGHT IN THEATRES.—We last week referred to the Paris Ambigu having been added to the list of theatres lighted by electricity; and, as this is stated to be the first complete application to a theatre in Paris, we subjoin a few particulars. The lights comprise 20 Jablochkoff candles (ten outside, one in the vestibule, two in the crush room, and seven in the auditorium) and 306 incandescent lamps (27 in the auditorium, 167 on the stage, 42 in the passages and on the staircases, and 70 in the offices and dressing rooms), besides 15 Jablochkoff candles which can be used for special effects on the stage, subject to the suppression of an equal number elsewhere. The current is supplied by self-exciting alternate-current Gramme dynamos, two of Type 1 for the Jablochkoff, and two of Type 2 for the incandescent lamps. This arrangement has been adopted to avoid total extinction in case of breakdown in either division, and because the premises do not admit of putting down spare plant. The motive power is given by a 70 h.-p. Sulzer compound engine, running at 80 revolutions a minute, and supplied by steam from two 40 h.-p. Denayer tubular boilers. The work was executed by the Société d'Eclairage Electrique, who encountered great difficulties owing to the insecure foundations and bad condition of the walls. The *Bulletin de la Compagnie Internationale des Téléphones* suggests that all the Jablochkoffs be placed in the hinder half of the auditorium, so as not to tire the eyes of spectators; and also that the globes be of a slightly yellow tint, as at the Châtelet Theatre.

ELECTRIC LIGHT AT TORONTO.—We glean from the correspondence of the New York *Electrical World* the following particulars as to the lighting of Toronto by electricity. On 26th March tenders were opened, when it was found that the Toronto Electric Light Company, using the Excelsior system, offered for 65 cents. per lamp per night, and the Canada Electric Light and Manufacturing Company, using the Van Depoele, for 62 cents. It was resolved that the two companies be invited to set up twenty-five lights each, at 62 cents. per lamp nightly, for a period of three months, the company not making the better show to withdraw. On 16th May the two companies started twenty-five lights each, which number was subsequently increased to 44. At the expiration of the contest, on 13th August, the five years' contract was entrusted to the Toronto Company. This company has now circuits of over 30 miles, and has erected a fine station, 100ft. square, with six "Excelsior" 130-light dynamos, two Armington and Sims 50 horse-power engines, one 60 horse-power Ide engine, two 100 horse-power steel boilers, and safety switches for each circuit. Additional plant was also being contracted for to enable the company to provide for all possible contingencies, and guarantee an uninterrupted service of electric light. On the other hand, the Van Depoele Company is constructing large central plant for maintaining about 200 lights, and has also undertaken the construction of an electric railway, four or five miles long, to be propelled by an electric motor on their system.

RACE BETWEEN TWO ELECTRICAL LAUNCHES.—A new electric launch, the "Australia," has just been completed and launched from the wharf of the Electrical Power Storage Company at Millwall. The hull of this launch has been built by Messrs. Forrest and Sons, to the order of Messrs. Stephens, Smith, and Co., engineers, for an Australian firm. She is of mahogany; length 25ft., beam 5ft. 7in., and she can carry sixteen persons comfortably. The motive power consists of Electrical Power Storage accumulators, placed as ballast at the bottom of the boat, and a Reckenzaun electro-motor, driving a two-bladed gun-metal screw of 18in. diameter and 11in. pitch. The Reckenzaun motor weighs 390lb., and is capable of working up to 6 horse-power mechanical, but ordinarily it will be worked at a lower rate in this boat—at the rate of 5 electrical horse-power. Weather permitting, a competitive trial trip will take place on Saturday next, at two o'clock, from Millwall to Charing Cross Pier and back to Greenwich, the competing launch being the well-known boat "Electricity," which caused some sensation when launched in September, 1882. This launch was designed at the time by Mr. A. Reckenzaun for the Storage Company. She is of iron, 25ft. long, and only 5ft. beam. A set of Electrical Power Storage accumulators supply the current to a Siemens D2 dynamo, weighing 658lb. The screw is of steel, made by Messrs. Yarrow and Co., 18in. diameter and 11in. pitch, and which screw formed a pattern for casting the one in the new launch. It will be arranged that during the trial both machines shall be supplied with the same amount of energy, viz., 3,730 watts, or 5 electrical horse-power.

EDISON ON ELECTRICAL APPLICATIONS.—The *Electrical World* is responsible for the following :—

"What is the latest thing in the application of electricity, Mr. Edison?"

"The funniest is the new process of making incandescent whisky."

"What's that?"

"Well, that is whisky, as my friend Amos Cummings would say, with the shiver taken out of it."

"How do they effect that with electricity?"

"Well, I am told they let down the incandescent light into a barrel of whisky, and in sixty-four hours they get all the flavour of old whisky. The light and heat seem to act on the fusel oil somehow. I am told they make an excellent brand of whisky out of 'rot gut.'"

"Have you tried it?"

"No."

"What is the most curious electrical phenomenon of late?"

"That is hard to say, there are so many. One of them is a live fish swimming in a tub of clean water, having swallowed a bait consisting of a little incandescent lamp. When the current is turned on, the fish is lighted up, so you can see through him and observe the circulation of the blood."

"What do you propose to show at the Philadelphia Electrical Exposition?"

"Only about ten per cent. of my stuff; but enough."

"Did you ever know of any practical use for the phonograph?"

"No, except as a curiosity. About all the colleges have them. I had to give it up for the electric light, where the field is immense."

SINGLE-FLUID BATTERY.—M. Georges Pierre writes from Poitiers to our contemporary *L'Electricien* to the effect that he has invented a single-fluid battery which he claims to be impolarisable for several days, even when short-circuited. The negative electrode is amalgamated zinc, and the liquid the white caustic potash of commerce, as usual. But the positive electrode is in the form of a flat box, of a certain thickness, perforated with rather small holes. In the thickness of this box M. Pierre places as many small iron points as possible, and it is to these that he attributes the constancy of the battery, which serves for electro-deposition and for medical purposes. At the commencement of the action there is a high E.M.F., which, however, falls somewhat in a few hours, and then remains constant for several days upon a closed circuit. The cell is only 10 by 20 centimetres (4 × 8in.), with zinc on one side

Digitized by Google

only; but by giving it from 25 to 30 by 25 centimetres, and surrounding the zinc on both sides with two iron boxes of the same kind, a "duty" in amperes equivalent to that of a Bunsen element may be attained. The advantage of the battery is that it consumes nothing in open circuit. If the caustic potash be prepared by the user in a large cast-iron vessel, the liquid containing the potash in solution, when the solution of carbonate of potash has been treated with quicklime, has only to be concentrated to half its volume by evaporation, and then cooled, to be ready for use in this battery. The zinc may be replaced by a lead plate in the same battery. Although lead is cheaper than zinc, the difference is nearly compensated for by a lower E.M.F. The same battery may also be fitted with copper instead of zinc, when it has also a high E.M.F.; but this makes the battery unnecessarily expensive.

Music by Telephone.—Under this head we recorded last week the successful transmission of instrumental music from Brussels to Antwerp. Intelligence now reaches us of an opera played in Brussels being heard by the King and Queen of the Belgians at Ostend. Six microphones on the Van Rysselberghe systems had been placed in front of the footlights, facing the performers. Two similar instruments were also fitted, one on either side of the conductor's desk, at the height of the musical instruments in the orchestra; and for future occasions it is determined to add a double microphone in the prompter's box. All these transmitters were actuated by a single Faure accumulator, placed under the stage with the microphone coils, the latter being all mounted in quantity, and really forming but one and the same transmitting instrument. As in the case of the experiments recorded last week, the circuit was formed by one of the overhead wires of the Bell Telephone Company, leading from the central office to the northern terminus, where it joined the State Telegraph line to the Ostend Station, which was in direct communication with two Bell receiving instruments, fixed in the drawing room of the royal châlet. M. Berlin, engineer, who had directed the installation with M. Van Rysselberghe, remained at Ostend, while the latter gentleman went backwards and forwards from the Monnaie Theatre (the Brussels Opera House) to the telegraph office at the northern terminus for watching how the instruments worked. These had been placed in the theatre during the day by M. Mourlon's men in charge of the foreman, Hobé. The experiment is reported to have again succeeded beyond expectation, and on the following day M. Van Rysselberghe had the honour of being received by the Queen, who is known to be an assiduous opera-goer as well as an accomplished musician. Her Majesty spoke of having heard perfectly all the details of the first and last acts of "Faust," and made some valuable suggestions for a permanent installation.

The Telephone in Spain.—There exists at present no public telephone system in Spain, though there are municipal lines at Bilbao and Valencia, military lines at Madrid, Valencia, Saragossa, and Carthagena, and a few private lines, none of which latter exceed six miles in length. A royal decree, published by the official journal, authorises the installation of a regular telephonic service in Spain. The subscribers will be put in communication with central offices, which will be open to the public for sending verbal messages on payment of a small fee. The laying and working of the lines will be retained by the Government, as well as the ownership of all instruments. There are to be two classes of subscription, one from 8 a.m. to 10 p.m., at £20 per annum, and the other for both day and night at £24. Clubs, casinos, hotels, cafés, theatres, and railway stations will be charged £40, on account of the large number of persons telephoning. Subscribers may forward and receive their telegraphic messages by telephone. They may also send, through the central offices' telephonic messages at the rate of 3d. up to thirty words. Private lines may only be laid between establishments belonging to the same owner; they may not be connected with any telephone or telegraph line; and the *concessionnaires* may only use them for their private communications. The State also reserves the right to suspend them when necessary for the maintenance of public order. All lines now laid in the country will be suppressed as soon as the Government system is laid in their neighbourhood. Lines for connecting the various towns of the kingdom may be laid, provided they communicate directly with a State telephone or telegraph line. The *concessionnaires* will have to lay down these lines at their own cost and risk, and may employ what materials they please, except telephone instruments, which must unite the conditions imposed by the Government, so as to communicate with the State offices. The duty payable to Government will be 23 per cent. of the gross receipts.

The Van Rysselberghe System.—*Apropos* of this ingenious system, the *Bulletin de la Compagnie Internationale des Téléphones*, in an article on Inter-urban Telegraphy, draws attention to the fact that the recent arrangements made for the transmission of music to a distance in Belgium were improvised. For instance, the connections which permitted the King and Queen of the Belgians to hear an opera at Ostend (recorded in *The Electrician* of this week) were not decided upon until after the successful transmission to Antwerp of the Wauxhall Concert at Brussels (described in our last issue). Our contemporary goes on to observe that if theoretically the conception of the inventor is one of ingenious simplicity, its practical application to the Belgian telegraphic system, with its 29,000 kilometres (18,020 miles) of wires, and 855 offices, presents great difficulties in execution. The method adopted for telephoning and telegraphing by the same wires does not depend on the use of microphones or special telephones, though the first experiments were made with their assistance. M. Van Rysselberghe sought, in the first place, by the use of a battery and a special microphone, to amplify the telephonic voice sufficiently to overcome telephonic induction, and he succeeded. But, considering all the difficulties in the way of a complete transformation of the existing plant, he endeavoured to solve the problem by setting himself as a fixed condition the retention of the present telephone instruments. He again succeeded, and in this case by neutralising the induction itself by a graduation of telegraphic currents. Moreover, it appears from experiments made by the telegraph engineers that the Blake microphone, used by the Bell Telephone Company in Belgium, is an excellent instrument, which, indeed, requires regulating; but the company takes the necessary measures for continually keeping the communications in good condition. With these instruments verbal messages have been exchanged between Ostend and Arlon, a distance practically equal to that between Paris and Brussels. It may therefore be affirmed that these instruments serve capitally for exchanging spoken messages between all points of Belgium—as they will be before long; and so much the more that, quite recently, acting on the advice of M. van Rysselberghe, the company has not hesitated to introduce into the batteries which actuate its microphones a modification which will considerably increase their power. The main point, which is now set beyond a doubt, is that by putting in action known and tried methods, telephonic communications, even international, may be established, and that,

Digitized by Google

with ordinrry telephones and microphones, verbal messages may be sent along telegraph wires, without diverting them from their original purpose, for such a distance as that comprised between the extreme points of Belgium.

COMETS' TAILS.—Professor R. S. Ball, in his lecture at the Montreal meeting of the British Association, thus accounts for comets' tails:—The next question that arises is as to the physical explanation of the repulsive force which produces these tails. We have to find this force of three different intensities, one about twelve times as great as gravity, one about equal to gravity, and one about a fifth of gravity. Before we postulate the existence of a new force of some unknown character, is is surely our duty to inquire whether there may not be some force already known which is competent to produce the phenomena. The best known repulsive force is of course that with which every one is familiar in connection with electricity. Electricity attracts electricity of an opposite type, while it repels that of the same type. We are also aware that in some mysterious manner the sun is connected with electricity. We know that the phenomena of terrestrial magnetism are connected with soler phenomena, and hence we are tempted to inquire whether the electricity of the sun may not offer an adequate explanation of the phenomenon of the comet's tail. Let us suppose that the sun is attracting a distant body by virtue of gravitation, and at the same time repelling that body in virtue of the fact that the sun and the body are both charged with electricity of the same name. When the attracted body is one of large dimensions, the attraction will vastly exceed the repulsion, and indeed the latter may be entirely neglected in most cases. There is, however, a radical difference between the nature of the electrical forces and the nature of the gravitational forces. The latter are proportional to the masses of the attracting bodies, while the electrical forces are proportional to their surfaces. The mass varies as the cube of the linear measurements, while the surface only varies as the square. The relative efficiency of the electric repulsion in comparison with the gravitational attraction increases as the radius of the particle decreases. It must thus necessarily follow that, no matter how great may be the preponderance of the power of gravitation on masses of finite dimensions, yet it must always be possible, other things being equal, to have a particle so small that the electrical repulsion shall exceed in any required ratio the intensity of the attraction of gravitation. As the comet draws near the sun, the heat it experiences increases, so that the materials of the comet begin to dilate, and to be driven off into a vaporous condition. The matter is thus resolved into a state of extreme subdivision. These separate particles are charged with an electricity similar to that of the sun, and in virtue of their minuteness the intensity of that repulsion has become sufficient to sweep off the particles in a stream, and thus generate the tail. Such is the modern view of the formation of comets' tails.

LIGHTHOUSE EXPERIMENTS.—When Dr. Tyndall resigned his position as scientific adviser to the Board of Trade and the Trinity House, he did so (says the *Journal of Gaslighting*) chiefly on the ground that he could not be a party to what he considered a one-sided investigation as to the respective values of gas, oil, and electricity as lighthouse illuminants. Inasmuch as Sir James N. Douglass, the engineer to the Trinity House, had a pecuniary interest in oil lamps, which he had patented, Professor Tyndall thought he ought not to have any voice—through his Board or otherwise—as an adjudicator in regard to the respective merits of the three illuminants. That Dr. Tyndall was right in urging this point soon became apparent, for the Illuminants Committee would not allow the Commissioners of Irish Lights to exhibit, in the experiments, the most powerful form of gaslight which Mr. Wigham had devised; and believing that the experiments would be quite futile unless this were done, the Irish Commissioners withdrew, and the committee was dissolved. Strange as it may appear, the Board of Trade subsequently entrusted the whole inquiry to the Trinity House; and the experiments frequently referred to of late in our columns have been organised and conducted by them with the assistance of their engineer. So far, they have carried out the programme precisely as the Illuminants Committee intended it to have been carried out. They have erected at the South Foreland three lighthouse lanterns—"A," containing the electric light; "B," the gas light; and "C," the oil light. The towers were placed sufficiently far apart to enable the lights to show to the horizon without blending. The Trinity House, being of the same mind as they were when in the majority of the Illuminants Committee, still, we understand, refused to allow Mr. Wigham's double quadriform gaslight to be shown; alleging, as their reason, that it had not yet been used as the illuminant in any lighthouse. They therefore, in the "B" tower, fixed an ordinary quadriform gaslight, such as is used at Galley Head. In the "A" tower they fixed an electric light of enormous power, produced by the action (combined or separate) of three of De Meritens' largest dynamos. No such electric light has ever been exhibited before at a lighthouse; and in showing this one at the South Foreland, the Trinity House seem to have forgotten the rule under which they excluded Mr. Wigham's best gaslight. In like manner, in "C" tower, they placed three of Douglass's patent oil burners over each other, although no such arrangement had ever been adopted at any lighthouse. The nearest approach is at the new Eddystone Lighthouse, where two such oil burners have been used. Thus, at the very outset of these experiments, gas seems to have been placed unfairly at a disadvantage. Nevertheless, the observations of the lights which have been made (now extending over many months) have shown that, in the ordinary state of the atmosphere, the electric light is the brightest (next comes gas, and last oil); but in hazy weather, and more especially in fog, the order has been: Gas, first; oil, second; electric light, last. If this be so, how much more markedly may we suppose gas will come to the front for lighthouse purposes when Mr. Wigham shows his double quadriform light. The arrangements of the Trinity House for the observation of the lights have been very elaborately and carefully made. Huts have been erected at various distances from the lights, and lines of observation staked out between them and the lanterns. Intimation of the experiments has also been given to mariners navigating the Channel, and they have been requested to observe the lights, and transmit their reports to the Trinity House. The observers in the huts are lightkeepers in the service of the Trinity House, and the masters of the lightships belonging to the Corporation have also been requested to send in reports of their observations. The American and French Governments have appointed representatives to observe and report upon the experiments. It would of course be premature to pass any conclusive judgment respecting the usefulness of these three lights for lighthouse purposes until the various reports have been completed and made public. But enough has transpired to warrant us in the expression of our belief that a great victory has been won by gas; and that if this mode of illumination be given full scope by lighthouse authorities, methods for its application as yet unthought of will speedily be adopted to the great and lasting benefit of seafaring men.

THE INDUCTION OF CURRENTS IN CORES.

BY OLIVER HEAVISIDE.

(CONTINUED FROM PAGE 388.)

Telegraph Cable Analogue.

Let the Telegraph Construction and Maintenance Company be instructed to construct a cable according to the following simple specification, all other details being left to them :—Its electrostatic capacity to vary in simple proportion to the distance from one end O. Its conductivity to vary in simple proportion to the distance from O. That is all, except that its self induction must be negligible. Let r = distance measured from O, then rc and r/k are the capacity and conductivity per unit length, c and k being constants. Let v be the potential at distance r from O, then the current there will be $-\frac{r}{k}\frac{dv}{dr}$, and the charge per unit length will be rcv, making the differential equation of the potential to be

$$r c \dot{v} = -\frac{d}{dr}\left(-\frac{r}{k}\frac{dv}{dr}\right), \quad \text{or} \quad c k \dot{v} = \frac{1}{r}\frac{d}{dr} r \frac{dv}{dr}.$$

This being of the same form as the equation of H in the core, all the previous solutions may be translated into the solutions of problems connected with signalling through the cable.

The strength of force at distance r from the axis of the core corresponds to the potential of the conductor at distance r from the end O; the strength of the circular current in the core to the strength of current in the cable divided by the distance from O. Let the other end of the cable be at P. This corresponds to the boundary of the core.

The cable being constructed, submerged, and a station opened at the end P, let an intelligent operator make connection between the cable and earth through a battery. The electrostatic potential will be propagated through the cable in the same manner as the magnetic force is sent into the core when the coil circuit current is similarly operated upon. There will be no current at the end O, because the conductivity is zero there, so it will be of no use to put a recorder there, though as the potential varies an electrometer might be made use of. But, by cutting a small piece off the end, we may let some current pass, and then use a recorder, without practically altering the nature of the potential propagation.

An artificial line approximately fulfilling the conditions would perhaps serve as well, in case it should not be found convenient to have the cable constructed. Or, it may be left wholly to the imagination.

Example 3. Coil of Any Depth.

When the depth of the coil is not small compared with the radius of the core, an appreciable fraction, or it may be a large fraction, of the magnetic energy is contained between the inner and outer boundary of the coil, *i.e.*, in the wire itself, its covering, and the air spaces, and requires to be taken into consideration, as it modifies somewhat the boundary condition, and the solution. Putting E = 0 in (19), and $H = 4\pi N\Gamma$, we have

$$0 = RH + (L - L_1)\dot{H} + \frac{L_1\rho}{2\pi\mu c}H'$$

for the boundary condition. Put $H = J_0(nr)e^{Dt}$, and it becomes

$$0 = \{R + (L - L_1)D\}J_0(nc) - \frac{L_1\rho n}{2\pi\mu c}J_1(nc).$$

Here, for generality, we let the boundary be at $r = c$, the space from $r = c$ to $r = a$ being air. Putting D in terms of n, we get

$$J_0(nc)/J_1(nc) = (L_1 n\rho/2\pi\mu c)\{R - (L - L_1)n^2\rho/4\pi\mu\}^{-1} \quad . \quad (95)$$

the determinantal equation, whose roots give us the admissible values of n, and therefore also of D.

In finding the coefficients A in the solution $H = \Sigma A J_0(nr)e^{Dt}$, we must remember that now $J_0(nr)$ from $r = 0$ to $r = c$, *i.e.*, from axis to boundary of the core, is not a complete normal system; to complete it, we have $J_0(nc)$ from $r = c$ to $r = a$, and $J_0(nc)\{1 - (r - a)/b\}$ from $r = a$ to $r = a + b$, if b be the depth of the coil. The three taken as a single set constitute a complete normal system to which the conjugate property $\Sigma v_1 v_2 r\mu = 0$ applies. Also remember that the permeability is μ in the core, and unity without it.

Thus,

$$\left.\begin{aligned} 0 = \mu\int_0^c J_0(n_1 r)J_0(n_2 r)rdr + \int_c^a J_0(n_1 c)J_0(n_2 c)rdr \\ + \int_a^{a+b} J_0(n_1 c)J_0(n_2 c)\left(1 - \frac{r-a}{b}\right)^2 rdr \end{aligned}\right\} . \quad (96)$$

is the expression of the conjugate property in its physically most meaningful form, *i.e.*, expressing directly that the mutual energy of two normal systems is *nil*.

Otherwise, use equation (76), putting $J_1(nc)$ in terms of $J_0(nc)$ by (95). We shall obtain, after reductions,

$$\frac{\mu l}{2}\int_0^c J_0(n_1 r)J_0(n_2 r)rdr + (L - L_1)\frac{J_0(n_1 c)}{4\pi N}\frac{J_0(n_2 c)}{4\pi N} = 0 \, . \quad (97)$$

expressing the same truth as (96), but now in terms of the normal systems of current in the coil (instead of magnetic force from $r = c$ to $r = a + b$), and the coefficients of self-induction.

Here $J_0(n_1 c)/4\pi N$ and the similar expression with n_2 instead of n_1 are the proper coil currents corresponding to the normal core magnetic force systems $J_0(n_1 r)$ and $J_0(n_2 r)$. Calling the latter H_1 and H_2, and the former Γ_1 and Γ_2, we may write

$$0 = \frac{\mu l}{4\pi}\int_0^c H_1 H_2 2\pi r dr + (L - L_1)\Gamma_1\Gamma_2 \quad . \quad . \quad (98)$$

expressing, in the simplest form, that the mutual energy of a pair of normal systems is zero, a principle to be considered in a later section. If, then, H_0 and Γ_0 be the complete initial core magnetic force and the coil current, the value of any coefficient A_m in the proper expansion is

$$A_m = \frac{\frac{\mu l}{4\pi}\int H_0 H_m 2\pi r dr + (L - L_1)\Gamma_0\Gamma_m}{\frac{\mu l}{4\pi}\int H_m^2 2\pi r dr + (L - L_1)\Gamma_m^2} \quad . \quad . \quad . \quad (99)$$

The value of the denominator in any case, and of the numerator in case H_0 = constant, is

$$\left.\begin{aligned} \text{Numr.} &= J_1(nc)\left\{\frac{\mu l c}{2n} + \frac{L - L_1}{4\pi N}\frac{\Gamma_0 s n}{1 + (L - L_1)D/R}\right\} \\ \text{Denr.} &= \frac{\mu l c^2}{4}\{J_1(nc)\}^2\left[1 + \frac{\{1 + (L - L_1)/(4\pi N)^2\}s^2 n^2}{\{1 + (L - L_1)D/R\}^2}\right] \end{aligned}\right\} (100)$$

It is useful to use Γ_0 and the coefficients of self-induction, for these reasons. First, not only may H_0 be arbitrary (a function of r), but Γ_0 may have any value we please, quite independent of H_0. Thus we might have it given that $H_0 = 0$; then we use only the second part of the numerator. Γ_0 having any stated value implies a certain distribution of force outside the core, constant between the core and the coil, and varying in the depth of the coil in the manner stated in the earlier part of this section. If there be no force in the core at the same time, there is a discontinuity at its boundary, implying a surface current in the proper direction, and of strength sufficient to cancel the magnetic force in the core due to the coil current. This boundary current is of course purely imaginary, having infinite volume density. But the moment the subsidence commences the discontinuity is rounded off, the surface current spreading into the core, becoming the real induced current accompanying the passage of magnetic force into the core from outside, where it previously existed.

Next, whilst in Example 2 (circuit closed, coil of small depth) we supposed there to be no self-induction in the external circuit, we may now remove this restriction, as well as that relating to the depth of the coil. There may be any amount of self-induction in the external part of the circuit, provided it be unaccompanied by induced currents in metal in the neighbourhood; *e.g.*, there may be other coils in the circuit, either without cores or with cores divided to stop

Digitized by Google

induced currents. This self-induction must be included in the value of L above, no other alteration being required, except in equation (96), which does not allow for the external induction.

(TO BE CONTINUED.)

THE BRITISH ASSOCIATION MEETING AT MONTREAL.

On a New Voltmeter.

BY CAPTAIN CARDEW, R.E.

It is quite unnecessary at the present day to dilate on the extreme importance in electric lighting, especially by incandescence, of keeping the pressure or volts on the lamps constant within very small limits. The necessity for this must have forced itself on the notice of all who have had any experience of this lighting. However perfectly the dynamo may be compounded or the engine governed, it is very desirable that the engine driver should have an electric pressure gauge to which he can refer as readily as to his steam gauge. The instruments about to be described were originally designed for the use of engine drivers, and are adapted to the meanest capacity. At the same time they give perfectly trustworthy readings.

There are two ways of measuring the difference of potential or volts between the terminals of a dynamo or any other points in an electric circuit, which we may call the statical and dynamical methods. The former, or measurement of the force of attraction between bodies charged from the two points respectively, is too delicate for the purpose in view, and the latter, or measurement by means of a current produced by connecting these points by a conductor, was therefore adopted. Now, when a current is passing in a conductor it creates a magnetic field in its vicinity by which an effect can be produced on other bodies. The measurement of the current is usually made by observing this effect on another body. This method may fail from two causes:—

1. Other things may affect the body obscuring the effect of the current.
2. Owing to a change in the condition or position of the body, the effect upon it of the current may be altered.

These were obvious objections to entrusting this method to an engine driver in a room full of dynamos and iron machinery, but the current energy produces another effect. It develops heat in the conductor, which causes an expansion of volume to take place in it. This effect of the current energy appeared likely to offer a solution of the difficulty.

The instrument now before you is the outcome of many experiments made with the view of utilising this effect for the exact measurement of the current passing, and thus of the difference of potential existing between the points to which the instrument is applied.

This instrument is extremely simple in principle and construction. It consists essentially of a very fine platinum silver wire, ·0025in. in diameter, enclosed in a brass tube.

The difference of potential to be measured is applied at the ends of the wire, which is heated by the current passing through it. The wire expands on being heated, but is kept stretched by a spring or weight, and the expansion is indicated by suitable apparatus.

The heat produced in any conductor, not containing an electromotive force, by any difference of potential applied to the ends is equal to $\frac{V^2}{R}$ per unit of time, where V is the difference of potential in volts, and R the resistance in ohms. The resulting temperature of the conductor for any difference of potential depends on the temperature and the rate of motion of the particles of the surrounding medium. It will be seen from this that the absolute stretch of the wire, which would accurately measure its rise of temperature, would not be an accurate measure of the current passing through it, or of the volts producing that current. Even when no current was passing the instrument would not maintain an accurate zero, since alterations of atmospheric temperature would affect it.

These defects are obviated by the use of the brass tube enclosing the wire.

The coefficient of expansion of brass for temperature is sensibly the same as that of platinum silver.* Hence, so long as they are both at the same temperature, the zero is unaffected by any alteration of it, or the variations in length of the wire are compensated. When, however, a current is passed through the wire its temperature is raised above that of the surrounding tube, and a perfectly regular current of heat is established between the wire and the tube since all external draughts are prevented. It is therefore the difference of temperature between the wire and the tube that is measured, and this is necessarily constant for the same difference of potential, except for the fact that the resistance of the wire varies slightly with its temperature.

This variation in the resistance has the effect of causing the reading for any volts to be slightly higher on a cold day than it is on a warm one, but as the alloy of platinum and silver used only varies ·035 per cent. per degree centigrade, this error is not worth consideration as long as the surrounding air is at an ordinary temperature.

The considerations guiding the choice of a wire for the purpose were as follow:—

1. It must absorb a minimum of energy, therefore the wire should be as fine as possible and of a high specific resistance.
2. It must follow all variations in the volts with extreme rapidity, and must therefore be formed of a metal of low specific heat, and must offer a large surface for its mass.
3. The material must not be liable to oxidation even at a high temperature.
4. The coefficient of variation of resistance for temperature must be very small.
5. Its elasticity and tensile strength must be high.

A fine platinum silver wire best answered these conditions.

The instruments are practically instantaneous in their indications, and quite dead beat.

Having determined by these considerations the most suitable material and size of wire, the next point to determine was the number of volts that could safely be put on any length of it. With this view one foot of the wire was taken, and the number of volts required to make it just visibly red in a dark room determined to be 21. As the rise of temperature for any number of volts varies as v^2 it is evident that 10 volts would only raise 1ft. to rather less than $\frac{1}{4}$ the amount required to redden it. This rise does not permanently alter the wire.

The working maximum number of volts is therefore taken at 10 per foot. For 200 volts, therefore, 20ft. of the wire is required, but this length need not necessarily be contained in the instrument, although it is advisable to use the same kind and size of wire throughout.

The instruments are generally made to work to 120 volts, and a sufficient length of wire supplied in a metallic box to extend the readings to any required number of volts.

For ordinary purposes it is quite sufficient to extend the limits to which the instrument will measure by putting an incandescent lamp in circuit with it. Thus an instrument for 120 volts has a resistance of about 360 ohms, and if an Edison lamp be added it will easily read to 200 volts.

In order to save the instrument from fusion by excess of current a safety fuse is placed in the circuit. This consists of a short length of finer platinum silver or iridium platinum wire.

As regards the application of the instrument to alternating currents, the presssure which it will indicate with these is the equivalent useful pressure of difference of potential—that is to say, it indicates a difference of potential which, with a continuous current would, if applied to the same wire, do the same amount of work per unit of time. This is evidently what is required to be known for all industrial applications. Of course the absolute difference of potential with an alternating current is continually varying between certain positive and negative limits much higher than the industrial mean, passing in each period of variation through the value 0.

The instrument, however, while indicating the industrial mean follows the variations of pressure sufficiently to emit a musical note corresponding in pitch to the number of alternations per unit of time.

* More perfect compensation is obtained by making two-thirds of the tube of brass, and one-third of iron or tinned iron.

Digitized by Google

In the more portable instruments on this principle the extension of the wire is multiplied so as to give a reading over a large dial by delicate wheelwork. This necessarily introduces some complication and chance of error, although the force of the spring is sufficient to easily overcome the friction.

For a standard instrument, not intended to be carried about, it was worth while to eliminate this chance.

In considering this the use of a beam of light as an index naturally suggested itself. As the natural motion in this case was rectilinear, and not angular as in a reflecting galvanometer, it was obvious that the best arrangement was a kind of magic lantern by which a greatly magnified image of a portion of the wire should be projected on a screen.

Two very fine cross wires are fixed on the wire within the field of the lens, which, of course, appear in the magnified image on the screen. The distance between the images of these cross wires constitutes the base line, which is always kept of a certain length, so many feet or inches, by slightly moving the screen or instrument. When the volts are applied the cross hairs move down by the extension of the wires, their images, of course, move up, the upper one soon disappears, but the reading is taken from the lower one, and having once standardised the instrument with a certain base line we can at once obtain the volts corresponding to any movement of the lower image by reference to the curve. The instrument in this form then is one of elementary simplicity, and yet may be called scientific. Here is a rough arrangement to illustrate the principle. It consists of the tube with the wire down the centre terminating in a spring, the lens arranged with the wire and cross hairs in focus, the dark lantern, of course, separate from the tube to avoid error from the heat given off by it and the screen. The instrument has not been standardised, but we will take readings on the portable instrument at the same time.

In order to make a direct reading instrument of this—that is to say, measure off the volts at once—it is sufficient to mark them off from the curve of the instrument on a piece of stiff card or slip of wood of the exact length of the base line.

This form of instrument can be made moderately portable by attaching a camera body to the tube, the image of the wire being received on a ground-glass screen with a scale marked on it. In this case the tube should act as a support to the camera, as the wire can be pulled up as well as down.

The instrument can readily be made to register ordinary variations of electric pressure on mains by simply fixing a very small incandescent lamp—the size used for surgical purposes answers well—on the wire, so that the current through the wire passes also through the lamp and renders it luminous. These lamps are made to take a current of about one-fourth ampere, which gives a good extension to the wire, the maximum current it can safely take being rather under one-third ampere. The image of the filament of the lamp, which in this case is nearly a straight line, is thrown by the lens on a sheet of paper sensitised by the bromide process, all other light being carefully excluded; so long as the volts remain constant the filament will simply produce a magnified image of itself, but any variation of the volts by causing the lamp to slightly shift its position will produce a vertical elongation of the mark.

After each night's work the paper can be developed, fixed, and examined, and the limits of variation of potential for the whole time obtained by simple measurement.

As the companies undertaking house-to-house lighting will be liable to fine if a certain limit of variation is at any time exceeded, registering instruments of this kind will become a necessity.

The only other form of this instrument which is worth mentioning as promising to have a distinct use is a pocket form, with tube not more than a foot long, in which the readings are taken by observing the movement of the wire with a simple microscope. In this case the wire is not pulled by one end, but in the middle, a very slight actual extension being sufficient to produce a perceptible sag in a stretched wire. This idea was suggested to the inventor by Dr. Muirhead.

Mr. Bottomley's Paper on "The Loss of Heat by Radiation and Convection, &c.," will be found on page 441.

ENDLESS SOLENOID GALVANOMETER & VOLTMETER.

BY PROFESSOR JAMES BLYTH, M.A., F.R.S.E.*

The instrument consists of a close spiral of insulated copper wire, about two inches in diameter, bent into the form of an anchor ring, so as to constitute an endless solenoid. The coil is placed in a groove of square section turned on the edge of a ring of brass or wood of suitable thickness and diameter, and is fixed therein by passing a fine cord two or three times through its convolutions, then pulling the ends tight and knotting them firmly together. In this way the convolutions of the spiral are close together on the inside of the groove, but a little wider apart on the outside, leaving V-shaped gaps between them. At both ends of the spiral short lengths of wire are left straight, which, after being well insulated, are twisted together and led to two terminals which serve as electrodes.

The ring containing the endless solenoid is fixed with its plane either vertical or horizontal, as most convenient.

A short magnet is provided, rigidly attached at its centre to the lower end of a fine stiff wire. This magnet is suspended, by means of a silk fibre passed through a fine hole in the upper end of the wire, so as to have its centre in the circular centre-line of the anchor ring formed by the spiral. To the upper end of this wire is attached a long glass fibre or other pointer, which moves over a disc graduated to degrees, or to show amperes directly. When the plane of the containing ring is vertical, the graduated disc is placed horizontally with its plane tangential to the ring; when the ring is horizontal, a graduated sector is attached horizontally to its upper face.

Where weak currents only are to be measured the suspended magnet is allowed to move simply in the field of force due to the earth's magnetism, and we get the following equation for determining the current strength, it being understood that the length of the magnet is very small compared with the other dimensions of the coil:—

Let n = the number of convolutions of the spiral,
r = the radius of the circular centre line,
H = the horizontal intensity of the earth's magnetism,
C = the current strength,
θ = the angle of deflection,

then $$\frac{2nC}{r}\cos\theta = H\sin\theta \qquad C = \frac{Hr}{2n}\tan\theta.$$

From this it will be seen that the galvanometer constant, $\frac{2n}{r}$ admits of easy and accurate determination, seeing that it depends only upon the values of n and r, the one of which is got by simple counting, and the other by careful measurement.

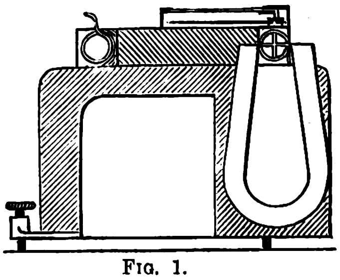

FIG. 1.

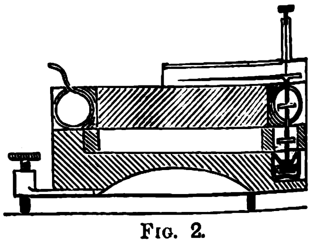

FIG. 2.

When strong currents are to be measured, the suspended magnet is made to move in a field of force of greater intensity than that due to the earth's magnetism. This is obtained by a permanent magnet of suitable form and dimensions placed so that the suspended magnet hangs in the line joining its two poles. When this is done, in order to get the current strength, we must replace H in the above equation by its value increased by the value of the intensity of the field due to the permanent magnet—a quantity which admits of experimental determination. In practice, however, with a controlling magnet, the constant of the instrument will be most easily determined by passing a known current through it and observing the deflection of the needle.

When the plane of the ring is vertical or horizontal, the controlling magnet is simply an ordinary horse-shoe magnet, placed

* A paper read before the Philosophical Society, Glasgow, April, 1884.

Digitized by Google

either vertically or horizontally, so as to clasp the ring with its poles opposite the suspended magnet. This form is shown in Fig. 1.

A slightly different form is shown in Fig. 2. In this case two short magnets are rigidly attached to the same axis, so as to form an astatic system. The distance between the magnets is so adjusted that, when the whole is suspended by a silk fibre, the upper magnet has its centre in the centre of the spiral coil, while the lower projects a little below the under surface of the containing ring. The controlling magnet is then fixed so as to have the lower magnet exactly between its poles, and in this way acts solely, or at least mainly, on the lower magnet. A convenient magnet for this purpose consists of a steel bar bent so as to form one convolution of a helix, its ends being kept at the requisite distance apart, as represented in Fig. 3.

This form of magnet admits of its being placed in the proper position relatively to the lower magnetised needle, without, at the same time, projecting at any part from below the containing ring.

This form of galvanometer has one distinct advantage over all others in which permanent controlling magnets are used. In them the current, in the act of being measured, creates a magnetic field of its own, which acts upon the magnetism of the controlling magnets. This action, often repeated, tends to produce greater variations in their magnetism than that due merely to their natural want of magnetic rigidity; and hence, in time, must produce serious alteration in the constants of the instruments. With the endless solenoid, however, no such effect can take place, seeing that, when the current circulates in it, it becomes a closed magnetic shell, and, in consequence, can exert no magnetic force at any point outside itself. Hence, when the constant is once carefully determined, the mere use of the instrument tends to produce no change in it, and any change which takes place must be due either to avoidable accident or to the natural disturbance which takes place in the magnetism of even the best made permanent magnets.

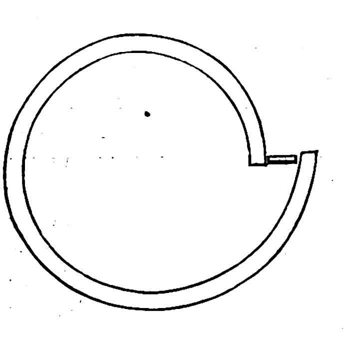

Fig. 3.

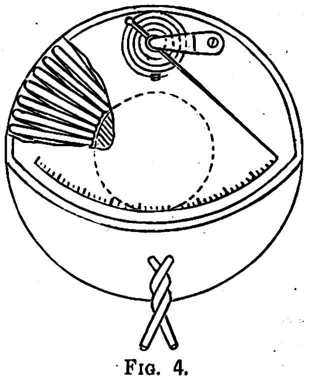

Fig. 4.

To avoid altogether the use of a controlling magnet, I have, in one form of the instrument (Fig. 4), replaced its directive action on the needle by that of a spring, which may either be a flat helical spring, like the hair-spring of a watch, or a cylindrical spiral like the balance-spring of a chronometer. In this form, the axis carrying the magnet, or astatic system, is pivoted between agate cups. The spring is placed a little above the upper surface of the containing ring, and has one end attached to the axis carrying the magnetised needle, while the other is attached rigidly to a suitably placed support. In this way the turning action of the spring on the axis is exactly similar to the action of the hair spring on the balance wheel of a watch. A long pointer is attached to the upper end of the axis, and is set so that the angle between it and the magnet is 45°. In this way the pointer can sweep over a sector having an angle of 90°, which allows it to be made of considerable length and the length of the scale divisions proportionally great. In fact, if $r =$ the radius of the circular centre line of the spiral coil, the length of the pointer is $r\sqrt{2}$ when the angle through which it turns is 90°.

When a current is sent through the solenoid the needle is deflected, until the couple, due to its electro-magnetic action in the needle, is balanced by that acting on the axis due to the flexural rigidity of the spring. The angle of deflection shows the current strength, and, for greater convenience, the scale is graduated so as to indicate amperes directly. With a delicate spring weak currents can be measured in this way. To measure strong currents with the same spring an arrangement is provided, whereby the attachment of the outer end of the spring can be rotated through known angles, as indicated by a separate and shorter pointer. In this way a greater electro-magnetic force is required to produce a given deflection of the needle, and, in consequence, stronger currents can be read. For each position of the short pointer a constant is experimentally determined whereby the indications of the long pointer are made to show the true current. I have also arranged a slight modification of this form, which will sometimes be found more convenient. In it the long pointer is placed parallel to the magnetised needle, and by rotating the outer end of the spiral spring is always brought back to the same position, that position being such that the magnetised needle is perpendicular to the circular centre line of the spiral coil. The position of the second pointer then shows the current strength. When this is done, the position of the magnetised needle is always such that the couple, acting upon it, due to the electro-magnetic action of the current, is greatest.

In the arrangement with a spiral spring, a magnetically astatic system can be dispensed with by simply tilting the plane of the containing ring to such an angle that the axis carrying the magnetised needle is parallel to the line of the dip. When this is done the needle moves in a plane at right angles to the lines of force due to the earth's magnetism, which, in consequence, has no action upon it.

The voltmeters are constructed precisely on the same plan as the galvanometers, the only difference being that the spiral is made of very fine wire, so as to introduce the requisite great resistance.

SELECTED CORRESPONDENCE.

The following correspondence on the subject of electric lighting appeared in *The Times* in continuation of that reprinted in our last issue:—

Sir: Allow me to correct one important statement contained in the letter of "E.G." which appeared in *The Times* of to-day.

He says, "So long as the industry was free and untrammelled it prospered." From this it may be inferred that the promoters of electric lighting previously to the legislation of 1882 possessed facilities at common law which have been taken away from them by that legislation. This is not the case. The first principle of the Bill of 1882, as stated by myself on behalf of the Board of Trade to the Select Committee, was that no existing legal power of supplying electricity should be taken away, and this principle was adopted by the Select Committee and by Parliament.

The legislation of 1882 was rendered necessary by the rush and scramble of electric lighting companies to obtain new parliamentary powers for taking possession of the public streets—powers which, as the experience of gas and water has proved, end in monopoly. The essential feature in the Electric Lighting Act of 1882 is the grant of powers to take possession of the streets, subject to certain conditions. Into the merits of those conditions it is not for me to enter. I merely wish to deny the statement or inference that the companies were by the Act of 1882 deprived of legal powers which they possessed before the passing of that Act.

Your obedient servant,

T. H. Farrer.

Board of Trade, Whitehall Gardens, S.W., Sept. 10.

Sir: The excellent remarks made by you this morning ought to be a sufficient answer to all who are disposed to condemn the Electric Lighting Act, but as it cannot be too often insisted on that this Act has done some good and prevented much harm, perhaps you will allow me to add a few words to what has already been said.

The crowd of professional witnesses who gave evidence before the various Parliamentary Committees to which the Lighting Act and the Provisional Orders Bills were referred, always took a most sanguine view of the situation, and everybody seemed to be more than satisfied when the period of monopoly had been extended from fourteen to twenty-one years; but as soon as the difficult problem of economical production and distribution actually stared electric light companies in the face, nothing was done, and it became necessary to invent excuses for their inaction. Thousands of pounds have been wasted, the public confidence is shaken, and the belief is rapidly gaining ground that "electric lighting does not go ahead" because it is not well enough understood.

The granting of a further extension of the monopoly period might induce many persons to subscribe new capital, but to what useful purpose could it be put by any of the existing companies?

A little firmness on the part of the Board of Trade will effectually put a stop to trading under false pretences—the hope and stay of rotten concerns, and time will prove that our much-abused Electric Lighting Act, with all its faults, has been a blessing to Your obedient servant,

London, September 10. Poor Investor.

PROFESSOR FORBES'S REPORT.

The report, which we reprint elsewhere from the Society of Arts *Journal*, is eminently unsatisfactory—unsatisfactory not from what is said but rather from what is omitted. Indeed the report is little more than an extended catalogue of the exhibits, and contains little or nothing of what is ordinarily understood to constitute a report. We suspect that Professor Forbes is not to blame for this state of things, and that the fault, if fault there be, must be laid at the door of the executive.

The Exhibition has been a success spectatorially and pecuniarily, and success in these days covers a multitude of sins. It is a thrice told tale to relate in terms of the highest commendation the work of the Royal Agricultural Society in connection with farming implements, and especially in connection with those in which steam power is utilised. Reference is made to this work, and there is no intention of dwelling at length upon it merely to strengthen the suggestion that the execution at the Fisheries, the Healtheries, the Inventories, &c., might have taken the same position with regard to electric lighting as the Royal Agricultural Society took in regard to farm implements. Success means a full purse. Why could not the contents of that purse be called upon to supply the necessary funds for substantial prize for the best dynamo, the best arc, and the best incandescent lamp to be awarded after a careful and exhaustive series of tests by the able men at the command of the executive? Suppose that Professor Forbes with say two colleagues and a secretary had been well paid to undertake these tests, we should then have obtained a report that would have been almost invaluable instead of the meagre scarcrow of a report which is now presented to us.

There are not many good openings for real patronage, but surely the electric light presents a field for patronage as yet unfilled. It may be argued that the idea we have mooted is not of the nature of patronage, but with all due deference to those who object, we maintain that it is. When we see firms of the highest reputation inventing, improving, and entering for competition, say, sheaf-binders at the Royal, it becomes unnecessary to do more than point to this fact to show how highly the prize of the Royal Agricultural Society is valued. The obtaining of £100, more or less, is of little import to the Hornsbys, Howards, Woods, or Samuelsons. The value is in the obtaining the prize. The public know that these trials are carried out without fear or favour by men whose reputation and ability cannot be surpassed. Let the executive of the next exhibition bear this in mind, and do for dynamos what the Royal is doing for sheaf-binders—select the jurors not from a clique, not from among those who may have an interest in becoming jurors, but solely with a view to obtain a thoroughly impartial and accurate series of tests.

An objection may be urged against this idea that such tests have been carried out. They have not, and we defy any man to prove that they have. The Munich and the Crystal Palace Exhibitions resulted in reports which are perhaps of more value than any other reports, but these reports are far from exhaustive. Admitting, however, that the argument is valid, admitting that we have had good reports, we reply that we want more good reports. Professor Forbes again and again indicates that progress has been made. What is the exact value of that progress? How about the engine trials of the Royal? Was it understood that one or two were enough? They were tried year after year, and the greatest eagerness was shown by eminent firms to evaporate the maximum quantity of water with the minimum amount of fuel. Year after year improvements were made till the trials were stopped, since when we doubt if similar annual improvement has continued. At any rate, we have not the same faith in stated improvements as when they were proved under the test.

Improvements in dynamos and other electric light accessories may be made and advertised; they are spoken of as great improvements, but their value must necessarily be estimated by interested parties and taken with some reserve. The public want to know the value of these improvements, and there are reasons why the value should be estimated by independent valuers. The inventor may indicate the conditions under which his machine is intended to run, and the machine should be rigidly tested under these conditions, and not under conditions which happen to prevail when the jurors come round. The electric lamp tests, again, should be carried out at the candle-power at which they were intended to run, and not at powers higher or lower. What is the use of telling us that a filament breaks at 600 candles when it is intended to last at six candles? We want to know how long it will last at six candles. We want to know what current it requires for these six candles, and also the E.M.F. required. It is expensive to supply current; it is expensive to give E.M.F. Where is the happy mean; that is, what is the least expensive, E.M.F. and current combined?

The tests we ask for would be expensive, but the only question to be considered is whether the results would warrant

Digitized by Google

such expense. We believe the results would be as important and as valuable as the results obtained by the Royal Agricultural Society with portable engines.

It must always be remembered that the public have not the necessary knowledge to enable them to judge of the value of a piece of apparatus, and they would be guided by any such independent authoritative statement as we have suggested. Electric light matters are moving; they would move faster if there was more confidence. The necessary confidence will only come with time and experience, but it would come much sooner and be far more complete were there an annual report detailing the improvements and estimating their value from competent hands.

J. L. PULVERMACHER.

This well-known inventor, whose name will always remain connected with portable voltaic appliances and atmospheric depolarisation, passed away, after a long illness, on the 12th inst. The work done by Mr. Pulvermacher has received in this country very little recognition amongst professional and scientific men, mainly by reason of the extensive system of advertising by means of which the inventor found it necessary to bring his appliances before the public. In justice to him, therefore, it should be pointed out that the portable batteries of Mr. Pulvermacher, however unscientifically they may frequently be applied in the absence of medical supervision, are essentially of a genuine and scientific character, and that they were devised by a man who had made the voltaic battery the study of his life. In this respect they are in strong contrast to the multitude of quasi-voltaic and "magnetic" appliances with which the advertising columns of the daily and weekly press have recently been inundated. It was mainly with a view to obviate the effect of this threatened prominence of sham voltaic curatives, through which the public are swindled on an extensive scale, that such men as Professors Petrina, Kreil, Ettinghausen, and Oppolzer, in Germany, and Golding Bird, Pereira, Ronald Martin, Locock, Holland, and Fergusson, in England, gave their unqualified testimony to the genuine nature and to the "great importance to scientific medicine" of Pulvermacher's voltaic batteries and galvanic appliances.

To Pulvermacher, originally a working jeweller, attending with enthusiastic interest the lectures on natural philosophy of Professor Hessler, at the University of Prague, belongs the merit of having first recognised the fact that in order to transmit a current through a high resistance, more especially when such resistance is that of an electrolyte exhibiting the effect of polarisation of electrodes, a considerable number of very small cells in series is far more efficacious than a single couple of large elements, or even than several such elements, necessarily of an inconvenient and unportable character. To him also is due the credit of recognising the importance of atmospheric depolarisation in the case of single fluid batteries; and his paper, "Sur une pile à un seul liquide se dépolarisant par l'action de l'air atmospherique," read before the Académie des Sciences, by M. du Moncel, in July, 1878, may still be perused with advantage by electrical students. The work done by Pulvermacher, as early as 1846, in relation to magneto-electric machines, may very posssibly be some day disinterred and found to present considerations of importance. But, as we have said, he will be remembered by reason of his work in relation to portable single-fluid voltaic batteries. As a contemporary has well observed, it may to the uninitiated appear a small matter to have invented and perfected a voltaic battery requiring no vessels to contain the "exciting fluid," and no depolarising oxidant save atmospheric air, charged in a few seconds, flexible and portable; but this, with the machinery for its production on a large scale, represents in truth the labour of a lifetime. In this case, it is one that has been better appreciated, from a scientific point of view, in France than in this country

CORRESPONDENCE.

PRACTICAL TELEPHONY.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: As in your issue of August 30th last you invite a reply to "Wendur," I append a brief answer to his queries.

I consider, if he is fairly acquainted with the subjects named, he is well enough up in theory, and simply requires actual practice in the work so as to become familiar with the construction, working, and adjustment of the apparatus used. The prospects are fairly good for a first-class man, but in the rank and file it is worthless, as the necessary requirements for ordinary inspecting are readily picked up by those who fit up and attend to the instruments, many of whom have had no mechanical training whatever. It is possible, however, with the growth of the business that inspectors will command a better standing than they do at present.—Yours, &c.,

MAGNUS VOLK.

Brighton, 15th Sept., 1884.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: Permit me as a practical man to offer "Wendur" a word of advice in reply to his letter to you of the 19th August. "Wendur" is a telephone inspector who wishes to make some progress in his profession, and he asks whether a knowledge of machine construction, mathematics, theoretical mechanics, electricity, telegraphy, and chemistry are "sufficient" to enable him to do so. In a word they are more than sufficient, at least for practical telephony. "Wendur" is undertaking too much. He should remember that a sound practical man is worth any dozen of persons who flaunt the theory alone of some half-dozen branches of electrical science.

Of course attention to business is understood in a "youth" who wants to get on. "Reading the papers" is not at all necessary, although a good joke may be had occasionally in *Punch*, and a real hair-elevator in the *Young Boys' Weekly Budget*.

"Wendur" further inquires—"Is the telephone profession one you would recommend a youth to follow?" It entirely depends upon the youth himself. If he displays any aptitude for the work by all means let him follow it out, the more so if he can bring perseverance, industry, and a sound theoretical basis to his assistance. Telephony is as yet only in its infancy, and there are splendid opportunities in the profession for the proper people.

"Has it good prospects?" asks "Wendur." That depends. If, like me, his tent should be pitched among a number of love-stricken maidens, the prospects are that ere long, instead of being the hairiest of men, he will subscribe himself as I do now,—Yours, &c., BALDHEAD.

AN ELECTRIC LAUNCH.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: In your issue of the 23rd of August last there was published a trial with an electric launch, by Mr. Banks, electrician, 32, Corporation-street, Bolton. The launch was 21ft. by 4ft. 16in. beam. The current was supplied by 20 F.S.V. accumulators ($\frac{1}{2}$ horse-power type) actuating a Reckenzaun motor coupled direct to the propeller shaft. The E.M.F. varied from 45 to 35 volts, and the rate of discharge was 31 amperes.

According to the numerous experiments I have made with the F.S.V. accumulators, I have found that the E.M.F. per cell is 2·16 volts just after it has been charged to its full capacity; but soon after the E.M.F. is only two volts, and by discharging run down in a quarter of an hour to 1·96 volt.

The total E.M.F. in Mr. Banks's experiment has thus been $1{\cdot}96 \times 20 = 39{\cdot}2$ volts. The current was 31 amperes (the proper current for $\frac{1}{2}$ horse-power cells is 17-20 amperes), and the energy in electrical horse-power $\frac{39{\cdot}2 \times 31}{746} = 1{\cdot}6$. The motor was constructed to work with 60 volts and about 25

Digitized by Google

amperes, and was therefore heated by the excessive current, which must have brought its efficiency down to, say, 54 per cent.

The actual energy given to the propeller has thus been $1{\cdot}6 \times {\cdot}54 = {\cdot}864$ horse-power. The pitch of the propeller was 11in.; and the motor made 450 revolutions per minute. Let us imagine that the propeller had worked without slip; the speed of the boat would then have been $\frac{450 \times 11 \times 60}{12 \times 5280} = 4{\cdot}69$ miles an hour.

The actual speed of the boat must have been about three miles an hour, instead of six miles an hour, as stated.—Yours, &c.,

CH. CAPITO.

THE AVERTISEUR ELECTRO-AUTOMATIQUE.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: I have recently returned from Paris, where I witnessed some most interesting experiments of electricity applied to the most practical purpose of every-day life.

Electricians have achieved much, but in many cases their work is as yet incomplete; it may therefore interest your readers to hear of an invention which has emerged from the embryo state, and being satisfactorily finished, as our French neighbours would say, *ne laisse rien à désirer.*

I allude to the automatic electrical fire alarm, which is mananged by the Société Française Protectrice Contre les Incendies, and which has its offices, 44, Boulevard Haussman, Paris, opposite the Grand Opera.

The method by which their system is worked is as ingenious as it is infallible. A simple wire, which also answers the purpose of the ordinary electric wire, is placed among the drapery of curtains, or along the panelling of a room, and as soon as the fire touches it, the continuous ringing of a bell is heard; at the same time the exact place of its outbreak is marked on an indicator placed in some convenient and prominent position.

The wire encloses in itself the two electric poles. The first is formed by a brass wire surrounded by cotton, and a layer of gutta percha as non-conductor; the second by several brass wires, to which a tin wire is added. The whole is enveloped in cotton and gutta percha, and finally surrounded by cotton or silk the colour of the furniture of the room in which it is placed. This, when artistically arranged, forms quite an additional ornament to the apartment.

At the Ministère des Finances, where this system is established in the most complete manner, an experiment was made some time ago, in the presence of M. de Lesseps, Colonel Conston, and other distinguished authorities, all of whom expressed both satisfaction and astonishment at the result; and I am convinced that the "Avertiseur Electro-Automatique" only requires to be as well known on this side of the Channel to be equally appreciated.

Numerous gold medals attest the success of the "Avertiseur" abroad. Besides being adopted by the Ministère des Finances, it is in full operation at the Mont-de-Piété, Banque de France, at the Exhibition of the Crown Jewels, and all the largest shops in Paris.

I should advise any of your readers in Paris to call at Boulevard Haussman, or 4, Rue Scribe, where the workshops are situated. They will be amply rewarded for their trouble by seeing the numerous purposes to which the "Avertiseur Electro-Automatique" may be applied, and to which it would be impossible to do justice here.—Yours, &c.,

G. F.

NON-MAGNETISABLE WATCHES.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: On page 406 of your issue of September 13th, headed "A Non-Magnetisable Watch," you state that you would like details of this wonderful watch. I cannot give these, but a simple remedy for *all* watches except those having real compensation balances (which should not be used near powerful magnets) is to have a brass balance and a gold or aluminium bronze *balance* spring fitted instead of the usual steel balance and balance spring. The cost of doing this should not exceed 20s. If watches with compensation balances are used or are already magnetised, they can be served the same way, as the errors due to a magnetised balance far exceed those due to change of temperature. There will then be nothing to prevent a new compensation balance being applied to the watch again when the wearer retires into private life.—Yours, &c.,

Brighton, September 15, 1884. MAGNUS VOLK.

OLD CABLE STORIES RETOLD.—V.

BY F. C. WEBB.

THE CAGLIARI, MALTA, AND CORFU CABLES.

(*Concluded from page* 416.)

On November 14 (1857), at 8 p.m., we started paying out, the "Blazer" towing for a few miles. Shore end was four and a half miles.

On the morning of the 15th it came on to blow, and by about 10 p.m. the ship was rolling very heavily, and the trough in which the cable was led from the fore hold to the brake fetched away, and was replaced by some temporary arrangements after some trouble. The ship was now lightening forward, but the sea came over the after part of the deck, and we were in about two feet of water at the brake, and had to put boards up in front of the door of deck house (which contained the saloon and cabins) and bale the water out of the saloon with buckets. Towards night the wind, which was logged down 6 (or half a gale) on board the "Desperate," moderated. The next day (16th) we sighted the Island of Maritimo, and soon after the "Elba's" engines broke down, and the "Blazer" took her in tow for a short time till we got our engines right. At noon we had payed out 230 miles, and logs showed 198. As regards testing arrangements, Mr. Löffler and another German gentleman, who had been sent from Messrs. Siemens, of Berlin, had brought induction coil Morse instruments for speaking, but for testing only horizontal needle galvanometers unfit for testing work at sea. I therefore rigged up a simple upright galvanometer and reduced battery power till we got a readable deflection. At one time when I was on deck Mr. Löffler pulled my connections down. I reported to Mr. Newall that we were thus paying out without any tests, on which he came down and told Mr. Löffler, in plain and forcible language, that if they interfered again he would throw all their instruments overboard. At one time we were alarmed by an increase of deflection on our galvanometer, and stopped and spoke to Cagliari, and found it had been raining, and thus the land lines had given more earth, so we went on feeling pretty sure this was the cause, and soon after the needle resumed its normal deflection, the sun having come out and dried the insulators. But it was not—speaking in a telegraphic engineering sense—a pleasant situation. We could not disconnect land line to make absolutely sure that cable was perfect, and as we had no picking-up gear we could not pick up, and having no buoys, could not have cut and buoyed. During the night of the 16th, at one time the cable kept slipping out faster than we wished, and Mr. Liddell and I kept putting more weights on, but with very little effect, and soon the cable was going out at nearly nine knots, and at last fouled round one of the horns of the rings in the cable-hold. We stopped, turned astern, and cleared cable, but could not detect what was wrong with the brake till Mr. Newall, coming out of the saloon in his night gear, listened, and his quick mechanical ear missed the slight grating noise of the iron brake strap on the cast-iron drum. On asking then in the engine room where they were pumping the water on to the brake from, we learnt they had turned the donkey-pump on to the bilge, and had thus been pumping greasy water on to the brake, and thus lubricated it. We cleaned brake with waste, and went on all right; but we had had a narrow escape of losing the cable through this thoughtless act

Digitized by Google

in the engine room. On the 17th we had a fine morning. At 4 p.m. we had 358 miles out and 308 by logs. Mr. Newall went on ahead in the "Desperate" to arrrange about landing place, the "Blazer" following her. At about 7 p.m. we came up to "Blazer" moored, and showing a green light to indicate position where we were to cut and splice on shore end. We cut, made splice, and payed out to a boat with a red light, moored at entrance to St. George's Bay, Malta. Tried to drag end ashore. Failed. Coiled into boats and payed out and landed end safely by 4 a.m. on the 18th. We had the assistance of two cutters and jolly boat from "Desperate," and a crowd of men. It was pitch dark work in the little rocky bay. When we had landed the end it was led up into a little hut of some sort, and a Morse instrument put in circuit by Mr. Löffler. A crowd of men-of-war's men and natives were trying to peep in and get a look at the novelty. I was quietly smoking a pipe away from the crowd, when two blue jackets, who had just had a peep, passed me, and I overheard one say to the other in a mysterious whisper, "What humbugs me up, Jack, is where the devil all that —— tape comes from?" The paper slip in those days was allowed to froth up all over the place, and had certainly a very Wizard of the North sort of effect. We went back to the "Elba" at 5 a.m., and several of the officers of the "Desperate" joined us over a glass of champagne. We were all very tired and untidy, and Mr. Liddell was sitting in a corner, with his hair rather out of order. There was a flagging of the conversation, when one of the naval officers suddenly exclaimed, "Why, Liddell, you look just like 'Dizzy' out on a spree!" We all looked up, and the likeness to the late Lord Beaconsfield in his younger days was at the moment so striking that there was a general burst of laughter, in which Mr. Liddell heartily joined.

At about nine we went into Malta, landed, and went up to Dunsford's Hotel, and I never shall forget the comfort that night of a clean English hotel, with snow white mosquito curtains to our beds, after our experiences at Cagliari. We were at Malta till the 24th surveying and erecting the land lines from Valletta to St. George's Bay, testing cable, and sending messages. I found a friend in Lieutenant George Campbell, of the 71st, an old schoolfellow of mine. His brother, Sir Donald, also an old friend, was one of the engineers on the construction of the Balaclava Railway during the Crimean War, and just after he died, a few years ago, Dr. Russell, who was at the Cape, noticing his death in the papers, wrote home half a column to the *Daily Telegraph* about Sir Donald, whom he had known in the Crimea, calling him the "genial clever engineer." Donald was always full of fun, and as he spoke French perfectly, and mixed both with the English and French officers in the Crimea, he had many a curious story to tell when he came home. George was a fine, tall fellow, and about the most lively, boisterous fellow in the regiment. He was my guide about Malta, and dined me at the club, and took me to opera, &c. Poor fellow, he, too, has joined the majority.

We had a party of Sappers to help us to put up the land line to St. George's Bay, and having started the work we left on the 24th in the "Elba" for Corfu. We arrived there on the 26th. The "Desperate" took soundings between Malta and Corfu, and came in on the 27th, reporting 1,800 fathoms as the deepest water, and this on that part of line nearest to Mount Etna. We were at Corfu until December 1st, and during this time drove several times across the island to the landing place for the cable, through lovely scenery, with masses of olive, cyprus, and orange trees. We went to a ball at the Governor's (Sir George Young), and saw there the Italian lady who for several years was known as the belle of the Ionian Islands, and has now long since been married to an English officer. That lady's beauty has much to answer for. Several of the "Desperate's" officers were desperately gone. I say nothing about our own party. But, however, belles have nothing to do with cable laying.

Just before we were at Corfu a regiment had been stationed there which had made itself celebrated by a trial in a court of law on a question of practical jokes on one of the officers who was not popular. The questions asked by counsel were nearly always answered by the convenient reply, "I really don't remember." This stuck to the regiment, and when the men-of-war's men at Corfu wanted to irritate a soldier of this regiment, they always said carelessly as they went by, "I say, Bill, I really don't remember."

On December 1st, we landed the end from the "Elba" at 9 a.m., and secured it in a ruined church. We paid out a mile and a half of shore end, and then got a kink just where shore end joined on to the 10 miles of cable we had picked up off Spartivento. We hauled back, cut it out, made a splice and started again by 2 p.m. The 10 miles of picked up cable was troublesome to pay out, and it was 6 p.m. before we got it out, and we then went on at a much faster rate. At noon on the 2nd we had payed out 109 miles and run 86 miles by log. The next morning we sighted Mount Etna. At noon we were about 70 miles from the Mount, which seemed to tower up as if it was only 10 miles off. Every little line and crack in the snow-capped summit was clear and distinct, while the lower part faded off into the haze. By noon we had payed out 253 miles, and logs showed 211. On the 4th we sighted Malta, and at half past noon had payed out 406 miles, when we anchored and spliced on shore end; then slipped anchor and steamed close into bay; anchored and landed end at 7 p.m., having payed out 408 miles. Tried to weigh anchor and carried away chain cable and went into Malta Harbour.

On the 9th Messrs. Newall gave a dinner at Dunsford's to the officers of the "Desperate" and some others, and we sat down a large party. When the breaking up was taking place on the landings of the hotel stairs the youngsters began knocking off all tall hats. I had saved mine once, and placed it in a room. I went in to fetch it, when I found a young midshipman quietly kicking it round the table all to himself, and I rescued it again. At last all had gone down stairs, and as I only heard a faint amount of conversation in the street I concluded it was safe to go out for a stroll, and, lighting a cigar, I went leisurely into the street. But directly I got outside the door there was a cry of "Here's another hat," and in an instant my hat was off and being played football with, for nearly all the party were there. The next morning I received in bed a flat brown paper parcel; it was my hat, sent to me with the compliments of the gun room mess of the "Desperate."

During our stay at Malta I dined once at the ward room mess of H.M.S. "Royal Albert," 131 guns, flag ship. A dinner on board this grand old ship, in full commission as flag ship on a crack station, with her fine ward room, the number of officers and guests, the band playing, and all the paraphernalia of a man-of-war was an imposing sort of entertainment not easily to be forgotten, and is scarcely to be equalled on board our modern ironclads.

We left for Cagliari and Marseilles on the 13th, leaving Mr. Löffler in charge of cables and land-lines.

Altogether the laying of these two cables was a success. The cone and rings and the brake answered perfectly; the dynamometer was the first ever used, and answered fairly well. As regards having no picking-up gear, Mr. Newall informed me that one had been made, but was so heavy he would not have it fixed on board. As regards buoys, I do not know why none had been supplied, for I had nothing to do with the work till I joined the ship at Cagliari. The next trip the "Elba" made we had a fine picking-up machine and bow sheave, which Mr. (now Professor) Fleeming Jenkin designed, with some little advice from me on some points, and we also had a proper set of buoys, ropes, and chains; but this does not belong to the narrative of the laying of the Cagliari, Malta, and Corfu cables.

NEW INSULATOR.—An electric wire insulator has been patented in the United States by Mr. George W. Prince, of Brooklyn, New York. It is formed with a special perforation and slots in its upper, and upwardly inclined grooves in its lower part, whereby the wire can be readily inserted and secured. The wire and insulator are not liable to become disconnected, even if the insulator should be detached from its supporting pin.

The six engines and eleven boilers may be thus classed and described:—

Engine No. 1 (Fig. 1) is a double engine, that is to say, there are two fixed horizontal engines coupled together. The cylinders are each 19in. in diameter by 32in. stroke. The power, which amounts to about 400 indicated horse-power, is given off by two flywheels, each 12ft. diameter, and weighing collectively 8½ tons. These engines are of an entirely new design, and present many important improvements. They are especially suitable for large electric light installations, also for driving machinery in mills and manufactories of all kinds, pumping machinery, &c. They are made sufficiently strong to work up to 120lb. steam pressure per square inch. The ordinary working pressure is 80lb. Engine No. 2 is of similar design, but the cylinders are 18½in. diameter by 32in. stroke, and the power is given off by one flywheel, 12ft. diameter, and weighing 5¼ tons. Engines No. 1 and No. 2 are both mounted on strong massive cast iron girder frames, and are in all respects constructed to meet the requirements of the electric light. Steam is supplied by six boilers, of the locomotive type, with fire boxes of specially made mild ductile steel. These boilers have been tested by hydraulic pressure to 220lb. per square inch. Engine No. 3 is a compound fixed engine (Fig. 2), with cylinders 15in. and 22½in. diameter respectively by 24in. stroke. Steam for driving this engine is supplied by two high pressure steel boilers. Engine No. 4 (Fig. 3) is a compound semi-fixed engine, with cylinders 12½in. and 20in. diameter respectively by 24in. stroke. Engine No. 5 is a semi-portable engine with two cylinders, each 10½in. diameter by 14in. stroke. Engine No. 6 is a semi-fixed engine, with cylinders each 12in. diameter by 14in. stroke.

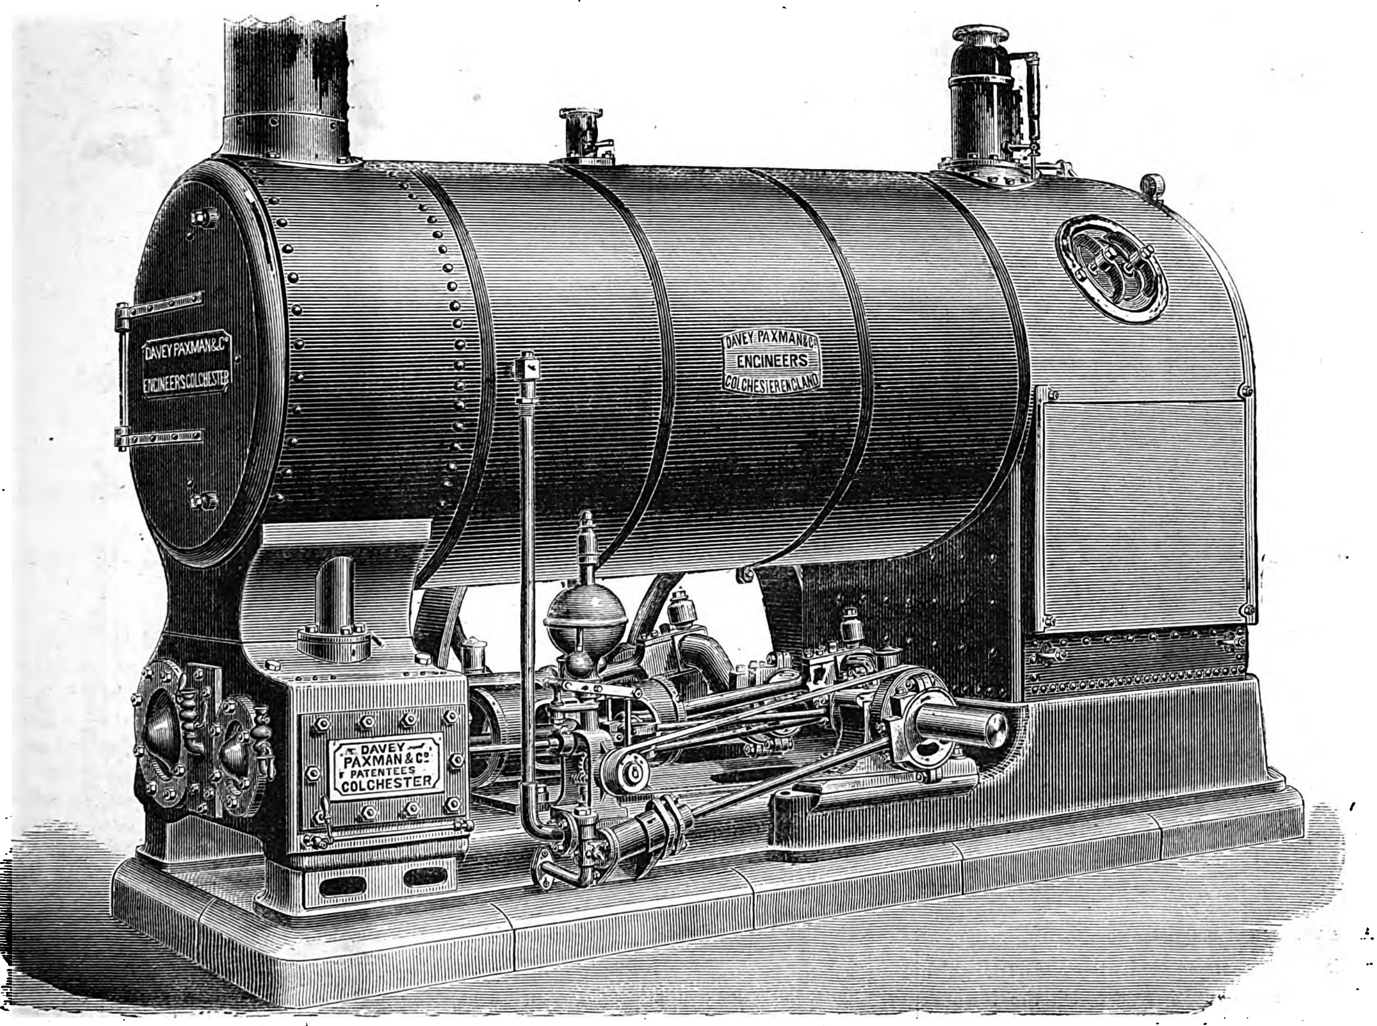

Fig. 3.

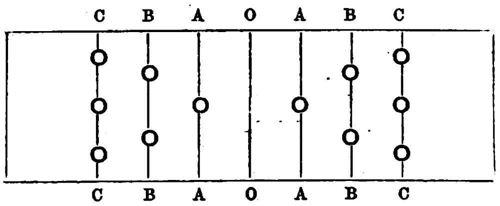
Continuing now our description of the exhibits of Messrs. Woodhouse and Rawson we resume, according to promise, with the meter of Mr. J. Cauderay. This instrument is described in a pamphlet issued by the inventor, which, together with the instrument, we have before us while we write. The improvement in dynamos, the possibility of supplying electric energy in large quantities at a moderate cost, and especially the distribution of this energy from house to house in a manner similar to that in which gas is distributed, called for a meter to measure the energy used. A number of such meters have been invented, the best known of which are those of Edison, Sprague, and Hopkinson, yet no one has been found generally acceptable. We cannot say if that of Mr. Cauderay will meet with more favour. It is a very ingenious piece of mechanism, but it has imperfections that will readily be seen without entering into detail. The main points are how the instruments work in practice, their prime cost, and cost of maintenance. Electrical energy meters should be cheap, and as trustworthy at least as gas meters. The one under discussion has this advantage, that it tells the user, by means of dials, the quantity used, and it requires no more education to read than to read an ordinary gas meter.

The instrument we illustrate on page 440 measures coulombs. A second, shown by Messrs. Woodhouse and Rawson, gives lamp hours. The principle is the same, and it will be seen admits of numerous modifications. The coulomb, or ampere per second, is a measure which, from a business point of view, has many advantages. Briefly, the principle is as follows:—An electric clock actuates a cylinder, which is caused to revolve once per hour or per 100 seconds, or other period of time deemed best suited for the purpose in hand. The cylinder is similar to those used for musical boxes, and is furnished with pins or teeth disposed in a special manner around the cylinder. Thus, suppose Fig. A represents the surface of the cylinder opened out, O O represents the zero circle, upon which no tooth is placed. The circles represented by A A A A at equal distances to the

Digitized by Google

right and left of the zero circle have each one tooth, B B B B have two teeth, C C C C three teeth, and so on. A pointer, *a*,

Fig. A.



carrying at its free end a bronze tooth moves through the arc of a circle, and, according to its position, catches one, two, three or more teeth of the cylinder per revolution, the number depending upon the position of *a*, and this depends upon the strength of current. The revolution of the cylinder pushes back *a*, and, according to the length of the tooth touched, the *vide* Fig. 5. Upon the same spindle as *b* is the pointer *a*, carrying at its free end the bronze tooth. Now if, say, five amperes of current go through the galvanometer D, the needle *b* is deflected to show five amperes current on the scale, while the pointer *a* is deflected opposite that circle on the cylinder which carries five teeth. The pointer comes successively into contact with these five teeth, and being pushed back at each contact, pushes back the lever T, which is connected by a series of levers to the first of a train of wheels, which is thus at each contact moved forward one tooth. The train of wheels is arranged to indicate units, tens, hundreds, and thousands. It will be understood that although we have described the measuring of amperes, any fraction of an ampere can be measured if desired. M. Cauderay claims that a mechanical apparatus is preferable to an electro-chemical, and that his instrument presents many advantages not to be found elsewhere. We confess to a strong admiration for the principle adopted, and hope to find that experience will show this adaptation

EXPLANATION OF DIAGRAMS.

Galvanometer.

A a permanent magnet.

a is a spring carrying at its free end a triangular stud of bronze against which the teeth of the cylinder, R, press.

b an indicator pointer.

c balance weights.

B soft iron pole pieces.

C moveable pole pieces, thus allowing the magnetic field to be changed as desired.

D galvanometer coils.

Clock Movement.

H a circular balance-wheel pendulum weighing about 700 grammes,

I regulated by means of the steel spring, I, to make a double oscillation per second, and kept in movement by the

K K L L electro magnets, K K attracting the armatures L L,

M fixed on the axis, M, of the wheel. The electro-magnets have a resistance of about 1,000 ohms, and are placed in a shunt circuit similarly to the plan adopted by M. Hipp

N for his regulators. M also carries the eccentric, N, which transmits motion by means of levers, P, to the cylinder, R. One complete revolution per 100 seconds is made.

O is a contact with a regulator by means of which the current to the electro-magnets is determined.

R is the most prominent feature of the apparatus, consisting of a revolving brass cylinder actuated by H as before described, carrying upon its surface a number of teeth disposed in a manner also described.

S a rachet wheel of 100 teeth, fixed upon the axle of R to alter the reciprocating motion of P into the rotary motion of the cylinder.

T T are transmission levers.

U U V V dials to show the energy passed.

first of a train of wheels is by this means revolved the distance of one or two teeth. Perhaps, however, this will be better seen by reference to Figs. 4 and 5, which have been engraved from drawings in the pamphlet, though slight modifications have been introduced into the instruments before us. Here we have the electro-magnet or galvanometer coils D D, the current through the coils is shown, by the needle *b*, upon a scale, the one before us indicating up to 20 amperes, suitable for the work. The clock portion of the apparatus has received little attention from us, as clocks electrically controlled are well known.

Messrs. Woodhouse and Rawson have other exhibits which deserve attention; indeed this firm is attempting to become a central supply station for electrical sundries, and bids fair to succeed. Staples, saddles, wire, dynamos, lamps, coils, batteries are all to be found in great variety.

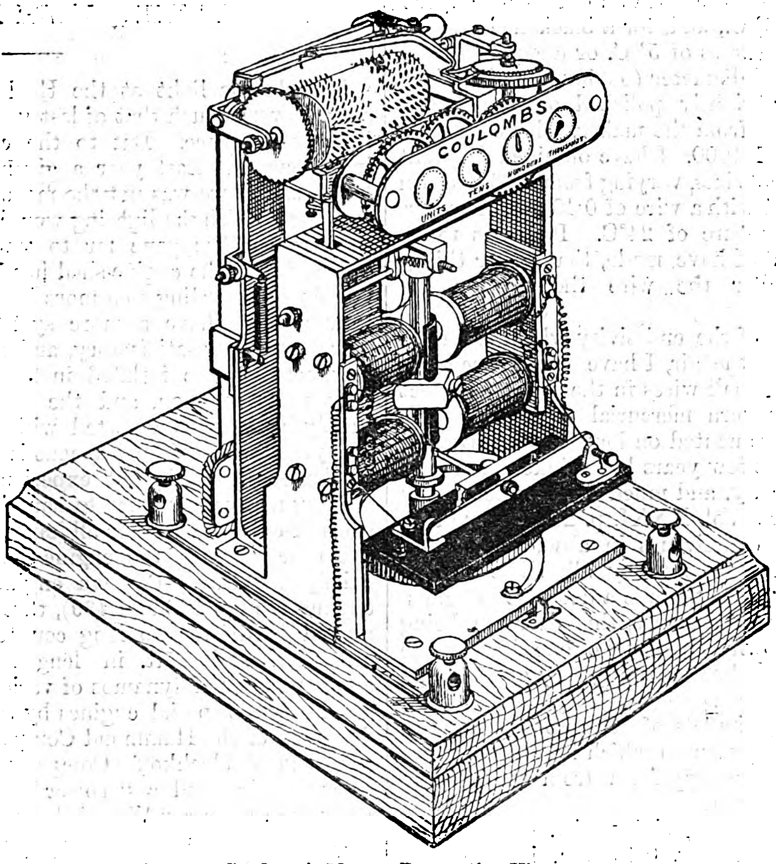
MESSRS. WOODHOUSE AND RAWSON'S EXHIBITS AT THE HEALTH EXHIBITION.



Cauderay's Meter—Perspective View.

THE BRITISH ASSOCIATION MEETING AT MONTREAL.

On Loss of Heat by Radiation and Convection, &c.*

BY J. T. BOTTOMLEY, M.A., F.R.S.E.

In the course of a series of experiments on the heating of conductors by the electric current, which were carried on during the past winter, I obtained a considerable number of results which both gave me the means of calculating the *emissivity* for heat in absolute measure of various surfaces under different circumstances, and also caused me to undertake a number of special experiments on the subject. These experiments are still in progress, and I am making preparation for a more extended and complete series; but a brief notice of some of the results already arrived at may not be without interest to the British Association.

The experiments were made on wires of various sizes, some of them covered and some of them bare, cooling in air at ordinary temperatures, and at normal and also at very much reduced pressures. The mode of experimenting was as follows:—

A current passing through a wire generates heat, the amount of which is given by Joule's well-known law

$$H = C^2 R/J \quad . \quad . \quad . \quad . \quad . \quad . \quad (1)$$

where C is the current, R the electrical resistance, J Joule's equivalent, and H the quantity of heat generated per unit of time, each being reckoned in C.G.S. units. Let l be the length of the wire, d its diameter, and σ_t the specific resistance of the material at temperature $t°$ (at which temperature let us suppose that the wire in the given external conditions is maintained by the current). Then

$$R = \frac{\sigma_t l}{\frac{1}{4}\pi d^2} = \frac{4\sigma_t l}{\pi d^2}$$

Hence from (1)

$$H = \frac{C^2}{J} \cdot \frac{4\sigma_t l}{\pi d^2} \quad . \quad . \quad . \quad . \quad . \quad . \quad (2)$$

Consider, now, that the wire suspended in the air is losing heat by its surface, and let us suppose that it neither loses nor gains heat by its ends. Let H′ be the quantity lost by emission from the surface per unit of time. Let e be the emissivity or quantity of heat lost per unit time per unit area of the cooling surface per unit difference of temperatures between the cooling surface and the surrounding; and $t°$ being, as has been said above, the temperature of the wire, let θ be the temperature of the surroundings. Then

$$H' = \pi d l \, . \, e (t - \theta) \quad . \quad . \quad . \quad . \quad . \quad . \quad (3)$$

But when the wire has acquired a permanent temperature, with the current flowing through it, there is as much heat being lost at the sides as is being generated by the current. In this case H = H′; and we obtain the expression for e

$$e = \frac{4 C^2 \sigma_t}{J \pi^2 d^3 (t - \theta)} \quad . \quad . \quad . \quad . \quad . \quad . \quad (4)$$

My experiments consist in measuring the strength of the current and the temperature of the wire, the latter being effected by measuring the electric resistance of a known length of the wire while the current is flowing through it, and hence inferring the temperature. These being known, and likewise the temperature of the surroundings, we have all the data for finding e, the emissivity of the surface in absolute measure. The experiments of Mr. D. Macfarlane giving emissivities in absolute measure are well known, and are of undoubted accuracy. They were communicated to the Royal Society (*Proc. Roy. Soc.*, 1872, p. 93); and the results are quoted in Professor Everett's "Units and Physical Constants" (chap. ix. sec. 137). These experiments were made with a copper globe about 4cm. in diameter, suspended in a cylindrical chamber, with top and bottom, about 60cm. in diameter, and 60cm. high. The results may be briefly summed up as follows:—

Mr. Macfarlane finds an emissivity of about 1/4000th of the thermal unit C.G.S. per square centimetre per second per

* Paper "On Loss of Heat by Radiation and Convection, as affected by the Dimensions of the Cooling Body; and on Cooling in Vacuum," read before Section A (Mathematical and Physical Science), British Association, Montreal, 1884.

Digitized by Google

degree of difference of temperatures between cooling body and surroundings for a polished surface, with an excess of temperature of a little more than 60° C., and, for a blackened surface, the same emissivity with an excess of 5° C. or under.

Using round wires of small diameter (0·85mm. and under), and with the surfaces either brightly polished or in common dull condition of a wire fresh from the maker, I have found a much larger emissivity than 1/4000. I have obtained different values of *e* for wires of different sizes, varying from 1/2000 down to 1/400, which was obtained with a wire of 0·40mm. diameter, and with an excess of temperature of 24°C. It seems to be shown by all the experiments I have made, that, other things being the same, the smaller the wire the greater the emissivity.

To do away with the part of the emissivity which is due to convection and conduction by the air, I have commenced experiments on loss of heat by small wires in the nearly perfect vacuum afforded by the modern mercurial air-pump. This part of the subject was experimented on long ago by Dulong and Petit, and within the last few years by Winkelmann and by Kundt and Warburg; lastly, and much more perfectly, by Mr. Crookes (*Proc.* Roy. Soc., Vol. XXXI. p. 239), though in no case, I believe, were the emissivities in absolute measure determined. The conclusion come to by all these experimenters is the same, namely, that there is a decrease of emissivity due to lowering of the air-pressure, this decrease being very small for a reduction down to one-half or one-third of the ordinary atmospheric pressure, but becoming very great as the vacuum approaches completeness.

The very interesting experiments of Mr. Crookes seem to show that, even with the high vacuum which he obtained, the effect of the residual gas in carrying off heat from the cooling body was far from being annulled.

The following table shows the emissivity of a copper wire with bright surface half a metre long, 0·40 mm. in diameter, and sealed into a glass tube about 1·5 cm. in internal diameter:—

Current amperes.	Pressure, 760 millims.		Pressure, 380 millims.		Pressure, 180 millims.		Very high vacuum pump worked continuously.	
	$t-\theta$	e	$t-\theta$	e	$t-\theta$	e	$t-\theta$	e
	°		°		°		°	
1	4·7	1/1822	4·5	1/1784	5·5	1/2176	17	1/6443
2	22·5	1/2084	21·5	1/1996	23·5	1/2174	68	1/5620
3	56	1/2114	58	1/2180	55	1/2082	140 ?	1/4606*

* Temperature probably much too low. The wire, sagging down, touched the inside of the glass tube in several points.

The following table may also be found interesting. It shows the emissivity in absolute measure of some materials commonly used as insulating coverings for wires:—

Specifying number B.W.G. and nature of covering.	Length of wire. Centims.	Resist. of 100 centims. B.A. units.	Dia. of wire in millims.	Dia. of covered wire, outside.	Current (amp).	$t-\theta$	Emissivity.

The estimated traffic receipts of the West India and Panama Telegraph Company for the half month ended the 5th September are £2,096, as compared with £2,404 in the corresponding period of 1883.

The traffic receipts of the Western and Brazilian Telegraph Company for the week ended 11th September were £2,630, after deducting the "fifth" of the gross receipts payable to the London Pratino-Brazilian Telegraph Company.

PROF. G. FORBES' REPORT ON THE ELECTRIC LIGHT AT THE HEALTH EXHIBITION.*

The electric light at the Health Exhibition this year resembles very much that of last year at the Fisheries Exhibition in the same place. But to the critical eye there is a vast improvement. Last year a gigantic system was installed in haste, and there was not the means to estimate properly the extent to which the lighting would be carried. The experience then gained has gone far to smooth away the preliminary difficulties. The engine-shed has been enlarged, and the plant laid down according to a more intelligible scheme, and all the arrangements have a more systematic basis. The result is correspondingly satisfactory, and serves as the best connecting link between the isolated installations which have hitherto been most common, and the centralised stations for large supply which it is expected will soon be generally demanded. The most evident improvement is in the general arrangement of the engine-shed; but experience has also done much in guiding many companies to sounder views as to the dimensions of cables and other all-important details.

To begin with the engine-shed, steam-power is supplied chiefly by Davey-Paxman engines (for illustrations of these engines see pp. 438 and 439), three of these engines being employed to drive two long countershafts in one line; these are 60ft. and 45ft. in length respectively. From these a vast number of dynamos of various kinds are driven. There are also three special engines by the same makers working the dynamos of the Hammond Company, the Gülcher Company, and the Jablochkoff Company respectively. A Hodgson rotary engine and a "Tower" spherical engine are also at work each upon a "Victoria" dynamo of the Brush Company. A gas-engine is also shown close by, driving another "Victoria" dynamo, to illustrate Mr. Dowson's system of generating gas for the purposes of motive power.

One of Lautensach and Bittner's gigantic thermopiles has also been placed in the engine-shed, but it does not seem to have been put in operation up to the present date.

Nearly the whole length of the building is occupied on one side by two large Davey-Paxman pairs of horizontal engines, and the six boilers required for this duty. These boilers also supply steam to the two rotary engines mentioned above.

These six boilers are all connected together. One main water pipe runs along the whole length of the six, and the pumps are so connected that if one fails the others act and supply through the main. The pumps are by Mumford, of Colchester. There is a throttle-valve attached for the feed of each boiler. Each boiler has an independent safety valve and stop valve. The exhaust steam is carried away by the funnels of these boilers. The steam pipes to the two engines are connected with all the boilers.

Each of the two large engines indicate about 350 horse-power. The one which drives the 60ft. countershaft has a 19in. cylinder and 32in. stroke. It is mounted on girders instead of being upon a solid bed-plate. This is for convenience of export. The cylinders are connected to the girders by strong brackets, which give great rigidity. The main valve is in a separate case to the cut-off valve, and this involves the use of less pressure to move the main valve. The cut-off can be varied from 0 up to ¾. There is a cylinder on each side of the driving wheel, and one governor acts upon both. The governor is supplied with a spring, to vary the action of gravity, so that the speed may be increased. It is not driven by belts, but by toothed-wheel gearing. The efficiency of one of these governors was shown on a recent occasion here, when the 21in. link leather belt broke when in full action, and the speed changed by barely a revolution a minute. Schönheyder's lubricator is used in this engine. There are two driving pulleys 12ft. diameter and 16in. wide. The engine runs at 72 revolutions, and the pressure of steam has been 85lb. These driving wheels have each a 15in. belt of linked leather driving a pair of 39in. pulleys on the long countershaft, the distance between centres being 31ft.

* The official report as published in the *Society of Arts Journal*.

Digitized by Google

The second large double cylinder engine drives a countershaft of 45ft. length. This engine resembles the first, but it has an 18½in. cylinder, with a 32in. stroke. It has only one driving pulley, 12ft. diameter and 24in. wide. The 19in. linked leather belt which broke on this work has been replaced by another, 24in. wide.

The third engine, of Messrs. Davey and Paxman, is a fixed horizontal compound engine, in use by the Hammond Company to drive the Ferranti 1,000-lighter alternate current machine, a 40-lighter Brush machine, and a Ferranti 200 incandescent lighter. It has a single gridiron valve and a cut-off valve. The exhaust valve is in the same case as the slide valve of the low-pressure cylinder; the latter cuts off at half stroke. The high-pressure cylinder has a diameter of piston of 15in. and a stroke of 2ft., and the low pressure 22in. with a 2ft. stroke. This engine has indicated up to 220 horse-power, with a pressure of 120lb. It drives two pulleys, one 10ft. diameter and 16in. wide for the large Ferranti machine; the other a smaller one for the other two dynamos. This engine is fed by two boilers called a 50 and a 16 horse-power boiler respectively. These have each a donkey pump and injector.

The fourth engine is a compound one used for seven Fülcher dynamos. It resembles the last, but the diameters of the high and low pressure cylinders are 12¼ and 20½in., and the stroke 2ft. It runs at 100 revolutions. With its attached boiler it can indicate 130 horse-power. The driving wheel is 8ft. 6in. by 16in.

Another semi-fixed compound engine on the top of its boiler works the Jablochkoff dynamos. It has no special features of interest.

The first large engine described is assisted in driving the principal countershaft by a 25 horse-power engine, working, it is said, up to 100 horse-power. Altogether over 1,100 horse-power is developed in the engine shed.

The main countershaft, 60ft. long, drives two secondary countershafts, one of them driving six Gramme machines of the British Electric Light Company—viz., two A's, one D, and three E's; the other driving 10 double Edison machines. It also drives the following dynamos direct:—One Bürgin, four Pilsen-Joel, one Siemens alternate current with exciter (small), and two Paterson and Cooper "Phœnix" machines, all these on one side of the countershaft, and on the other side one huge Siemens direct machine for 420 amperes and 80 volts, a Clerk machine with Siemens exciter (for the "Sun" lamps), two large low resistance Siemens alternate current machines with exciter, and another Siemens direct current dynamo. An Elphinstone and Vincent 400 lighter machine is also in place and at work.

The second countershaft, 45 feet long, drives three Hochhausen dynamos, one Brush (23 arcs), one Opperman with exciter, and one Gerard.

A great deal of interest attaches to the large machine exhibited by the Hammond Company. This is a 1,000 incandescent lamp alternate current machine by Ferranti. It resembles his well-known type of machine in many respects, but is conspicuous for the perfecting of details of construction, and for some novelties which are introduced. It is fed by a large quantity of Siemens direct current dynamos, attached to the same shaft as the alternate current machine. The shaft has a large bearing on each side of the Ferranti armature, of the fly-wheel, and of the Siemens armature, and has in addition a thrust bearing. These bearings are lubricated under pressure, the oil being collected in a reservoir, filtered, and pumped up to a supply reservoir. In the other types of Ferranti machine it has been found that, to prevent abrasion, the collecting rings must be oiled, and the resistance thus introduced is in many cases equal to the total resistance of the armature. In the present type of machine the terminal wires are attached to rings on the shaft which rotate within hollow rings, the intermediate space being filled with mercury to complete the electrical contact. This arrangement seems to work admirably. This device was patented by me in 1883. It has been said that the direct and alternate machines are on the same shaft. This is not strictly so, for the shaft of the Siemens machine is driven from that of the Ferranti machine through a leather ring clamped to each of the shafts. The Siemens machine gives 30 amperes and 120 volts, and works through the two sets of 24 Ferranti field magnets, each set of 24 being connected in parallel. The Ferranti machine gives 400 volts at 600 revolutions. It supplies Woodhouse and Rawson lamps in the Aquarium refreshment bar and the dining room in the conservatory.

Another large machine deserving special attention is the Siemens machine, exhibited by the water companies. It is called a B 2 dynamo. It is designed to give 420 amperes current, with 80 volts electromotive force, and is used for the fountain illuminations. On the armatures there are ribs of copper from end to end, held bound by strong metal bands enclosing them. These bands have their greatest width radial, to prevent local currents being developed, and are in pairs, and two pairs go to each terminal commutator. There are about 20 arms to the commutator. There are two pairs of brushes, each pair being side by side. The width of each brush is 4in. The position of the brushes is adjusted by a worm wheel. The machine is compound wound, the series winding goes through the four arms of the field magnets in parallel, and is of wire about ¼in. diameter; the shunt winding goes round all four arms in succession, and is of No. 12 wire. The mechanical and constructive details of this machine are worthy of close inspection.

A machine shown by the Brush Company shows the enormous improvement which can be introduced by recognising, and so dispensing with, the local currents in the mass of iron constituting the armature. In this machine the armature is built upon a coil of hoop iron, with H pieces let in during the winding to support the coils. A very great gain is said to have been obtained by this alteration.

The Hopkinson-Edison type of machine, manufactured by the Edison Company at New York, is exhibited by the Edison-Swan Company.

Of other machines mention may be made of the cheap classes of direct current and alternate current machines shown by Oppermann. The Gerard Company also show some small and cheap machines; among these is a very small compact laboratory machine, suitable to work with a treadle, which works four incandescent lamps.

The Victoria dynamos are on the model of the Shuckert machines, which, as turned out at Nürnberg, have acquired so high a reputation. In the Victoria, however, there are four

Digitized by Google

poles, and the resulting pairs of coils on the armature are in parallel, so that there are only two brushes.

The Gramme, Hochhausen, Gülcher, Jablochkoff, Bürgin, Phœnix, and other machines require no special notice here.

In the Consolidated Company's exhibit their secondary batteries are charged by a compact Parker-Elwell machine, with an 8in. armature, giving 25 to 30 amperes and 130 volts; when run for a short time it can give 60 amperes without injury.

Having thus passed in review the dynamos at the Exhibition, it becomes a matter of interest to learn the size of cables used by different firms, and the current carried by them. In the accompanying table (A) the name of the firm, or other distinguishing mark, is given in the first column. The number of cables in parallel, or sections, is given in the second. Size of wire is in the third, thus 7/16 means 7 wires of No. 16 in a cable. The current in amperes fills the fourth, and the fifth gives the amperes in volts.

The total illumination is over 5,000 incandescent lamps, besides some 300 arc lamps. It is worthy of remark that Sir F. Bolton's fountain display uses up from 120 to 180 horsepower in the illuminations. As this exhibition is to a great extent illustrative of what can be done on a large scale, the nature of the lighting is worthy of record. The following facts have accordingly been compiled for the purpose:—

Arc Lighting.—The small corridor and the south promenade and vegetarian room are lighted by 11 Ball lamps with 1 Ball dynamo; the electric machinery room by 6 Werner and 6 Cardew lamps, fed by 1 Brush machine; the west corridor and the south annexe by 8 Clark Bowman lamps with 1 Phœnix dynamo; Old London by 5 Lea lamps with 1 Gramme dynamo; the south central avenue and part of the east and west central gallery are lighted by 60 Jablochkoff candles with 3 machines, and there is a fourth spare one; in the west central gallery, 7 Brockie lamps and 1 Gramme dynamo; west and east annexes, 23 Brush lamps and 1 dynamo; east corridor, west and east quadrants, east arcade, and Du-Val dining room, 40 lamps and 1 Brush dynamo by the Hammond Company; west gallery, 39 Pilsen lamps, 3 Schuckert dynamos; central gallery, 29 lamps, and 1 machine by Hochhausen; central fountain by 1 lamp and machine by Crompton, 10 lamps and 1 machine by Clerk, the latter being also distributed in the cascades and water pavilion garden. The Clerk machine is designed for 3 circuits of 10 lamps each. The Queen's-gate entrance has a Fox lamp and Oppermann machine; the masthead has 6 lamps on 1 machine by Hochhausen, and the conservatory has 4 lamps on 1 machine by Siemens.

Incandescent Lighting.—Ten Edison machines light the following spaces:—Entrance vestibule, 23 Swan lamps and 107 Edison lamps; the arts gallery, 172 Swan and 122 Edison; Bertram and Roberts' dining rooms, 64 Swan and 264 Edison; cheap dining room, 31 Swan and 115 Edison; literary superintendent's room, 20 Edison. The south gallery, 2 Siemens alternate machines with 2 exciters—1,063 Swan lamps; dairies, 2 Gülcher machines, 370 Crookes lamps; Old London, 1 Gramme and exciter, and 30 lamps by Mackie; east central gallery, 340 Gatehouse lamps and 1 Elphinstone-Vincent dynamo; water company pavilion, 1 Oppermann alternate current machine with exciter, and 234 Woodhouse and Rawson lamps; Prince of Wales Pavilion, 1 Siemens with excitor, 180 Swan lamps, and 1 Siemens with exciter to 40 Woodhouse and Rawson 25 volt and 10 candle-power, besides ten of 50 volts and 20 candle-power; the aquarium, west arcade, and west dining rooms and tea rooms, 1 Ferranti alternate current dynamo with Siemens exciter, and 909 Woodhouse and Rawson lamps; refreshment bar, 1 Phœnix dynamo and 40 half Bernstein lamps of 25 candle-power; cocoa tavern, 1 Victoria dynamo, and 100 Victoria lamps of 100 volts and 20 candles; Chinese restaurant, 204 Crookes 50 volt lamps, which with 300 more are fed by 6 Gülcher machines; Indian Court, 38 Bernstein lamps on a Hochhausen machine. Nineteen of these are series on two parallels. Doulton's pavilion has 24 Gerard lamps of 50 candles on 2 Gerard machines.

The only secondary batteries in regular action are those of the Consolidated Company in the machinery in motion gallery. The plates are made of corrugated strips of lead coiled into a disc and pressed into a square form.

Twice the lighting has failed up to this date (August 14). Once a driving belt gave way, and once a boiler-feeding valve stuck, and the boilers being all connected together the steam escaped. (It may be said that the boilers being connected in parallel, and one of them short circuiting the mains, the whole of them were burnt up or run dry.)

Mr. W. D. Gooch has superintended all the arrangements. Everything seems to be as well arranged as is possible with so great a mixture of systems in use. This is the most extensive application of electric lighting hitherto seen in this country.

Direct Spanish Telegraph Company.

Report of the directors for the half year ended 30th June, 1884, to be presented at the general meeting of shareholders, to be held on Monday, 29th inst. The accounts for the half year ended 30th June, 1884, show a balance to the credit of profit and loss of £3,844 5s. The traffic receipts are £334 18s. 8d. in excess of those for the corresponding half year of 1883, and show an increase of £243 11s. 5d. over those for last half year. The original Bilbao cable which, as mentioned in the last report, broke down on the 10th of February, was restored on the 9th of April. The Marseilles-Barcelona cable remained in perfect working order throughout the half year, and continues so. The duplicate cable between Bilbao and England was successfully completed on the 12th of May, and was opened to traffic on the 13th of June, since when it has worked perfectly. The original Bilbao cable broke down again on the 17th of July last, but as the new cable is sufficient for the requirements of the service, the directors do not contemplate restoring the original cable at present. The cost of the repairs of the original Bilbao cable in April last amounted to £4,292 19s. 10d. Of this amount, £3,092 19s. 10d. have been paid out of revenue, and £1,200 have been taken from the reserve fund, which is thereby reduced to £884 1s. 10d. After providing for the payment of the debenture interest (£590), of the dividend on the Preference shares (£3,000), and of £200 towards the reduction of the preliminary expenses account, there will remain a balance of £54 5s., which it is proposed to carry to next account. The dividend warrants on the preference shares will be issued when the remittances from Spain for the balance of telegraph accounts to 30th June last are received, and these are expected in the course of next month.

NOTES.

American Telegrams.—The average number of words in American telegrams is 14 by day, but rather higher during the night, when messages are sent at reduced prices.

Personal.—Mr. C. H. Baker, formerly assistant-superintendent Eastern Telegraph Company, Suez, has been appointed to the managership of the Central and South American Company's station at Panama.

Electricity and Adulteration.—The electrolysis of red wine, with a microscopic examination of the deposit formed, is, according to L. Monrad Krohn, a certain means of detecting extraneous colouring matter.

Society of Telegraph Engineers and Electricians.—The list of members, corrected to the end of June last, shows that a total of 1,256 was then reached, including 369 members, 179 foreign, 3 honorary, 668 associates, and 37 students.

The Electric Light at Midgley.—Mr. G. Bedford, of Brearley, has made arrangements with Mr. W. Farrar, agent for a firm in Leeds, to have the electric light in his brewery. This mode of lighting is becoming very common in the district.

Military Telegraphy.—It is reported that during the autumn manœuvres of the Belgian army more than sixty messages were despatched in less than half an hour; but all reached their destination promptly and without blocking.

The Paris Institute.—The meetings will recommence on 18th October next, and on the 25th October the annual public meeting of the five academies will be held, under the presidency of M. Eugène Rolland, president of the Academy of Sciences.

Electricity and Submarine Exploration.—In an invention recently patented for facilitating submarine exploration, the oxygen required for supporting respiration is to be produced by decomposing sea water by means of the electric current.

New Telephone.—Mr. John F. Sims has invented a mechanical telephone for facilitating the transmission of sound mechanically, for properly adjusting the strain upon the transmitting wires, and for providing simple and efficient means for signalling.

Electric Light in Schools.—Trials have been made at the Collége Sainte-Barbe and the Lycée Louis-le-Grand, Paris, under the superintendence of the architects, with a view to adopt Edison incandescent lamps with frosted globes for the lighting of the class rooms.

Underground Lines in New York.—The Mayor of New York has refused to sanction the privilege, lately granted to the Commercial Cable Company, to lay down wires in the streets, on the ground that this would give the company right to lay underground pipes in all the streets of the city.

Foochow.—The Great Northern Telegraph Company announce that the steam launch service between Sharp Peak and Foochow has been resumed. Telegrams for Foochow, in code or plain language, can now be accepted to go forward by this service at sender's risk, and at the rate of 8s. 4d. per word.

The Telephone at Leeds.—We have just received the list of the National Telephone Company's subscribers at Leeds. The first telephone was placed in Leeds about October, 1879, and there are now in operation about 300 exchange and 40 private lines. This speaks well for the success obtained at Leeds, and especially so as new subscribers are added daily.

Improved Arc Lamp.—The Rheinische Elektricitäts Gesellschaft has introduced an improvement into its differential solenoid lamps by adding to them a variable resistance, which has the effect of regulating the intensity of the current in the shunt circuit, and a resistance coil, introduced automatically, for compensating the resistance of the lamp when the latter is switched out of circuit.

The British Association in Canada.—A Central News message from Port Arthur, dated 8th September (probably out of telegraph range), states that the Rocky Mountain contingent of members had arrived at that place, but were prevented from proceeding by a storm of wind and rain, which, besides exerting a most depressing effect on the *savants*, had wrecked a bridge and destroyed a portion of the track.

Old Eddystone Lighthouse.—This time-honoured light, a hundred feet high, and massive in proportion, has been transferred from its original position in the Channel to the Hoe at Plymouth as a memorial to its engineer, John Smeaton. The foundation stone of the re-erection was laid by the Duke of Edinburgh a year ago, and on Wednesday last the monument was inaugurated in the presence of 10,000 spectators.

Dynamos for Telegraph Lines.—During the trials recently made at Berlin, with a view to substitute dynamos for batteries on telegraph lines, we learn that the current was supplied by a Siemens continuous-current dynamo working twelve underground and two overhead lines provided with Hughes instruments, eleven underground and twelve overhead lines provided with Morse instruments, and three closed circuit lines.

Telegraphic and Pneumatic Despatches.—The report of the Post and Telegraph Administration of Lower Austria shows for the telegraph department, a net profit of 1,281,292 florins (£128,130) for 1882, and of only 1,013,478 florins (£101,350) for 1883. This falling off is accounted for by a diminution in the number of telegrams, which was 947,814, or 42,040 less than in 1882. On the other hand, the number of messages sent by pneumatic tube has greatly increased.

Electric Lighting at Madrid.—The Sociedad Española de Electricidad, which possesses a large piece of land behind the Ministry of War at Madrid, has lighted that building with Maxim incandescent lamps, and the approach with Gramme and Siemens regulators. The clumps of trees and alleys in the Prado, adjoining, are also illuminated during the fine season by arc lamps placed on candelabra seven metres high, while from the balcony of the Buenavista Palace the electric light is thrown by reflectors.

Electric Discharge in Gases.—Herr Lehmann, in *Wiedemann's Annalen*, considers that the electric discharge in a Geissler tube is always non-continuous, even when the discontinuity is not apparent. A portion of the discharge is effected by convection—that is to say, the air or the gas becomes electrified, and carries the electricity from one pole to another. The electro-chemical action due to electricity, thus accumulated in the gaseous mass, would contribute to give the discharge in the gases the varied forms which it presents.

Second Balloon Ascent at Meudon.—A second ascent was made at Meudon, near Paris, on 12th inst., but this time with by no means the same success as on the first. The balloon rose, but did not return to its starting point, nor answer its helm as on the 9th August. The inventors say, however, that the balloon is not yet perfect, and that the

Digitized by Google

wind blew with greater force than that actuating the propeller. M. Chincholle, who appears to have been the only journalist admitted to the School of Ærostation, says that the balloon is not at all like a cigar, but "very like a whale."

THE EXHIBITION AT NEW ORLEANS.—The management of the World's Industrial Exhibition at New Orleans have concluded contracts with various electric light companies for lighting the buildings and grounds of the exhibition. Engines of 1,500 horse-power will be required to drive the electric light, which will cost over 100,000dols. Negotiations are progressing for the construction of an improved elevated electric railway in the grounds. Mr. Burke, the director-general, reports that he will shortly have railway connections into the main building and the Government buildings, and that he will then receive exhibits.

SWIMMING CONTEST OF THE LONDON POSTAL AND TELEGRAPH SWIMMING CLUB.—A large number of Postal and Telegraph *employés* of the eastern, south-eastern, south-western and other districts assembled at the Rotherhithe Baths, on Tuesday, to witness the second annual competition of the members of the East London Postal and Telegraph Swimming Club. There were forty entries for the competition, both senior and junior officers competing. The prizes, a silver cup and numerous sums ranging from £1 to 5s., were won by the officers Beszant, Lynch, Flynn, Woodmansee, Killen, Ruggins, Beek, Taylor, Newman, Leeper, Kemp, and Godfrey.

ELECTRO-CHEMICALLY COLOURED RINGS. — At a recent meeting of the Paris Academy of Science, M. Decharme set up a comparison between electro-chemically and thermically-coloured rings. When a copper plate is exposed to the fixed and narrow jet from an enameller's lamp, iridescent rings are formed on the metal round the point heated; and, under favourable conditions, fixed coloured rings are obtained, which appear unchangeable in the air. These thermic rings are exactly similar to the electro-chemical rings of Nobili; and, like them, they give rise to one another, being propagated in waves. In both cases the colours succeed each other in the same order, which is that of Newton's rings, seen by transmission.

TELEGRAPHIC COMMUNICATION WITH THE EDDYSTONE LIGHTHOUSE. — On Wednesday a deputation from the Plymouth Chamber of Commerce waited on the Trinity Brethren to urge the importance of establishing telegraphic communication with the new Eddystone Lighthouse. The chairman, Mr. Bellamy, said that it was proposed to form a small local company to construct and lay the cable, which would then be worked by Lloyd's Committee, the Trinity Board having full control over it, and being only required to consent to the scheme. The importa nce of such a cable to vessels passing up and down Channel was pointed out, and the Brethren promised to give the matter their earnest consideration.

ELECTRIC LIGHT IN LIGHTHOUSES.—An electric lighthouse has just been completed at the entrance to the Bay of Rio di Janeiro, Brazil. It stands on the island of Raza, and is 85 feet high, resting upon a rock 230 feet above the level of the sea. The light is of 2,000 candle-power, and the current is produced by a Gramme machine, worked by a stationary surface-condensing steam engine. All the fittings are double, to prevent unforeseen accidents; and in view of the possibility of a double accident, an oil lamp is always kept in readiness for use. The light is a revolving one, with one red and two white discs succeding one another at fifteen minutes' interval, and the light is visible at about 35 miles distance.—*Sanitary Engineer.*

DISTRIBUTION OF CURRENT IN NEW YORK.—Last week we referred to the arrangements being made by the New York Steam Company to supply the public with electric current as well as steam. In connection with this subject, we learn that the steam supplied by this company is used, in many cases, to run dynamos for electric lighting. The new Mutual Life Assurance Company has steam laid on by a 6in. pipe, for heating the building, working the lifts, and running the dynamos for 1,800 electric lights. As by far the larger proportion of steam used for other purposes than electrical lighting is not required at night, electric light can be furnished direct, at very low rates, from this company's own dynamos, by utilising the surplus steam.

ELECTRIC LIGHTING OF THE STOCK EXCHANGE.—The contract for lighting the new and old buildings of the London Stock Exchange has been entrusted to Messrs. Woodhouse and Rawson, of 11, Queen Victoria-street, E.C., and the work is to be proceeded with at once. This firm has other contracts on hand, among which may be mentioned Messrs. Guinness's Brewery, Dublin; Messrs. Ambuhl, Loebel, and Co.'s, Hamburg, and Messrs. Keyser and Co.'s, Cornhill. They have also the following private country residences to light:—Gortmore House, Dundrum, Co. Dublin, the residence of E. G. Burke, Esq.; Paddockhurst, Worth, Sussex, belonging to Robert Whitehead, Esq.; and Colonel Freemantle's residence, The Chuffs, at Maidenhead.

THE TELEPHONE IN FRANCE.—Since obtaining a prolongation of its concession for five years the Société Générale des Téléphones has been studying several important improvements demanded by the subscribers, who will ere long be put in communication with the telegraph system, so as to receive and transmit their messages direct. In conjunction with the company, the Minister of Posts and Telegraphs is arranging for a number of public telephone offices to be started in connection with the system. The *Bulletin de la Compagnie Internationale des Téléphones*, from which we cull the above information, says that a number of business men who are in frequent relations with notaries contemplate boycotting, or at any rate sending to Coventry (*mettre en interdit*) those members of the cloth who do not place themselves in telephonic communication.

THE OLDEN TIMES.—*Apropos* of Oliver Wendell Holmes, the following story is authentic:—In the early heroic days of ocean telegraphy—at a time when, although great difficulties had been encountered and a connection had at last been successfully established, the discouragement of many failures still hung over the undertaking—a triumphant dinner took place, to which prominent Englishmen and Americans, among others Dr. Holmes, were invited. The poet was unable to come, and in his absence his health was drunk and the fact communicated to him at Boston by the new submarine wire. Dr. Holmes sent in reply the following prompt and grateful message:—"You send me a message *de profundis.* I reply *sursum corda.*" It is said that the electricians were a little puzzled by the Latin, but that Mr. Cyrus Field, who was present, and who is never at a loss, set them right.

THE EARTHS'S MAGNETISM.—Under this head we recently (13th inst.) described the six subterranean chambers constructed at the Paris Observatory for studying the earth's magnetism. The greatest difficulties met with are those connected with damp and ventilation. The former is combatted by means of lime and sulphuric acid; and a gas stove, combined with ventilating shafts, will counteract any efflorescence on the walls. All the scientific instruments will be preserved

Digitized by Google

from oxidation by being coated with special substances, so as to permit of observations being commenced before the walls are quite dry. It will be *de rigeur* not to admit any object whatever made of iron, as that would influence the magnetic needle. These subterranean chambers are not the deepest in the Observatory. Those that approach the nearest to the catacombs contain the central clock, that which regulates all the pneumatic clocks of Paris.

RAPID TELEGRAPHY.—As a feat in telegraphy (says the *Melbourne Herald* of the 1st August) the shortness of the time occupied in the transmission of Reuter's telegrams announcing the result of the Goodwood Cup, run in England yesterday, may be mentioned. The race was run at three o'clock in the afternoon, Greenwich time, and the telegram was despatched from London at 3:17 p.m. It reached the office here at 2:50 a.m., Melbourne time, and was published in this morning's papers. Allowing the 9 hours 40 minutes which Greenwich is behind Melbourne in point of time, this makes the actual time occupied in transmission from one end of the woıld to the other 1 hour 53 minutes. This message probably came through more quickly than any message previously transmitted either way, and is regarded as the "best on record." The message sent by the Marquis of Normanby to the Queen and the Prince of Wales announcing the opening of the Melbourne International Exhibition occupied about three hours longer in actual transmission.

PROTECTION AFFORDED BY OVERHEAD WIRES.—During a recent thunderstorm at Minneapolis, the drill hall at the State University was struck by lightning, when a series of electric lamps were lighted and as suddenly extinguished. A loud report followed; and balls of fire were seen following the wire away from the building, where four thousand persons were assembled. The fine wire circuit for maintaining the lamps was afterwards found to have been fused. On the other hand, we learn from the *Western Fireman* that, at Louisville, during a gale of wind, an arc light wire crossed a fire-signal wire, which carried the full force of the current to the central fire-alarm station. In an instant the room was ablaze with a blinding and intensely hot light, followed by total darkness. Investigation showed that about three hundred alarm boxes had been wholly or partially destroyed; so that, in addition to the monetary loss, notices of fire breaking out in the city have to be sent by messenger, failing a telephone.

SPECTACLES FOR THE ELECTRIC LIGHT.—Dr. W. H. Stone, F.R.S., who recently read a paper on the Physiological Bearing of Electricity on Health, at the International Health Exhibition, on the occasion of the conference held there by the Society of Telegraph Engineers and Electricians, has devised a pair of spectacles or eye protectors for persons who are in the habit of working by or with electric light. The spectacles consist of front glasses of blue with attached side glasses or "blinkers" of red glass. The danger to the eye from the incandescent lamp is likely to arise from the red or heat rays, that from the arc lamp is due to excess of blue or actinic rays, hence the use of two glasses. In looking at the incandescent light through the blue glasses the glare is removed, and irritation from the intense yellow and red rays prevented, while after folding down the red side glasses over the blue front ones, the arc light can be looked at with safety through the joint media. The tints of the glasses are selected and combined by the help of the spectroscope.

METALLURGY CLASSES AT KING'S COLLEGE.—The syllabus of the metallurgical evening lectures in Professor Huntington's department is now published. There is to be a course of lectures, from 8 to 9 on Monday evenings, on the Properties of Metals and Alloys and their Uses in the Arts (which is intended to be of assistance to candidates for the examination of the City and Guilds of London Institute), in Metal Plate Work, Plumbing, and Iron and Steel; another course, from 7 to 8, on the same evening, by Mr. W. G. McMillan; the Demonstrator in Metallurgy will treat of Fuel and its Applications, and will include the subjects required for the Institute's examination in Fuel. The laboratory for practical work, besides being open on Friday evenings from 7 to 9, will be available as usual every day during college hours (from 10 to 4, on Saturdays 10 to 1) for "occasional students, and for those who are passing through the college engineering course." The first lecture will be on the 6th October. We are glad to find that the fees are to be reduced this year for the evening classes.

THE TELEPHONE ON THE CONTINENT.—The use of the telephone is generally on the increase in most parts of the Continent, the subscription in France being at the rate of 200f. (£8) per annum, reduced to 170f. when there are over 300 subscribers. The manufacturing towns of Lille, Roubaix, and Turcoing are now in communication, the average number of messages per day between the two latter places being 657; and the system is in force also at St. Quentin and Troyes. Rheims is the best served town in France for its size, and contains 210 subscribers, or 23 out of every 10,000 inhabitants. This is the highest number comparatively in the whole country, Paris, Lyons, and Bordeaux having but 14 to every 10,000; Calais and St. Pierre, 22; Havre, 18. The total number of French telephone subscribers is 5,535, while Germany has only 4,000 in 21 cities and towns. The proportion at Berlin is nine to the 10,000 inhabitants, Vienna four, and Brussels 11. Munich has 393 subscribers, Leipzic 285, and Chemnitz 101. A system has just been inaugurated at Mons, in Belgium, so that the inhabitants of the Borinage coal district may converse with Brussels, Antwerp, Charleroi, Liége, and Verviers.

MILL LIGHTING BY ELECTRICITY.—The Park-lane Twist Company, Preston, have undertaken an improvement in their mill, which must prove a great advantage in many ways. They have decided to fit up the greater portion of the buildings with the electric light, which has been successfully carried out by Mr. Frederick D'A. Goold, of the "Volta" Electrical Works, Manchester. This is the first mill in Preston, we believe, in which the light has been introduced, and all concerned seem to be well satisfied with the results. There are 65 lights of 16 candle-power; 24 are in the lower reeling room, 22 in the upper reeling room, 10 in the carding room, and nine in the chapel reeling room. The dynamo machine which regulates the current is worked by an electromotive force of 90 volts. It is contended that in the great majority of cases there is an ample surplus of power in large works to drive all the machinery necessary for the production of the electric light, thus minimising the cost for maintenance, and under these conditions insuring a far superior and more healthy light at a less cost than gas. The light is said to be more brilliant, cheaper, and safer in a room where so much "fluff" is continually flying about.

VARIATION WITH THE TEMPERATURE OF THE RESISTANCE OF BISMUTH AND ITS ALLOYS.—In some notes on this subject, M. A. Leduc remarks that, contrary to bismuth, the resistance of which increases about four thousandth parts for every centigrade degree between 12 and 60 degrees C., the resistance of an alloy of bismuth and lead of equal weight increases about

Digitized by Google

one and a half thousandth parts under the same circumstances. In the hope of finding an alloy the resistance of which should not vary appreciably between rather considerable limits of temperature, he combined one equivalent of lead with two, three, four, and five equivalents of bismuth successively, and obtained wires of these alloys by causing the liquid metal to rise in glass tubes. The resistance of all increased (between 13 and 8 ten-thousandth parts) on the temperature being raised. He again tried commercially pure bismuth, made into a wire by the above-named methods, when the resistance increased three thousandth parts of its value per degree. The remarkable difference between this wire and the band before experimented upon is believed to be due to the method of their preparation and the very different speed of their cooling. M. Leduc remarks that pure bismuth and the last alloy experimented with considerably increase in volume on solidifying, and in this case finds an exception to the rule regarded as general that "for metals which increase in volume on solidifying, the resistance diminishes on the temperature being raised."

COMPETITIVE TRIAL OF ELECTRIC LAUNCHES.—The trial trips of the "Australia" and the "Electricity" came off successfully on Saturday last. The boats started from the wharf of the Storage Company, Millwall, at 1:55, reached London Bridge at 2:20, Blackfriars at 2:25, and Charing-cross at 2:32, the "Australia" being very slightly in advance. The "Australia" was propelled by a Reckenzaun motor, weighing 390lb., and taking a current of 37 amperes from 50 E.P.S. accumulators placed at the bottom of the boat. Eight passengers were carried, the E.M.F. being 100 volts. The screw propeller of the "Electricity" was worked by a Siemens D2 machine, weighing 658lb., and 40 E.P.S. accumulators of a larger and heavier type than those of the "Australia." The motor took 47 amperes, the E.M.F. of the cells being 80 volts. There were seven passengers on the up journey, and eight on the down. Part of the way there was a strong wind, with tide against the boats. The return journey from Charing-cross commenced at 2:40. There was a ten minutes' stoppage off the Tower to cool and slacken the gland of the "Australia's" stern tube, and another stoppage about the same period at Millwall to bale out a quantity of water which had been shipped by the "Electricity" on passing some large steamer. Greenwich Pier was reached at 4:10, both launches arriving at the same time; and they cruised about on the river until 6 p.m. On the "Electricity" were Mr. J. J. Courtenay and Mr. Thornton, of the Storage Company, Mr. Simpson, of Siemens Brothers, and others; and on the "Australia," Mr. Stephens, Lieut. Robinson, R.N., H.M.S. "Vernon;" Mr. A. Reckenzaun, C.E.

THE HOCHHAUSEN SYSTEM.—In our announcement last week of the practical contest between the Toronto Electric Light Company and another company, which resulted in the bestowal of a five years' contract with the former, it is right to explain that the system used in America under the name "Excelsior" is identical with the Hochhausen system. This is in the hands of the firm of Messrs. Edmunds and Goolden (late Henry Edmunds, jun.), of 2, Victoria-mansions, Westminster, who have recently established and fitted up a factory at Halifax, Yorks., for the manufacture of the Hochhausen dynamos and lamps, and other electrical apparatus. Messrs. Edmunds and Goolden acquired all the patterns and drawings of the Gramme dynamos at the sale of the effects of the late firm of Emmerson and Murgatroyd, who were the sole makers of that machine in this country, together with a large number of complete Grammes and armatures, &c. Mr. Edmunds is, moreover, intimately connected with the firm of Armington and Sims, and has just made arrangements for the manufacture of the well-known Armington and Sims engine by one of the leading firms of engine builders in the Midlands. We are informed that Mr. Edmunds is at present making similar arrangements on the Continent. The name "Excelsior" is retained only in connection with the carbons. This firm has several important domestic installations in hand near London, together with several mills and factories in the North. Several of the leading shops in Halifax are lit by electricity from their factory, with the result that a powerful Armington and Sims engine is, we believe, being erected for this purpose to meet the applications for light in the town.

SHIP LIGHTING.—The paddle steamer "Saturno," built by Messrs. A. and J. Inglis, of Glasgow, a magnificent saloon vessel (300ft. long, 60ft. broad), for service on the River Plate, has been lighted throughout by Messrs. W. Harvie and Co., of Glasgow, the well-known ship lamp patentees, who have secured a license for the manufacture of the Elphinstone and Vincent dynamo-electric machine. The installation consists of 320 Swan lamps of 20 candle-power. Each of the three decks has two separate circuits, one for lighting the passages and centre lights of saloons, and lights required all night, the other for state rooms and table lights of saloons. Each state room has a separate lamp and switch, and the saloons are also controlled independently. There are six circuits on the main switch-board, each controlled by a double contact switch to ensure good connection, also a fusible plug. Close to the main switch-board is an adjustable resistance in the field magnet circuit, and an Auld's reducing valve for controlling respectively the electromotive force and speed of the dynamo. The current is supplied by an Elphinstone and Vincent dynamo, size E, for supplying 400 20-candle-power lamps. The steadiness of the light and general good working of the machine were much appreciated by the owner and builders of the vessel, and also by a large party of visitors, to whom it was exhibited before proceeding down the Clyde. The machine used is in every respect similar to that now working at the International Health Exhibition, where it is lighting numerous stands, &c. The circuit is continuous, and of low tension; the terminals, or any of the wires, may be held in the bare hand without inconvenience whilst the machine is giving its most powerful current.

THE ELECTRIC LIGHT ON BOARD SHIP.—Last week an important trial was made, at the instigation of the Admiralty, at Portsmouth, having reference to the practical utility of the electric light for side lights and mast-head lights on board Her Majesty's ships. The following gentlemen were present: Captain Carr, H.M.S. "Crocodile"; Captain Douglas, H.M.S. "Serapis"; Captain Dyer, H.M.S. "Sultan"; Mr. Marshall, Assistant-Constructor, Portsmouth Dockyard; and other naval and dockyard officials, together with Mr. Lane, the electrician, Portsmouth, and the Edison and Swan Company's engineer. After arranging to place 50 candle-power Edison lamps in the ordinary port, starboard, and mast-head lanterns of H.M.S. "Crocodile," and an ordinary oil light on the South Eastern Railway Jetty, alongside which the "Crocodile" is lying, as a standard to compare the electric light with, a launch, which was used in making the trial, proceeded to the "St. Vincent" training ship, a distance of about a mile, the electric lights showing up in a most brilliant manner; and here a signal was made to the "Crocodile" to substitute 16 candle-power Edison lamps for the 50 candle-power Edison lamps, the oil lights remaining the same. Naturally the result of this was to diminish the effect, but it enabled a little more careful comparison to be made between the electric light and

Digitized by Google

the oil. When the 50 candle-power lights were in, the difference was so great that no fair comparison could be made out; with the 16 candle-power lamps in, the electric light appeared approximately to be twice as bright as the oil. The launch then steamed about another mile further off, until she came abreast of the Clarence Pier, when, owing to a slight haze, the oil light became invisible, while the electric light was still well in sight. The result of this trial was that the officers and other gentlemen present expressed their complete satisfaction as far as the illuminating power was concerned; and we believe it is confidently expected that the Admiralty will now generally adopt the use of electric signal lights on board the ships fitted with the necessary plant; and as the prejudice against the use of incandescent lamps for signal lights has been and still is of a rather determined nature, we trust that this trial made by the Admiralty, and the opinion that they have come to, will materially help in reducing the prejudice alluded to, and that we shall before long see all our large mercantile ships using electric signal lights.

THE E.M.F. OF AMALGAMATED ZINC.—In a note on this subject by M. G. Lippmann, in the *Journal de Physique*, he observes that generally a greater E.M.F. is attributed to amalgamated than to pure zinc. If a plate of each of the two substances be immersed in a sulphate of zinc solution, a couple is formed in which the amalgamated zinc forms the negative pole, inasmuch as it is the more readily acted upon by oxygen. Such, at least, is the result obtained if special precautions be not adopted. In a recent work M. W. Robb shows that, if care be taken to use pure zinc obtained by electro-deposit, and also sulphate solutions which have been deprived of all free acid by remaining on carbonate of baryta, the element will not manifest any appreciable E.M.F. The negative result obtained by M. Robb may be confirmed by the following line of reasoning, founded on Carnot's principles. If the zinc and amalgamated zinc couple had a fixed E.M.F., it might be possible, by closing the circuit, to cause the current to produce some definite mechanical work. On the other hand, since the amalgamated zinc behaves as the metal attacked, the effect of the current is to get rid of the amalgam, separate the mercury, and tranfer the zinc which it contained to the surface of the pure zinc. In this way, at a very small cost, the couple might be regenerated by collecting the zinc thus deposited and conveying it mechanically to the mercury side, where it would again become amalgamated; in fact, definite quantities of work might be produced while only expending the insignificant labour of transferring the zinc by hand. Now this would be incompatible with Carnot's principle. Not that it would be incompatible with the principle of equivalents, for the amalgamation of zinc produces cold, so that the heat absorbed by this amalgamation might be the exact equivalent of the work done. This is even, as explained by M. J. Regnault, the working of the element by the dis-amalgamation. But, according to Carnot's principle, the transformation of heat into work can only take place if there be a simultaneous passage of the heat of a hot body into a cold body. In other words, it is not possible to construct an apparatus which produces work on the simple condition of producing an equivalent quantity of cold. Now the zinc and amalgamated zinc battery would be precisely a case in point. On the other hand, the cadmium sulphate pole of the cadmium and amalgamated cadmium element manifests an appreciable E.M.F. The pure cadmium is dissolved and transferred by the effect of the current to the amalgamated cadmium. In this case, the above line of reasoning cannot be adopted; and Carnot's principle is no longer applicable. This pole cannot, in fact, be regenerated except by depriving the cadmium of its amalgam. Now, this operation cannot be performed mechanically; and to be effected electrically, it would require an expenditure of power at least equal to the production of the work due to the current.

NEW ZINC ACCUMULATOR.—One cannot help being a little amused at the way in which inventors are continually ringing the changes on secondary battery arrangements. M. Reynier has lately devised a zinc accumulator, which has, to use the usual formula, given good results. It comprises four large Planté positive electrodes, bent and perforated, and three negatives, consisting of smooth lead plates, which are coated with zinc by electro deposit from an acidulated solution of sulphate of zinc, in which the element is immersed. Glass tubes attached to the negatives by lead wires prevent accidental contacts inside the battery. The seven electrodes are carried by as many separate cross bars, made of paraffined wood, which rest on the edges of the cell, and keep the plates at a certain distance from the bottom. The place of a cover is taken by these cross bars, which touch one another. Each plate is provided with a terminal, the four positive poles being on one side and the three negatives on the other; and two brass rods, terminating in binding screws, connect the poles of the same name. The cell consists of two wooden rectangular boxes, one inside the other, with a space of several millimetres between, lined with a watertight cement, supple and non-conducting, of tar base. The complete insulation of the case, and of all the parts, the purity of the metal deposited, and its amalgamation, are said to reduce to a minimum the local attack on the zinc, which was considerable in the old Nantua battery. The consequence is that what is called the *co-efficient of restitution* may now be compared with that of the Planté accumulators. The following are the leading particulars of the new accumulator:—

E.M.F.	2·36 volts.
Mean resistance	0·02 ohm.
Normal intensity of discharged current	25 amps.
Intensity of charged current........................	5 to 10 „
Capacity of accumulation after 200 hours of formation	550,000 coul.
Effective surface of the four positive electrodes ....(3,100 sq. in.)	200 dm².
Effective surface of the three negative electrodes ....(2,015 sq. in.)	13 „
Weight of positive electrodes ....(18lb.)	8·2 kg.
„ negative electrodes ....(3lb.)	1·4 „
„ the cell ....(6lb.)	2·7 „
„ the fluid ....(10lb.)	4·4 „
„ the lead wires ....(1lb.)	0·46 „
Total weight ....(38lb.)	17·16 „

The total amount of electrical force stored up is 130,000 kilogrammetres (950,000 foot-pounds), or 7,600 kilogrammetres (55,000 foot-pounds), per kilogramme (2·2lb.) of accumulator. Theoretically, a zinc accumulator should store up double that amount; and if this form gives less, it is—at least so is said in *Les Mondes*—because M. Reynier has designedly increased the strength of the cell and the bulk of the electrodes beyond what is necessary. It should also be remarked that this capacity of 7,600 kilogrammetres per kilogramme is higher than that of any accumulator hitherto made in France. Therefore, notwithstanding the great weight of the cell and the positives, this new form of accumulator is relatively light, which renders it suitable for use in electric locomotives as well as in fixed plant. Independently of their use as accumulators, zinc secondary batteries may be utilised as "regulating voltameters" in incandescent lighting, and for counteracting irregularities due to the piston stroke, accidental stoppages, and other causes.

THE PHILADELPHIA EXHIBITION.—I.

(FROM OUR SPECIAL CORRESPONDENT.)

PHILADELPHIA, SEPT. 11.

Although the Electrical Exhibition has been open for ten days, it is not yet ready to be reported in detail. The exhibitors have been hard at work since the opening, but work is still going on, and even the completed displays suffer from the confusion that surrounds them. For the present, therefore, I can give you only a general idea of the Exhibition, reserving description of particular exhibits for future letters.

The building erected for the display is irregular in form. The main hall is rectangular, 100ft. by 200ft. in size, with a Gothic roof span springing from the ground. A gallery extends all around this hall. A large annexe, triangular in shape, and with a low roof, completes the structure, except that at each corner there are towers two and three stories in height, where the offices, committee, Press, and other rooms are situated. The building is roughly built of wood and glass, and is little better than a shed, although made somewhat picturesque in appearance by its numerous towers. Directly opposite the Exhibition hall is a large brick structure formerly used as a depôt by the Pennsylvania Railway Company. This was put at the disposal of the Franklin Institute, under whose auspices the Exhibition is held, and is now connected with the main building by a bridge spanning the street. In the railroad depôt there is a museum of apparatus of historical interest, including many original inventions contributed by the Patent Office and various institutions of learning. Here also is a large hall used for lectures and concerts, a restaurant, &c. In the open area adjoining the depôt the larger exhibits of electrical railroad switches, signals, &c., are erected. A boiler house adjoins the main hall, and there are several locomotive boilers employed to furnish steam stationed in the open ground near he building.

In the centre of the main hall a fountain was erected which, besides the usual central sprays rising from rockwork, has a number of streams converging on the rockwork from the outer circle of the pond or tank. Back of each of these streams there is an electric light, whose rays are directed by lenses along the axis of the stream. They are thus rendered invisible until refracted from the spray where the water breaks against the rock. The effect is very beautiful, especially when various coloured lights are used. The fountain, however, like many other things, is not yet in perfect working order, and is usually shown with coloured lights thrown directly upon it from locomotive head lights. The fountain occupies the centre of the hall. Ranged about it are the very fine Government exhibits, a miniature telephone station, Delaney's synchronous multiplex telegraph exhibit, and various exhibits of philosophical apparatus. All along the boiler-house side of the building are ranged the dynamo machines, of which there is a large display, though no great variety of models. There are two large exhibits of electric lights in the main hall, but nearly all the lights and motors are shown in the triangular annexe on the side of the building opposite to the boiler-house.

There is also a general display of arc lights in the main hall, each of a dozen arches carrying about nine or ten lamps. The illumination, however, is not remarkable, the lamps being suspended from 40ft. to 60ft. above the floor.

The power employed for driving the machinery is 2,000 horse. There are about 1,000 arc and 5,000 incandescent lamps in and about the building, and 100 or more motors, most of the latter being small in size. Several gas engines are also employed to furnish power for driving dynamo machines.

Several exhibitors have erected within the building small furnished rooms in which to display methods of domestic lighting, but they are cheaply constructed, and do not have a very good effect. A large organ in the main hall is operated by electricity, and an enterprising clothier shows a complete working establishment, with sewing machines operated by electric motors. There is also a printing press run by the same power, and on which the regular edition of the *Electrical World* is printed.

The Exhibition is quite attractive to the public, but contains very few novelties to the electrician. Its most interesting features to professional men are the personal exhibits of Weston, Edison, and Thompson, and the historical museum. In these displays one is enabled to see how discoveries have been made and what is the process of invention. Edison has a remarkably fine display, covering the whole range of applied electricity.

The Conference of Electricians, called under Government authority, has been in session during the week, but has thus far done little more than discuss questions relating to electrical units and the action that should be taken by the Government in establishing standards of measure for public use. It is probable that before the week is ended definite action will be taken on these subjects. A long discussion was held to-day on the theory of dynamo machines, which developed serious disagreements between the doctors. Of this I shall send you an account as soon as the debate has taken definite shape.

It is quite likely, however, that the reports of the Board of Examiners now in session will prove of more value and interest to electricians than the Exhibition itself, or the conference mentioned above. A very capable Board has been appointed, which has been divided into committees, each of which is making exhaustive tests of apparatus submitted to the Board. No medals are to be given to exhibitors, but a more valuable prize for some of them than any medal could be will be the report of the examiners. I do not suppose that any of these reports will be made public until after the Exhibition closes, and it is quite probable that some of the tests will be continued beyond the six weeks allotted to the Exhibition.

The weather has been excessively warm ever since the Exhibition opened, the thermometer marking from 85 to 95 degrees each day. Although this interferes to some extent with the Exhibition, the attendance has nevertheless been quite good. Next week, when the exhibits are all in order, and the weather has improved, the hall will probably be crowded every night.

ELECTRIC LIGHTING OF THE IRONCLAD "RICHELIEU."*

The use of electric lighting on board men of war has been generally adopted for night searches by means of projectors; and a few Powers, including England, France, Italy, and Austria, have applied electricity to the internal lighting of several war vessels. In most cases, incandescent lamps have successfully stood all the tests of practice. They give a very agreeable light, while, at the same time, simplifying the electric illumination and preventing any chance of fire. They also permit of increasing the power of the side lights, and of giving night signals with as much safety as rapidity. The advantages of electric lighting have been recognised by the principal companies of the merchant marine; and the recent application made by Messrs. Sautter, Lemonnier, et Cie., on the French ironclad "Richelieu" have proved that the same is the case for the navy; but in this case, the conditions to be fulfilled being more numerous and essentially different, it was necessary to devise and apply a combination of new arrangements.

The Gramme dynamo-electric machine, which maintains 211 incandescent lamps of 8 candles each for the internal lighting, and 16 of 30 candles each for the head lights, the side lights, and the signals (as shown in Figs. 1 and 2), yields a current of 200 or even 250 amperes. With a normal speed of 580 revolutions, the E.M.F. at the terminals is from 51 to 52 volts; and the internal resistance does not exceed 0·008 ohm. The electro-magnets are excited in shunt circuit by a current of 22 amperes.

The distinguishing characteristic of this machine consists in the fact that it has a constant E.M.F. at the terminals, whatever be the number of lamps in the circuit. The armature coil consists of 100 copper bars, forming a cylinder of 180 mm. (7in.) diameter, insulated one from another by cardboard dipped in Jews' pitch. The ends of this cylinder (Figs. 1 and 2) are turned so as to form the collectors *c c*, on which rest the brushes *j j*.

* Reproduced from the *Revue Industrielle*, to the editor of which we are indebted for the illustrations.

Digitized by Google

formed of silvered copper wires. At a distance of 75 mm. (3in.) from each of these, spokes, *d d*, are sunk in semicircular recesses, and fixed to the bars by two copper rivets and a tin solder joint. The cylinder *a* is covered on its outer surface by a layer of insulating cloth, on which is rolled the iron wire for forming the soft iron core *b* of the coil, and which is itself insulated with cloth. The coil is connected with the steel shaft *l* by means of eight iron keys; it terminates in copper bars, *e e*, of trapezoidal section, the two ends being recessed into each of the spokes, to which they are fixed by a solder joint. Care is taken to mount the two ends of the spokes, butting on two successive bars, so as to form a helicoidal coil. These external bars are insulated from each other by bands of cardboard; and the whole is encircled by cloth covered with brass wires soldered.

The electro-magnets are formed of eight round iron bars, *f f*, 0·8 metre (about 3ft.) in diameter, connecting the base *g* of the machine with the upper plate *h*, and carrying in their middle the cast-iron poles *i i*. These soft-iron columns are transformed into electro-magnets by the current of the shunt circuit, which traverses the copper wire surrounding them. The wire has a diameter of 44 tenths of a millimetre; and the length rolled upon each half column is 83 metres (272 feet). The coiling is so effected that the consequent points of the electro-magnets are formed on the armature itself, as in all Gramme machines. The poles *k*, whence the current is taken off, are

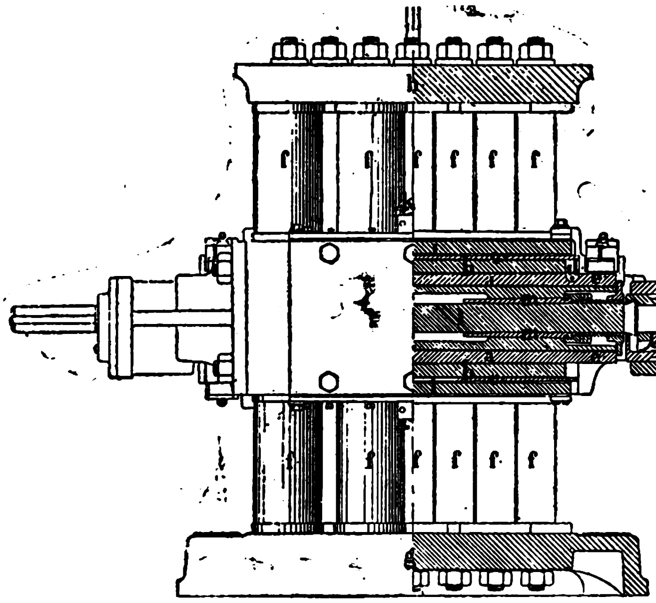

Fig. 1.

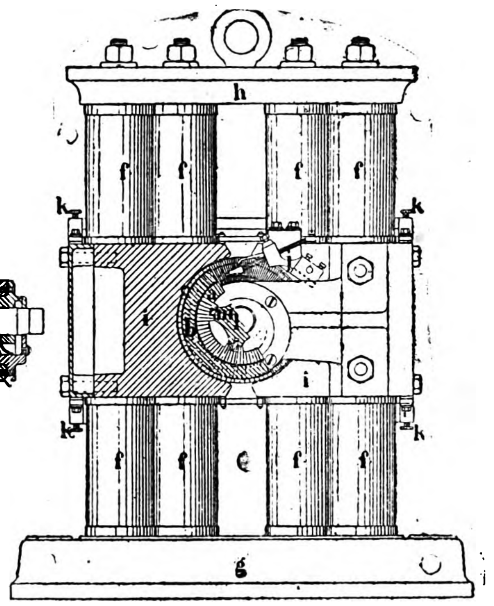

Fig. 2.

placed right and left, for facilitating the departure of the circuits.

The machine, thus constituted, is very strong. At a speed of 580 revolutions it absorbs 25 horse-power, while maintaining 400 lamps of 8 candles, or 200 lamps of 16 candles; but this speed, rather high for a direct-acting motor, may be, without inconvenience as far as the dynamo is concerned, increased to 900 revolutions. The E.M.F. and the effort absorbed are thus practically doubled; and 800 lamps of 8 candles, or 400 lamps of 16 candles may be maintained. Notwithstanding its power, this machine occupies but little room, less than a square metre of base, and about a metre high. When run at low speed, it is very suitable for lighting war vessels, because it remains considerably below its maximum degree of production, which ensures a long duration of service.

The 227 Edison lamps fixed on board the "Richelieu" have been divided into seven circuits, as follows:—

1.	Day circuit	68 lamps of 8 candles.
2.	Night circuit	79 lamps of 8 candles.
3.	Fighting circuit	16 lamps of 8 candles.
4.	Engine circuit	22 lamps of 8 candles.
5.	Sea circuit	22 lamps of 8 candles.
6.	Side-light circuit.........	6 lamps of 30 candles.
7	Signal circuit	10 lamps of 30 candles.

All these circuits constitute the main divisions of the installation, and respond each one to a special requirement of the service. 1. The day circuit is maintained day and night; it illuminates the lower portions of the vessel, which are dark even during the day. 2. The night circuit lights the berths, cabins, &c. 3. The fighting circuit serves the ammunition bunkers. 4. The engine circuit permits of walking round and inspecting the various parts of the engine, and doing repairs. 5. The sea circuit completes the illumination of the engine and boilers when at sea. 6. The side-lamp circuit includes three lamps astern, two side-lights, and one head-light in the top. 7. The signal circuit maintains the lights placed on the masts during the night.

For the different circumstances in which the vessel may be placed, the lighting has been provided for in the following manner:—

In port during the day	94 lamps
In port during the night...............	171 "
At sea by day	116 "
At sea by day and fighting............	132 "
At sea during the night	211 "
At sea during the night and fighting	227 "

All the lamps excepting the head lights, the side lights, and the signals, are Edison B lamps of 8 candles, requiring 50 volts and 0·75 ampere.

They have been fixed to brackets, the form and arrangement of which vary with the places to be lighted; but, throughout, special precautions have been taken for counteracting the

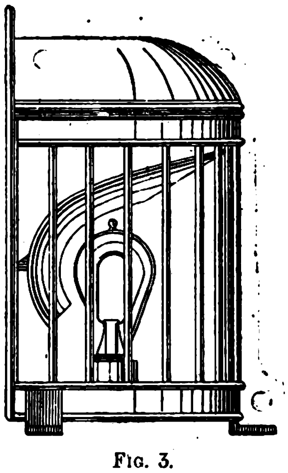

Fig. 3.

vibration due to the engines, and to the shocks caused by firing. With this object, a felt washer from 10 to 15 mm.

Digitized by Google

(⅜in. to ⅝in. thick) has been interposed between the sides of the vessel and the point where each bracket is fixed; secondly, each lamp is connected with its bracket by two small wood sockets and spiral springs, an arrangement which considerably deadens the shocks. In all the berths and places for the crew the lamps are enclosed in lanterns, which can only be opened by special triangular keys.

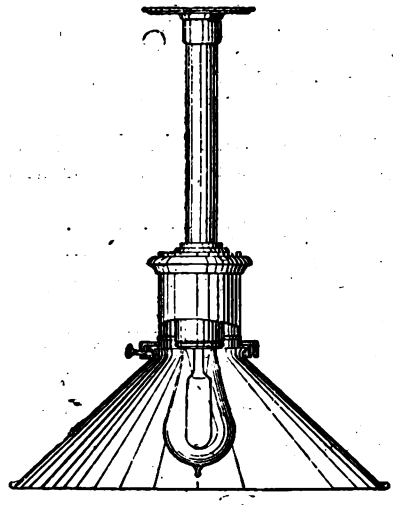

FIG. 4.

The lamp, shown in Fig. 3, lights up the gun battery and the berths. A few places have required the use of movable lights, which are, for this purpose, suspended by three small chains (Fig. 6). Thus, in the officers' state rooms and

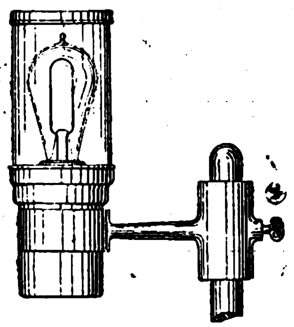

FIG. 5.

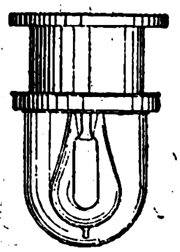

FIG. 6.

cabins the brackets have the form of an arm (Fig. 7), or a straight pendant (Fig. 4), which are very similar to the ordinary forms used with candles. All these appliances are nickelised or tinned; and the lamps are provided with opal

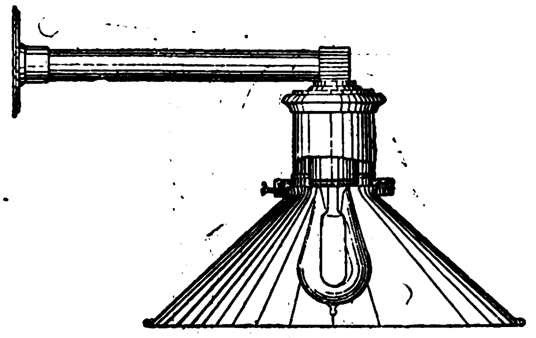

FIG. 7.

shades. The cabin of the petty officers is provided with similar fittings simply bronzed, and with tin shades. Similar types are fixed in the engine room; and Fig. 5 shows the manner in which the lighting of the pressure gauge and water-level of each boiler is effected. Lastly, the type shown at Fig. 8 is very suitable for the bunkers and passages.

The seven circuits enumerated above start from a switchboard (Fig. 9) placed near the electric machine. Each one is worked by a switch, which permits of turning on or extinguishing the light, on the word of command being given by the officer in charge. Moreover, in each circuit a certain number of lamps are provided with separate switches, having special keys.

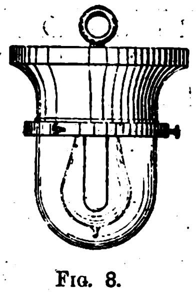

FIG. 8.

The leads, which are perfectly insulated, have been laid on boards fixed to the sides of the vessel, or passed through metal pipes; and, after laying, they were protected by being covered with wood. Forty-eight cut-outs divide the installation into as many groups of lamps, in such a manner that, if accidentally the wires of any one lamp should come into contact, the whole group controlled by the corresponding cut-out would be automatically switched out of circuit.

The four first circuits have a common return wire, which terminates at the switch-board in a single commutator; and the two other circuits, 6 and 7, which are more exposed to damage, have a special return wire, bearing a notice to this effect on the switch-board. It is therefore always possible to separate completely the wires of these circuits from the rest of the arrangement.

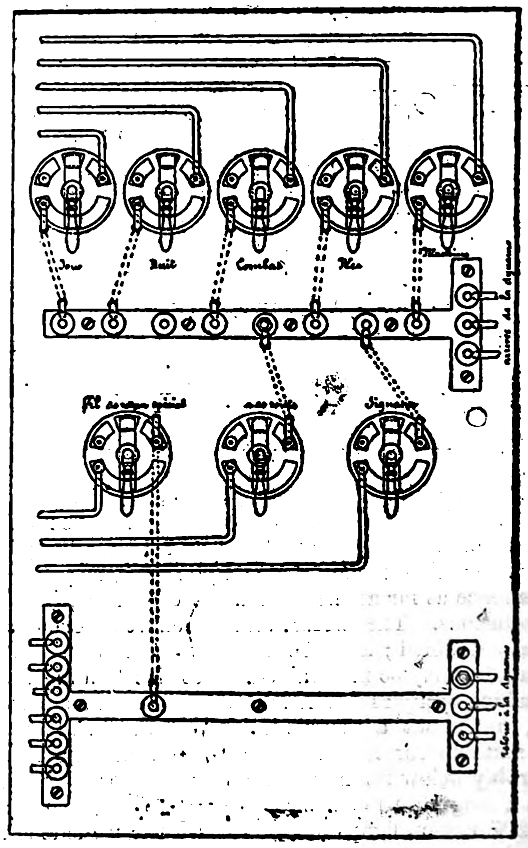

FIG. 9.

Consequently, the areas of the conductors have been calculated, and the starting points of the principal shunt circuits chosen, so that, in each circuit, the differences of potential between the two wires of the furthest lamp do not differ by more than one volt from the diminution at the switch-board. As, on the other hand, the fall of potential at the terminals of

Digitized by Google

the machine is practically constant, the total intensity of the current is always proportional to the number of lamps in incandescence. There is therefore no need of any regulation at the time of lighting, or extinction of one or more circuits. It is sufficient to turn the corresponding switch on the switch-board, always leaving a few minutes' interval between working two switches, so as to allow the governor of the steam engine time to regulate the speed. The apparatus, which permits of working the necessary changes for the signal lights with as much rapidity as precision, consists in the production of a luminous *schema* before the commutator, even of the lamps placed on the masts.

Messrs. Sautter, Lemonnier et Cie have devised a method which may be employed in arranging a system of electric lighting on board a war vessel, by which, without differing too much from the arrangements described above, it would be easy to work a projector by a group of machines identical with those connected with the internal illumination. One of these groups might provide for the illumination of lamps constantly lighted, and the other be held in reserve both for the projectors and for the internal lighting. It would also be possible, by means of very simple arrangements, to utilise the available currents for the transmission of motive power to certain portions of the vessel—to the repair shop, for instance. In brief, this project would consist in establishing, in a very restricted space, a central station for the production of electricity, which might be utilised for the internal illumination, for the projectors, for the maintenance of arc lamps, for embarking and disembarking, and, lastly, for the transmission of motive power.

It is certain that the progress made in electricity permits of practically carrying out these different applications.

ALBERT MARNIER.

KETTELL'S ELECTRIC CLOCK SETTING MECHANISM.

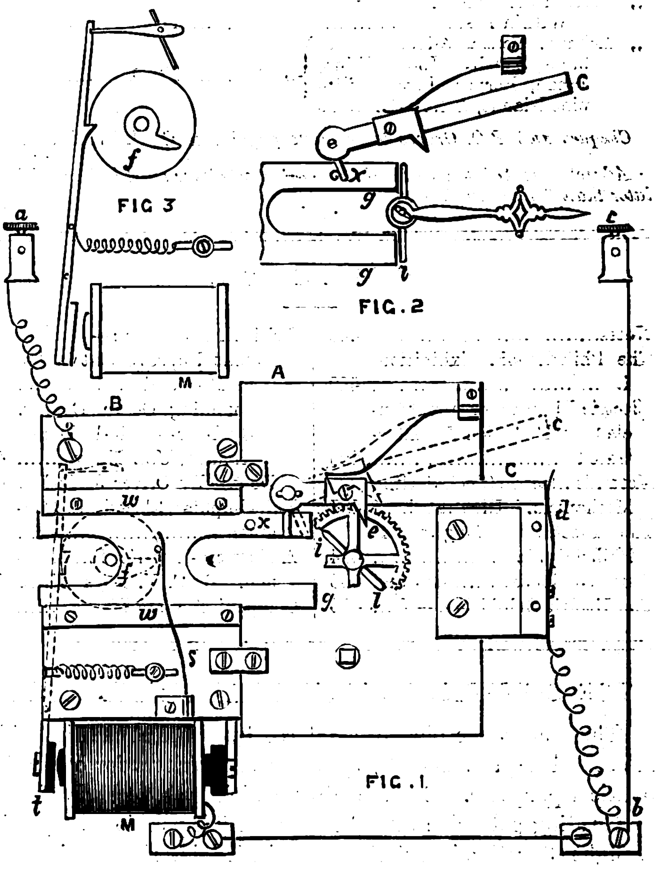
The object of this device is to set a great number of clocks synchronously with a far less amount of battery-power than is possible by the apparatus in use up to the present time. Clocks in which electricity is the motive agent are subjected to so many disturbances that it seems to be the common opinion that some device for setting the clocks periodically must be substituted. A broken wire or a short circuit, and we have no time. Expense is a great consideration, and few persons can afford to buy new clocks or to pay the price demanded by the companies for delivering to them the standard time.

The above-mentioned disadvantages are avoided by the Kettell mechanism, which is thoroughly effective, can be attached to the nicest parlour clock without in any way spoiling its beauty, for it is placed within the clock, and it can be furnished, moreover, very cheaply. A break in the wire does not interfere in any way with the going of the clock, and a poor clock can be made to indicate exact time by means of this device.

In Fig. 1 the device B is shown attached to the clock A, which as shown can be set from the telephone or telegraph wire, thus necessitating no extra line. This is accomplished by the lever C, which is moved by a pin attached to the wheel carrying the hour hand.

Except at the time when the clock is to be set, the lever C rests in the position shown in Fig. 1 by the full lines. The course of the current is then, binding screw *a*, lever C, spring *d*, to *b*, binding screw *c* to line. In this position telephoning or telegraphing can be carried on through the line. When, however, the clocks are to be set automatically by the pin *e* on the hour wheel, the lever C is raised to the position indicated by the dotted line, and then the current must pass through the electro-magnet M. By the central office regulator the line is broken for a few minutes before the time for setting, and the clocks being as shown in the dotted lines Fig. 1, when the regulator again makes the circuit, the current, passing through M, releases a train of wheels in B, and the cam *f* regulates the clock. This is accomplished as follows:—On the arbor of the minute hand are fastened two pins, *i i*, and when the current from the central office regulator, sent through the magnet M, releases the train of wheels in B, the cam *f* pushes forward the slide bearing the arms *g g*. These pressing against the pins *i i*, bring the minute and hour hands to their proper position. When the arms *g g* impinge the pins *i i*, the pin *x* throws the lever C forward, as shown in Fig. 2, and allows it to fall back into its proper position, so that succeeding impulses do not affect the magnet M. The spring *s* brings the slide back to its position ready for another setting. Thus all the current required is simply what is necessary to attract the armature *t* of the magnet M. Its action is as sure as a Morse instrument. Fig. 2 shows clearly the action of setting the hand, and Fig. 3 the magnet and cam wheels.

In case it is not desirable to use the telegraph or telephone wire for setting the clocks, then the only circuit needed would be through the magnet M, and the shunting device C *d*, &c., would disappear. The current would then be sent at the proper time from the central office by the regulator, automatic in its action, release the wheel work in B, and set the hands.



The works in B are simply the striking works in a clock, and in case the clock has a striking device, it can be used to do the setting.

We have seen this apparatus at work at 17, Devonshire-square, where those in charge will welcome investigation.

RATS AND UNDERGROUND CABLES.—*Iron Age* gives an amusing incident in connection with the laying of the underground cables in Washington. The receptacle for the wires had been laid for four squares and covered over very carefully, when it was discovered that no wires had been placed in the receptacle, and the whole thing had to be taken up. As a companion piece, a Washington telegraph manager tells of a similar incident which happened in London many years ago. One of the lateral wires connecting with an underground cable had been drawn out for repairs without attaching a leading line to it by which it could be drawn through again. In this case the remedy consisted in fastening a fine steel wire to a large rat and setting him at liberty in the pipe. A ferret was started in after the rat, and the latter ran the entire length of the pipe, bringing the wire with him.—*Sanitary Engineer.*

THE ELECTRICAL CONGRESS AT PHILADELPHIA.

There are some phrases gendered by political studies which are seized with avidity by speakers and writers for other than political purposes. Such is that which was recently framed by a leading politician when he spoke of "legislation by picnic." A slight alteration into "science by picnic" describes the itinerant meetings and congresses annually held under the auspices of various scientific bodies. There is no doubt that science does largely benefit by these meetings, and they form an opportunity for mutual discussion that could not be obtained in any other way. Few men would care about travelling a more or less great distance—putting up with the inconvenience of crowded hotels, and so on—were there not a corresponding amount of pleasure, and we may be sure that this pleasure is not altogether obtained in the meeting room. It is found in the meeting of old friends and making new ones. The meeting this year of the British Association at Montreal enabled many of our most able scientific men to visit the American Association and the Congress of Electricians at Philadelphia. Our correspondent at Philadelphia has commenced a report of the Exhibition now being held in that city, and has pointed out that the report of the Congress given in the *Public Ledger* is a fair abstract of the proceedings. Pending the arrival of a more complete report we give that, showing the many important subjects discussed at the Congress. The President advocated the formation of physical laboratories, and there is one remark of his worth all the comment it may obtain. "Let," he said, "the professors be given a liberal salary, so that men of great talent may be contented." It seems to us that the present system is altogether wrong. A college is established, and the professor is given a salary that is inferior to the wages of many a cook or valet. It is necessary, therefore, in order to live respectably, that the professor undertake extraneous work, such as that of a consulting engineer, chemist, or electrician, otherwise he may find it necessary to proceed to that most objectionable practice of frequenting the Patent Office. We strongly hold that a professor should eschew that modern attraction—that working as he does with public funds, directing as he does the minds and hands of students, it is, to say the least, scarcely honest to go with the results of such work to the Patent Office. That man is not worthy of the position of professor whose idiosyncracies are not so constituted as to make him feel the great responsibilities of his profession. It is his duty to give his pupils and the world free and exhaustive information as to his discoveries—his privilege is to write and to teach. Unfortunately nowadays the title of professor is taken by many who have no more right to it than they have to the title of duke or prince. By all means let us hasten the time advocated by Professor Rowland, let us restrict the use of the title to those who may legitimately use it, and let us pay them in such a manner that they may be content. It is a singular fact that professors at Oxford or Cambridge do not haunt the Patent Office, that the bad example has come from north of the Tweed, and that it is being followed by far too many. It is well known the professors are not overpaid in Scotland; and although the Scottish Universities can boast of a proud succession of eminent names, it must be remembered that the times are changing, so that classical and metaphysical knowledge is giving place to physical, bringing the student more and more into contact with business and the remuneration obtained in business. The opinion we have expressed is not very general; but we assume this is because professors are not well paid, and are therefore not content. It has been pointed out again and again that if the manufacturers of the country and the country at large benefit by the work of students, it is but fair that an adequate return should be given to the student. We hold very strongly to the opinion that almost if not quite all the professors of physical science are underpaid to an extent that is not generally understood. A good chemist can command a fair income; a first-class chemist—a man among men, among those from whom professors are made—can command a very high salary if he cares to enter the field of applied chemistry. The science of chemistry has done more for the industries of England than any other branch of science. There is hardly a manufacturer of iron or steel but has a special department devoted to the chemistry of the subject, and it may be employs a number of men to make analyses and researches in a certain direction. Professor Rowland certainly opened a wide field of discussion when he referred to the subject of the payment and contentment of professors. There is no class of men so badly paid as those engaged in education. The prizes of the educational profession are few, the work all important. The value of many of the "chairs" in the newer colleges is from £300 to £400 a year, and for this we ask an able man to devote his whole time to the education of the world. The salary is not that of many a foreman in a works.

There is another question we should like to refer to now, as it seems one that is being energetically pushed for solution. It is the adoption of a new unit for horse-power. Let us assume that this question is important, that its solution should

Digitized by Google

not be delayed. Yet we think it possible to be too precipitate. The energy that electricians have to deal with is as yet comparatively small. One of the Atlantic liners develops more energy from its engines than all the electric light apparatus in the world, and it would therefore seem somewhat uncharitable if electricians attempted to force a new standard of horse-power upon engineers. We would suggest that a committee selected by the societies connected with engineering as well as the British Association be requested to report on the subject. Surely our notation and nomenclature are sufficiently mixed already without adding to the confusion. According to the Congress, the horse-power is be one thousand, instead of seven hundred and forty-six watts. Will engineers accept this? If not, we shall have one series of books and papers retaining the old standard and another series following the new standard. The subject cannot be said to have received due consideration, and therefore the acceptation by the Electrical Congress in Philadelphia may be regarded merely as tentative, the real adoption of the standard even by professed electricians awaiting further authoritative recognition. We may further point out that while the adoption of such units as the "ohm," "ampere," "volt," &c., interests electricians only, the alteration from the recognised standard of horse-power has a far wider interest. The one concerns a few score of men at the most; while the other interferes with recognised practice throughout the whole world. The two questions here referred to seem to be the most important mooted at the Congress, and we trust will receive that careful consideration they undoubtedly demand.

CORRESPONDENCE.

COMPOUNDING DYNAMO MACHINES.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: I do not think the practical application of the numerous theories for compounding dynamo machines has been discussed in your pages. The subject is interesting from a scientific point of view, and of the utmost importance commercially, and therefore, with your permission, I will state what I have learnt on the subject, in the hope that my letter may be amplified or corrected by other correspondents.

A well-compounded dynamo running at a fixed speed will keep the E.M.F. at its terminals the same whether the circuit is completed by, say, one lamp or 100 lamps. We may infer from this that the magnetic field in which the armature rotates remains the same under all conditions, and as the E.M.F. at the terminals is constant, the current through the shunt wire is also constant. When the machine is maintaining *one* lamp only, the field must necessarily be due almost wholly to the current through the shunt wire on the field magnets, as the, say, one ampere flowing through the few turns of the series wire can make no appreciable difference; when 100 lamps are in circuit the current through the shunt will remain the same as before, but the current through the series wire will be, say, 100 amperes. In both instances the magnetic field, as a whole, remains the same, and therefore the magnetism caused in the last case by the series wire must be neutralised in some way, no doubt by the field set up by the armature. Is this consistent with high efficiency? I know it is very convenient in practice, but I should be glad if some of your correspondents would give figures to show at what cost the convenience is gained. The latest Edison machines arrived from America are simply shunt wound, and I am not aware that Edison is slow in adopting improvements.

I should also like to be informed if there is any machine actually in the market that will keep the current fairly constant when the external resistance is altered so that a variable number of arc lamps in series may be maintained without increasing or diminishing the candle-power of each lamp.—Yours, &c., L. MILLER.

London, Sept. 20.

[We insert the above letter, not that it refers to a subject that is new, for not only has the subject of "compound machines" been dealt with by Mr. Kapp in our columns, but it is referred to in recent electrical text-books, such, *e.g.*, as that of Professor S. P. Thompson. This letter, however, may show the necessity of keeping abreast of the times by the constant reading of the most recent publications.—ED. *E.*]

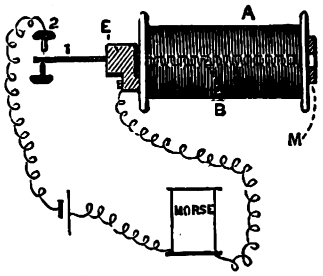
RELAYS.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: I should feel much obliged if you or some of your readers would give me any information on the following subjects:—

The relay, as will be seen by the accompanying diagram, is composed of a bobbin of ordinary copper wire, A; but instead of having a fixed iron core it has a tiny soft iron bar, B, carrying a brass arm with platinum points, pivoted at E. Its movements are quite free within the hollow of the coil, and can be controlled by a movable magnet, M, attached to the end of the bobbin frame. On the passage of a current through the coil the soft iron bar moves, the local circuit is closed by 1 pressing against 2, and the "Morse" is acted upon.

It would seem that by means of this arrangement any change in the resistance of the line, say of a thousand ohms, more or less, does not affect the signals, and no readjustment of the relay is necessary.



What I wish to know is whether the inventor has done well in patenting this instrument, or whether it is another case of "nothing new," &c.

I have a very vague idea of some such arrangement being once used by the late Mr. Varley, but my memory cannot help me further.

My second question relates to the working speed of various instruments. In Hospitalier's *Formulaire Pratique de l'Electricien* for 1884, page 268, it is stated that the "Wheatstone" can only transmit 90 twenty-word messages an hour, whereas the "Baudot," with six keys, can transmit 240 twenty-word messages an hour, the "Hughes" 60, the "Recorder" 25, and so on.

Now, I have always understood that the "Automatic Wheatstone" was capable of much better work than this, and I should like to know if the speed as above given is the result of French or English experiments.

Apologising for trespassing on your space.—Yours, &c.,
20th September, 1884. X.

PROFESSOR FORBES'S REPORT.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: *Re* your leader and Professor Forbes's report on the electric light at the Health Exhibition, I went on Monday last to try to find the two curiosities therein mentioned, viz., "Fülcher" dynamos, and the 1,000 lighter Ferranti, fed by a "large quantity of Siemens's direct current dynamos." I failed to find either.

Professor Forbes also says that the only secondary batteries in regular action are those of the Consolidated Company, but I found some Elwell-Parker cells lighting some furnished rooms

Digitized by Google

in the South Gallery, and the man in charge assured me they had been in regular action since the opening.—Yours, &c.,

September 24th, 1884. OBSERVER.

TREES AND LIGHTNING.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: In your issue of Sept. 6th, on page 397, you republish a very interesting letter, written by Mr. F. G. Heath, with regard to the dangers of lightning. Mr. Heath stated he was surprised to read that a remarkable suggestion had been made, viz., that metal rods should be fastened to the trunks of trees at their bases, to divert the lightning from the killing of human beings who might be taking shelter under them, *for it is well known that the fluids of an animal body are much better conductors of the electric fluid than any of the metals.*" [The italics are mine.]

Question 1. As leading electricians have invariably stated that the metals are the most perfect conductors, and Professor Silvanus Thompson places *the body* in the list of *partial* conductors, it would be rather unfortunate if this apparent contradiction was not cleared up. Is this correct?

Then the writer proceeds to give "a very striking illustration of this fact in the death of Mr. Crosse, who had a gigantic electrical apparatus *and an enormous Leyden jar* [the italics are mine] set up in his house, and he was wont to tap the clouds by means of long conductors. During a terrific thunderstorm he became so deeply absorbed in the great sparks which were going "click," click," into the metal knob of his jar, that he approached a little too close to it, and was killed."

Question 2. In this striking illustration of the supposed better conductivity of the human body than the metals, the writer does not consider the fact that "an enormous Leyden jar" was a kind of storage battery, and that the pent up energy had no means of escape—*no metal conductor to carry it silently to the ground*—but a human body in proximity. Is this correct?—Yours, &c., S. E. K.

AN ELECTRIC LAUNCH.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: I notice in your issue of the 19th a letter referring to an electric launch which I recently tried on the Bolton canal. With reference to a great number of reports which appeared in the various papers of this trial, most of them were grossly inaccurate; for this I am not responsible. Some of them contained statements as to speed, &c., which every one who has had to do with launches knows were simply impossible for a boat that size. But, with regard to the maximum speed obtained, if your correspondent had been on the banks of the canal and had made good use of his understandings he would have been fully convinced. I may say that after the report appeared I found an error in my calculations, but it was so slight that it was not considered worth while to trouble you with the correction.—Yours, &c., W. BANKS.

Bolton, 23rd Sept., 1884.

NON-MAGNETISABLE WATCHES.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: Mr. Volk gives a good idea in his letter of last week as to a method of making a non-magnetisable watch. I met an officer of the American war ship "Shenandoah" in South America a year or two ago, who had a watch in which all steel was omitted, the spring, screws, &c., being made of a species of phosphor bronze throughout, and he assured me it kept good time. I tested its non-magnetisable properties with great success. If such could be produced in England at a reasonable rate, I am sure they would be eagerly bought.—Yours, &c., A. GRUNDY.

Law Courts, September 24th, 1884.

HEALTH EXHIBITION.—X.

THE ELECTRICALLY ILLUMINATED FOUNTAINS.

The number of visitors to the "Healtheries" has already exceeded the total number that attended the "Fisheries;" so there is every reason to believe that, by the close of the present Exhibition, it will have been visited by a number of persons equal to the population of Greater London, of Holland, or of Belgium. Even the most ardent hygienist or social reformer can hardly suppose that all these masses are attracted by a desire to study the laws of health; what to eat, drink, and avoid; or how best to secure the well-being of themselves and their fellow men. A certain percentage of such there is no doubt, but the great majority has not yet attained so high a standard. No, the attraction has been a magnetic, or, rather, an electrical one. The people of London have now got a place, brilliantly lighted, where, after business hours, they can instruct themselves and get new ideas, perhaps; but, at any rate, have the senses of seeing and hearing, to say nothing of tasting, gratified in a rational manner, and see many a thing of beauty which shall be a joy for ever.

There can be little doubt that one of the principal, if not indeed the principal, attraction of the present show is the perfectly unique display of fountains, in conjunction with the electric light, devised by that potent water sprite, Colonel Sir Francis Bolton, and carried out and worked under his personal superintendence. Through his kindness we have had an opportunity of a "peep behind the scenes," and of seeing how the whole thing is done.

We were first put in charge of Fred. Phillips, the colonel's coxswain or right-hand man, who, from the specially constructed house or kiosque near the lake, had us rowed over to the island in a little dinghy made of Willesden waterproof cloth. Access to the chamber, 22ft. square and 4ft. 6in. high, which is half under water, is gained by clambering through a narrow horizontal opening scarcely more than a foot high. To those who have been admitted to the hidden mysteries known as "behind" in a theatre, this chamber at once recalls the mazarine, or more properly mezzonine floor, where are worked the traps that launch the beautiful faries into, it may be, "the glittering realms of refulgent light." Here is an apparently inextricable confusion of pipes and electric leads, the latter communicating with five hand-worked lamps arranged in parallel, the carbons of which last half an hour with setting up. The carbons form a slight angle with the horizon, the positive carbon being at the bottom instead of at the top, as usual, so as to get the crater to shine upwards.

Each lamp is of 5,000 candle-power, so as to make sure of carrying all the current generated. This is supplied by a Siemens B2 dynamo, compound shunt wound, giving 420 amperes at 84 volts, placed in the electric lighting annexe, while the current that goes through the lamps is 60 amperes. It is led by a double cable of nineteen No. 12 copper strands, insulated with gutta percha and cross-webbed braiding, which is further protected by a lead pipe for the portion laid in the water between the shore and the lake. In the island, the cable branches off into six cables of nineteen No. 14 strands. Above the lamps are holophotes, such as are used in lighthouses, for directing the rays upwards, and concentrating them on the water jets. Above the holophotes are frames with variously coloured glasses sliding in them, for producing those beautiful "effects" which are so much admired; and above all are plates of stout plain glass, for excluding the water as it falls down with a splash. Three incandescent lamps in the kiosque (not chamber on the island) are worked off the same circuit. The lamps are managed by Mr. Urquhart, Sir Francis Bolton's principal assistant for the electrical portion. The wires were laid under the direction of Mr. G. Schülz, assistant engineer of the electrical department, of course under the general superintendence of Mr. W. D. Gooch, engineer in charge.

In the chamber on the island is a sixth lamp for dissolving-view apparatus, which throws pictures on a water screen, at the back of the basin in front of the Prince Consort monument. The water rises from a slightly curved pipe, through small transverse slots sawn in its upper surface, alternately on

Digitized by Google

either side of the centre line. The dissolving-view apparatus is, however, but little used now, as the varied effects produced by the fountains, combined with the electric light, are sufficient to last out the half hour to which the display is limited.

This lamp and six of 1,500 candle-power for lighting up the cascades from the water columns, now seldom used, with aluminium shields at the back for reflecting the light, are all supplied with current from the same dynamo as the five 5,000-candle lamps in the chamber.

The water for the fountains is laid on by the West Middlesex Company, through one 12in. and three 8in. Tyler meters, with a pressure due to a maximum head of 160ft. and average of 150ft. The pipes were laid by Messrs. Simpson and Co., of the Grosvenor-road Engine Works, and the ornamental flower jets supplied and fixed by Baskerville and Co. There are five principal cocks and 22 valves, besides the centre one for causing the jets to jump. There are three rings of jets in the basin, surrounding the central jet, which attains a height of about 120ft., and the four jets round it about 60ft.

But an electric call resounds through the chamber from a telegraph apparatus, made by Archbutt, the current of which, supplied by a powerful Lane battery, is sent through two wires (one for return), from the clock tower. This announces that Sir Francis is in the tower, and that in five minutes the show will begin. Then come, in succession, the signals "Stand by," "On centre lamp," "On four side lamps," "On centre jet," then "On side jets," then, it may be, "On centre ring," or "On the four convolvulus," and then, perhaps "Jump centre jet" or "Jump side jets." These words of command are also varied by orders to put on the differently coloured glasses over the lamps, in constantly varying combinations. There is a regular programme of changes; but it is rarely adhered to, as the water sprite is constantly devising new effects and combinations, each one more beautiful than the last. Besides, the not knowing what signal may come next has the effect of keeping the men up to the mark; and it is surprising with what rapidity each command is carried out.

With five or six electric lamps, and six men working, in a perfectly closed chamber of the dimensions given above, to say nothing of interlopers like ourselves, it may be supposed that the temperature and the atmosphere soon became unbearable. In the early days of the illuminated fountains the thermometer stood at 110 Fahr., and sometimes attained 120. But Mr. F. H. Smith has put in three of his automatic syphon ventilators, of 6in. internal diameter, each of which reduces the temperature by 10 degrees. On the night of our visit the external temperature was 78 degrees, that of the chamber before commencing the display 70 degrees, and at the end 80 degrees. The action of the ventilator depends on the effect of a current of warm vitiated air, ascending, simultaneously inducing a current of cold air to flow in to take the place of that which has been displaced.

During the second display we mount the clock tower, whence is obtained the best view possible of the fountains. Here is Sir Francis, *en costume de guerre*, who gives the order, "Umbrella up sharp at the half hour." The "umbrella" is the covering of red tammy that is hoisted up to dim the brilliancy of Edmunds' mast light, so that it may not interfere with the light specially thrown on the fountains. The display begins; and the Colonel, looking out through a peep hole, with his telegraph before him, watches the effect produced by the various combinations of jets and coloured lights. No sooner, apparently, does he give the signal, than the change is made. But other effects are worked directly from the clock tower. Here are two stationary lamps of 2,000 candle-power, with lenses for directing rays on to the fountains; and above, a Siemens projector of the fifth order, of 6in. focus, for following up the jets when they are "jumping." There are also two other lamps in "crows' nests," one on either side of the clock tower, and at some distance off, for throwing rays diagonally, but these are now rarely used.

The two fixed lamps in the clock tower are in the general Brush circuit, which maintains 24 lamps about the buildings and grounds; and the current for the projector and the two lamps in the crows' nests is supplied through a separate circuit from a Bürgin dynamo made by Crompton.

This display of electrically illuminated fountains was at first given only on Wednesday and Saturday evenings; then Monday was added. Now they are shown on every evening except Tuesday, and such is their popularity that they will henceforth be shown every night until the close of the Exhibition. On the occasion of the hospital *fête* the display lasted three hours and a quarter. Notwithstanding this immense "run," there has not been a single hitch in working; and not a joint in the pipes has yielded, although the pressure is so great. Certainly the fountains at the Crystal Palace, at Versailles, Saint-Cloud, Baden Baden, and Wiesbaden are larger, more elaborate, and more magnificent than those at the Health Exhibition; but they have not that special charm due to the peculiar method of illumination devised by Sir Francis Bolton. Then, again, we know that there was a fountain at the old Panopticon in Leicester-square, on the site of the present Alhambra, that was illuminated by the lime light reflected from above; and fountains have been illuminated by rays from the lime or electric light projected upon them through coloured glasses for many years past, but never before have such beautiful and varied effects been produced; and the question arises, What greater attraction can be devised for the succeeding exhibitions, viz., the "Inventories" next year, and the "Colonies" in 1886?

THE BRITISH ASSOCIATION MEETING AT MONTREAL.

The following abstract of a paper on deep sea sounding will be interesting to all engaged in cable work, and they will be able to corroborate the testimony as to the efficiency of Sir W. Thomson's apparatus and its modifications. The paper is entitled

Recent Improvement in Apparatus and Methods for Sounding Ocean Depths.

BY REAR-ADMIRAL DANIEL AMMEN, U.S. NAVY.

The intended laying of the Atlantic telegraph cable some thirty years ago, awakened a general as well as a specific interest in relation to the depths of the sea and in gaining a knowledge of them. Fair results were then obtained by Lieutenant Berryman and others, considering the imperfect appliances known at that time, to sound the relatively small depths of the North Atlantic. Shortly after, the simple and effective device of Lieutenant Brooke, U.S.N., for detaching the sinker, was in use; and also the cup of the late Rear-Admiral B. F. Sands, for securing specimens of the bottom. Able and thoughtful men were these pioneers in sounding the depths of the sea, and substantial results came from their labours, but owing to imperfections of one part or another of the means employed, the operation of sounding was painfully slow, only approximately correct, and at times grave doubts existed as to some of the actual depths obtained.

In the autumn of 1871 scientists and the public were informed of the success of Sir William Thomson in sounding in a depth of 2,700 fathoms in the Bay of Biscay. He used pianoforte wire, Birmingham gauge 22, weighing 14½lb. to the nautical mile, capable of bearing a strain of 230lb. His dynamometer, had three miles in length of this wire been wound upon the drum, would have been still so portable that one man could have carried it with ease. What was accomplished by it excited the hopes of hydrographers, which time has wrought into the most gratifying and undeniable realisation.

Early in 1873 the Navy Department was preparing to make extended soundings in the Pacific Ocean. The Chief of Bureau of Navigation, charged with the execution of this work, asked the advice and assistance of Sir Wm. Thomson. He was good enough to order wire and such apparatus as his personal experience suggested, and to send carefully prepared instruc-

Digitized by Google

tions for effecting the object in view; in short, he did everything within his power to make the use of his apparatus successful. The substitution of it and its effective manipulation by Captain Belknap, United States Navy, marked an era of progress in deep sounding and in possibilities of obtaining true ocean depths as truly as did the steamship mark an advance in traversing wide and stormy seas with celerity and certainty. At that time Belknap commanded the "Tuscarora," and until the sounding apparatus was sent, had only the fitments that belong to vessels of war. Notwithstanding these disadvantages, the results obtained were eminently satisfactory. For specific information the scientist is referred to No. 54 of the Hydrographic Office publications, entitled "Deep-Sea Soundings in the North Pacific Ocean," 1874.

In a letter to the Chief of Bureau of Navigation in July, 1874, difficulties were stated in the use of the apparatus that happily had been overcome by Belknap. Sir William wrote: "I have therefore resolved to alter the apparatus considerably, and am preparing for trials on a new plan which I hope to carry out in the five or six days we shall remain here, and, if possible, shall write you reporting the result." In reply to this note, he was informed with as little delay as possible in relation to the several modifications made by Belknap, which enabled him to get soundings in the most satisfactory manner in depths of more than 4,000 fathoms. Sir William expressed by letter, and publicly, his gratification at the admirable results obtained by Belknap, and his thanks for the specific information sent him relating to the modifications of apparatus that had been made.

In depths of 2,500 fathoms, Belknap found it necessary to make several additional revolutions of the drum by hand, on the sinker striking the bottom, to prevent jerks and strains on the wire which otherwise would have occurred from the rolling of the ship. This necessity was due to the almost instantaneous ceasing of the drum to revolve on the sinker touching the bottom. He reported his soundings at this depth as probably more accurate than many casts in depths of 100 fathoms with an ordinary lead and line. He added: "I expect to accomplish all the work with it (Sir William Thomson's apparatus) which the department has assigned me, and, if I succeed, no greater compliment could be paid to the genius of the inventor."

The winding up of miles of wire on a light drum gave a cumulative pressure on the original apparatus in deep soundings such as to make a continuous system of repair necessary, and finally the substitution of steel drums in the naval service.

To fully appreciate the advance made through the use of this apparatus, it is necessary to bear in mind the tons of rope required to reach depths of four or five miles, and its rapid deterioration from use, the cumbrous apparatus, the slowness of the process even under the most favourable conditions, and what is of greater import, the uncertainty as to the actual depth sounded, arising in part from the under currents of the ocean carrying great bights of rope in one or more directions, and in part from the very small proportion the weight of the sinker must bear to the hemp line, but in a more marked degree from the "stretch" of the rope under tension, and the gradual shortening of it as soon as the sinker reached the bottom.

The report of the Secretary of the Navy for 1874, p. 61, discusses the advantages gained by the use of wire as follows:—The small amount of weight and space required for the apparatus; the large weight of the sinker relatively with the weight of the wire necessary even in sounding the greatest depths, and the very little surface friction of wire in its descent. Miles of wire have very little "stretch" at ordinary tension, and hemp line a great deal, from which, in the first case, the indications of the dynanometer would be almost instantaneous, and in the second would be obscure and quite uncertain as to the exact depth and moment when the sinker reached the bottom. Other advantages are the ease with which the wire is preserved from deterioration. It is stated further, "The problem of measuring the exact depths of the ocean and bringing up parts of the soil from their beds may now be regarded as solved."

The deepest sounding known was taken by Belknap off the east coast of Japan, 4,655 fathoms, a little more than 5¼ statute miles in depth. He took 304 soundings of 1,000 fathoms or upwards, mean time of descent for the first 1,000 fathoms, 10min. 6sec.; 161 of 2,000 fathoms or upwards, time of descent in the second thousand, 11min. 36sec.; 38 of 3,000 or upwards, time of descent for the third thousand, 12min. 40sec.; 9 of 4,000 fathoms or upwards, time of descent for the fourth thousand, 15min. 54sec. The rate of reeling in by hand was much slower than now attained by the use of steam power, yet it was surprisingly rapid and easy in execution in comparison with the reeling in of hemp line.

In the great depths off the east coast of Japan, with the strong currents, Belknap's appliances were in fact taxed beyond a perfectly satisfactory execution, the wire having parted on one occasion at a depth of 4,643 fathoms, before reaching the bottom, and again in reeling in, after sounding in a depth of 5¼ statute miles. Larger wire and heavier apparatus can develop beyond a doubt the depths called by the Germans the "Tuscarora Deep." As now supposed from the soundings taken, this deep water lies at a mean distance of 120 miles from and parallel to a line drawn from the most northerly Cape of Niphon and the most northerly Kurile Island. This is a general direction of N.E. ½ N. It appears to be at least 250 miles in length, and is probably much longer. Captain Belknap justly says that these extraordinary depths contiguous to a region of elevations afford a field of operations of great interest to the hydrographer.

The soundings made by Belknap comprise an arc of a great circle between the northern part of the Island of Niphon, the Aleutian Islands, and Puget Sound; another line between San Diego, Calvia, the Sandwich Islands, and the Bay of Yokohama; and a development of the true ocean bed from Puget Sound to San Diego. They reveal a dozen or more submerged elevations, veritable mountains "full many a fathom deep."

In fact, these soundings furnish the first extended and undeniable development of extraordinary and abrupt inequalities in the depths of the sea far away from the land. We owe this to the inventive genius of Sir William Thomson, and to the professional capacity of Captain Belknap, who not only knew how to make the best use of what he was furnished with, but also had the capacity to cure defects in the apparatus, such as they were. In depths of 3,000 fathoms he used a detachable sinker of 55lb. In greater depths he supplemented this with 20lb. to 30lb. of lead. In order to secure specimens of the bottom in larger quantity, Belknap designed several cups, one of which is now unsurpassed for efficiency by whatever modification or other design, as it did its work perfectly.

Although at the time these soundings with wire were determined on the superintendent of the Coast Survey of the United States hardly hoped a favourable result from the use of wire, as it had not been adopted by the "Challenger," which had been fitted out for scientific investigation some months before, so able a scientist was not slow to adopt what Belknap had shown was so admirable. In Sigsbee's "Deep-sea Sounding and Dredging," published by the Coast Survey, Washington, 1880, we find, chapter 1:—"In August, 1874, the 'Blake,' Commander John A. Howell, U.S.N., was provided with one of Sir William Thomson's sounding machines for wire." Commander Sigsbee in the following months made modifications in the apparatus, giving additional facility and rapidity of execution in sounding, but nothing could be added to the accuracy of the results that had already been obtained by Sir William and Belknap.

In the soundings of the Coast Survey, executed by Sigsbee, Bartlett, Tanner and others, we have a veritable revelation in the contours and depths of our coasts. They have brought to our knowledge the wonderful cleft in the crust of the earth on the line of the Hudson River extended 100 miles beyond Sandy Hook. Scarcely less interesting, but not so startling, are the plaster casts of the Gulf of Mexico, and of the Carribean Sea. It is a grateful duty to indicate to whom honour is due that the depths of seas are no longer an unrevealed and unfathomable mystery; that much is now known, and that

Digitized by Google

ocean depths in all navigable seas will ere long be placed on maps with far more accuracy than are the heights of mountains above the level of the sea.

Dust.

In his evening lecture before the British Association, Professor Lodge performed a number of experiments, electrical and otherwise. The following is a short description of these experiments:—The first experiment was one of Aitken's, in a tube described by Tyndall as optically empty. This tube had been exhausted of ordinary air, and then air had been allowed to filter quickly into it, passing through tightly-packed cotton wool, which was moistened with glycerine, then through dry cotton wool, and lastly through water. This tube was placed opposite a lantern containing an electric light, and on the room being put into partial darkness, and the beam of light being turned on to the tube so as to pass through it, although the light was seen beyond the tube, the tube itself was in comparative darkness, as the dust-free air would not exhibit the light. Clouds are formed of condensed vapour of water with dust, and not simply of vapour. He fully explained the formation of clouds and of vapour, after which he named the methods of removing dust from the air, as follows: (1) Filtering through tightly-packed cotton wool; (2) allowing it to settle; (3) condensing vapour in it several times; (4) calcining it; (5) electrifying it.

The second experiment was to explain this—that when fine particles of dust were introduced into the same tube and condensation being then caused to take place, the necessary dust particles or nuclei were introduced by the heating of a fine piece of platinum wire, which did not show any diminution in the finest scales; and yet it must do so, as plenty of dust was present. After the wire had been heated, the condenser was then applied, when the tube at once appeared full of mist, as there were plenty of nuclei for the globule to form round.

The next experiment the lecturer said was a childish one to illustrate the action of nuclei in condensation, and better understood by children than grown-up people; it was simply writing on glass which was made visible by breathing on the glass. This was due to the fact that on the surface of the glass were particles of dust; these were partially cleared by the scraping of the pencil or finger, consequently the condensed vapour settled unevenly. This was shown by placing a piece of glass so that it was shown on the lantern screen, and on the lecturer writing and then breathing on it it was very apparent, even the globules being apparent.

Turning to fog, such as was seen about the Straits of Belleisle, which made icebergs so dangerous, the electric light was powerless to penetrate it. But if the electricity were discharged from the masthead on a small scale it would coagulate it into globules, which would fall as rain, the effect being somewhat similar to that of oil on water.

The fourth experiment, to show that heat dissipates the small particles, a beam of light was turned on from the electric lantern through a magnifying glass; the dust was easily seen, but on a Bunsen burner being placed underneath, the dust disappeared, and a black space appeared. That this was not smoke was proved by a turpentine lamp being placed underneath, when the smoke appeared to be white instead of black.

The lecturer referred to a diagram showing the circle of clear air round an electric wire, which the dust-particles seemed to avoid.

Taking a bell glass, Professor Lodge placed under it two lamps, and said that supposing one to be a vessel of hot water and the other of ice, if the bell jar was filled with smoke, after an interval of time the smoke would be found deposited on the cold vessel but driven off the warm one.

If a piece of crystal were suspended in a vessel full of smoke, and then a beam of light were directed upon it and it became electrified, the smoke would solidify in a brush-like form all round this crystal, exactly as iron filings did round a magnet. To illustrate this, a bar of iron was magnetised and iron nails at once became attached to each other and to each end, and it was exactly the same way in the case of smoke round an electrified crystal.

One way of dissipating fog was illustrated, but Professor Lodge explained that he had brought two large, specially made globes, and having got them successfully through the Custom House at Quebec they were brought up to Montreal. On unpacking, however, one was found to be broken. The other was carefully put into its position and the experiment tried. Everything went on right, but as they turned to leave it, the globe broke to pieces; consequently the experiment had to be tried with a less satisfactory globe, and was probably hardly so successful. The globe in question was placed on a framework, with the open mouth downwards; projecting into it was a pointed wire connected with a plate electrical machine. Magnesium wire was burnt in the globe until it was filled with a dense white smoke. The current of electricity was then turned on, when the smoke was seen to be settling in streamers on the points of the wire, then to be crystallising or solidifying into filaments all through the globe and settling in a similar way on the sides. In conclusion, to alter the familiar adage, the best advice to young investigators proved to be: "Stick to pure science, and applications will take care of themselves." And those who devoted themselves to scientific pursuits would find themselves amply repaid for their labour and trouble.

PHILADELPHIA ELECTRICAL CONGRESS.

On the first day of the meeting of this Congress nearly all the seats in the hall were occupied, many of the members of the British and American Associations for the Advancement of Science being present. The meeting was called to order by Professor Simon Newcomb, who, in briefly announcing the objects of the Conference, remarked that it was only in consequence of the reduction of electricity to mathematical laws that it had become possible to make it of such great practical use.

The President of the Conference, Professor H. A. Rowland, of Johns Hopkins University, read an elaborate review of the progress made in electrical science, especially during the last three hundred years. He said it was only after the invention of the Leyden jar that the idea of forming a current of electricity occurred to man. Two hundred and twenty years of study were necessary before the telegraph was possible. "We are still but children, studying the A, B, C of electricity," he said. "Electricity cannot exist without matter. When we know what matter is we will know what electricity is and what magnetism is." He favoured the adoption of international standards for the measurement of electricity.

"To-day," he continued, "our country, by its liberal patent laws, encourages applied science. We point to our inventions with pride, and our machinery in many of the arts is not surpassed. But in the cultivation of the pure sciences we are but children in the eyes of the world. Our country has now attained wealth, and this wealth should partly go in this direction. We have attained an honourable position in applied science, and now let us give back to the world what we have received in the shape of pure science. Thus shall we no longer be dependent, but shall earn our own science as well as inventions.

"Let physical laboratories arise; let men of genius be placed at their head, and, best of all, let them be encouraged to pursue their work by the sympathy of those around them. Let the professors be given a liberal salary, so that men of talent may be contented. Let technical schools also be founded, and let them train men to carry forward the great work of applied science. Let them not be machines to grind out graduates by the thousand, irrespective of quality, but let each one be trained in theoretical science, leaving most of his practical science to be learned afterward, avoiding, however, over-training. Life is too short for one man to know everything; but it is not too short to know more than is taught in

Digitized by Google

most of our technical schools. It is not telegraph operators, but electrical engineers that the future demands."

Sir William Thomson, Vice-President of the Conference, made an address, in which he said that one of the most important subjects to be taken up by the Conference was the foundation of a system of electrical measurements.

"We want instruments," he said, "that will be as quick and convenient as fish or sugar scales." He spoke of the self-sacrificing spirit of such scientists as Faraday and Henry, who devoted their time to scientific study, letting others profit by the application of their discoveries to practical use. The two-fold purpose of this Conference, he said, was to promote the application of electrical science to the wants of man, and to enable the investigators assembled to get the benefit of one another's observations and experience.

President Rowland announced that the afternoon's programme would begin with the discussion of "The Work of the United States Signal Office in Relation to Electrical Observations." Professor Cleveland Abbe and Lieutenant James Allen, both of the Signal service, opened the discussion. The subject of "The Necessity for a National Bureau of Standards, Including all Electrical Standards," was opened by Professor M. B. Snyder, of this city. The other topics were "The Adoption of an International System of Electrical Units" and "The Theory of Dynamo-electric Machines."

The second day's session of the Conference was held in the Annexe of the Exhibition. The meeting was called to order by the President, Professor Rowland, who introduced Professor Cleveland Abbe, of the United States Signal Service, who delivered an interesting address on the "Work of the United States Signal Service in Relation to Earth Currents and Atmospheric Electricity." He referred to the almost total neglect of the subject previous to the years 1880 and 1881. In those years it became necessary, he said, to train a special set of observers, who were to accompany the Greely expedition and make observations on the electrical and magnetic phenomena of the far North. Professors Trowbridge and Rowland, who were selected for this work, had afterwards continued their instructions to other chosen members of the Signal Service Corps. It was hoped to gradually extend the number of stations where electrical phenomena might be properly observed when the meeting of the International Conference of Electricians was held in Paris. At this conference the co-operation of the various Governments in this very line of work was asked, and the resolutions transmitted to our State Department at Washington, and by them to the War Department, had come to the Signal Service as orders, and hence a series of questions had been prepared and transmitted to practical electrical engineers all over the country in order that the extent of private co-operation with the Government efforts might be known. Professor Abbe had also been instructed to draw the attention of this Conference to the questions. He moved that a committee be appointed to consider the questions, and with instructions to report to the United States Electrical Commission in three months' time.

After some discussion the motion was adopted.

The President then introduced Professor John Trowbridge, of Harvard College, who opened the discussion on the adoption of the International Electric Standards. He read a letter from the Department of State to the Electrical Commission, enclosing the resolutions passed by the International Conference at Paris, asking the various Governments to legalise the measures of force as a standard in their several domains.

These resolutions fix the legal ohm as the resistance offered by a column of mercury of a cross section of one square millimetre and a length of one hundred and six centimetres at the temperature of melting water. The ampere is represented by one divided by ten in the C.G.S. system. The volt is the electromotive force which sustains the current of one ampere in a conductor whose resistance is equal to one ohm.

The next resolution was in reference to the gathering of statistics in relation to atmospheric and terrestrial electrical disturbance.

The final resolution fixes the unit of each simple light as the quantity of light of the same character emitted from a surface of one square centimetre of melting platinum at the temperature of solidification.

Professor Trowbridge submitted these resolutions to the Conference, suggesting that they be considered separately.

Professor Sir William Thomson, as one of the Paris conferees, explained how the length of the standard ohm came to be established at 106 centimetres. He stated that it was his impression that a majority of the conferees believed that the actual length of the conductor should be more accurately 106·2 centimetres, but that as there was quite a difference of opinion, amounting to three or four millimetres, it was the opinion of the Conference that the measure should be fixed at 106, as the nearest whole number, and that when observations should be more extended, and the value of the ohm definitely fixed, the length could then be altered. In the meantime, he urged the adoption of the number 106 as the means of unifying scientific work. He asked Professor Rowland to give the Conference the results of his experimentation, which he had been conducting to determine the true length of the ohm.

Professor Rowland referred the Conference to his colleague, Professor A. L. Kimball, of Baltimore, who gave these results as far as they had gone, as follows:—One British Association ohm was equal to ·9864 of the accurate ohm, and this figure must be within one three-thousandth of accuracy. The specific resistance of mercury was ·9539 in British Association units, and hence the accurate ohm should be a column of mercury of one square millimetre in section and 106·278 centimetres in length.

The motion that the Commission be directed to take the proper steps to legalise the ohm adopted at the Paris conference in the United States was adopted. Similar motions with respect to the resolution regarding the volt and the ampere were also adopted.

The resolutions concerning the collection of statistics with regard to atmospheric electricity were, on motion, referred to the same committee to which the former resolution on the same subject was referred, with instructions to render a preliminary report to the Conference, and a final report to the Electrical Commission.

The resolution with respect to making a new standard unit of light was then considered. Professor Trowbridge explained Siemens's method of studying this unit, and moved that its consideration be referred to a committee, with directions to report to the Electrical Commission. A conferee, who was also one of the examiners of the exhibition, proposed an amendment that the committee be directed to render a preliminary report to the Conference. The resolution and amendment were adopted.

Mr. W. H. Preece, of London, introduced a resolution to appoint a committee to consider the advisability of the substitution of the watt as a measure of dynamic force in the place of the foot-pound or the horse-power. He stated that the watt, since its introduction by the late Professor Siemens, had practically been adopted, but lacked any official confirmation. At the Paris Conference the proposal was negatived, on account of the German opposition to adding more technical terms, and to the fact that there was no "w" in the French language. There are 746 Watts in the present horse-power. It would cause but slight confusion to increase the nominal horse-power so that one horse-power would represent 1,000 Watts. The resolution was agreed to, and this committee was also directed to render a preliminary report to the Conference.

Professor A. Graham Bell, of Washington, called attention to the very bad acoustic properties of the hall. He moved that the chairman be directed to procure better accommodation for the Conference.

Mr. William P. Tatham, president of the Franklin Institute, offered the use of their hall to the Conference.

On motion the Conference accepted the invitation, and on motion of Professor Trowbridge the Conference adjourned. President Rowland announced the order of discussion as follows:—"The Establishment of a National Bureau of Physical Standards," opened by Professor M. B. Snyder; "The Theory of the Dynamo-Electric Machine," discus-

Digitized by Google

sion opened by Professor H. A. Rowland; and "The Electrical Transmission of Energy." He desired it to be understood that the meetings of the Conference are freely open to the public, and that they would hereafter be held in the hall of the Franklin Institute.

The Conference assembled in due course in the lecture room of the Franklin Institute. The Conference was called to order by Professor Rowland. The President announced the committees directed during the previous day's proceedings as follows:—

On the question of the adoption of the unit of light and on the adoption of the watt as a unit of power—Professor Trowbridge, chairman; Messrs. Preece, Cross, Edison, Pickering, Barker, and Heap. On the means of gathering statistics of atmospheric and terrestrial electrical disturbances—Professor Abbe, chairman; Messrs. Allen, Trowbridge, Yates, Preece, Gisborn, and Nipher.

Professor M. B. Snyder, of the Philadelphia Central High School then opened the discussion on the "Establishment of a National Bureau of Physical Standards." After some considerations of the necessity of the legal fixation of standards of a physical measurement, and some reference to the Government work done by the Bureau of Weights and Measures and of the Coast Survey, he stated the requirements for a successful supervision of this important work. He said that the work must of necessity be a Government work to give it sufficient means to determine the scientific questions, and to give force and authority to their determinations.

It would be necessary for the department to provide first for the very best and most scientifically accurate work, and second for furnishing the public with the practical results of that work. He did not think it should be connected with any of the present Departments of the Government, lest its work should be hampered in other directions. It should include both a laboratory and observatory as well as be a centre for the deposition of standard weights, measures, and means of determining every form of power.

Professor W. A. Rogers, of Cambridge, said that there was undoubtedly a need for such an institution as Professor Snyder had suggested, but that it was a debatable question whether the ends would be reached best by founding a new department, enlarging the old bureaus, or depending upon private munificence independent of Government control. He thought that the majority of the conference would agree with him that, in order to gain proper authority, it was necessary that the institution should be under Government control. Its functions, he thought, should be more limited than Professor Snyder had indicated, and should be restricted to the determination and control of units of power only, leaving the questions of dividing or multiplying and of making new standards to private enterprise and investigation.

Professor Hilgard, of the Coast and Geodetic Survey of the United States, did not agree with Professor Snyder as to the advisability of forming an entirely new department. He thought such an institution would paralyse individual enterprise, and be productive of no good result. He was of opinion that the great function of government was to maintain equity and not to define the microscopic divisions of modern science. The United States was already a subscribing nation to the International Bureau of Weights and Measures, and this, he believed, was as far as the Government should at present be asked to go. He mentioned incidentally that he had received intelligence the day before that Great Britain, after long holding out, had also joined the International Bureau. He also referred to the work of the Coast Survey, and stated that they had several times measured base lines of ten miles and over with a smaller error than one one-millionth.

Lieutenant Allen, of the Signal Service, presented some of the work of the Signal Service Bureau of the War Department, in the way of accurate measurement of heat and the pressure of the air. He presented no opinion as to the advisability of a new department of the Government, but merely some of the scientific work done in his own department. He believed that fixed standards, especially of electrical units, was a great desideratum.

Professor Simon Newcomb thoroughly believed in the necessity for the formation of such a department. He pointed out the authoritative character of the Government stamp, and believed that an action had been taken during the closing hours of the last Congress looking to the consolidation of several of the scientific bureaus, that the present was a most favourable time to urge the formation of the department.

Sir William Thomson believed that the United States would find it absolutely necessary to have a bureau of standards much more extensive than that which it now possessed. He called attention to the good work done in England in thermometric observations by the Kew Commission. He was sure that both Governments would soon be compelled to found complete bureaus, and he was anxious that the United States bureau might be founded, and that its good work might serve as another argument for the foundation of a British bureau. Instead of restricting Professor Snyder's idea, he would rather expand it, and establish in every large city an official inspector of weights and measures. He thought that the success of incandescent lighting was now assured; that it was certain before long to become the ordinary house-to-house system, and that hence the determination of the legal volt-ampere would be as important as that of the metre or the yard.

Mr. W. H. Preece said that England was very like America in the general desire of the average citizen to be let alone by legislative restrictions, until the need for Government interference is distinctly felt. It was, consequently, necessary to constantly urge the Government action in questions like this. He hoped that the United States Bureau might be established, because Englishmen, who could be reached in no other way, would have their national pride injured by the sending of English ampere-metres to be verified in the United States.

Professor Houston thought that the establishment of such a bureau would have a most useful effect in familiarising the public with the strange terms of electric measurement.

Professor Snyder moved that a committee of seven be appointed to consider the feasibility and manner of establishing a National Bureau of Physical Standards, and report to the Commission before December 1st. After some informal discussion he withdrew his motion to allow of further discussion.

Professor Abbe, of the U.S. Signal Service, was anxious that the barometer should especially be examined. Mr. N. S. Keith stated that unless the measures of electric force were soon legalised a most complicated question would soon be before the courts to determine in the case of legal difficulty concerning electric lighting.

Additional remarks were made by Professors Wead, J. K. Trowbridge, Abbe, Meyer, Rogers, and Prof. Silvanus P. Thompson, of England.

Professor Abbe moved that the Conference approve of the formation of a National and International Bureau of Physical Standards. Professor Rogers proposed as an amendment that a committee of three be appointed to draw up a resolution which should express, if possible, the opinion of the Conference. After considerable discussion the amended motion was carried, and after another motion had been adopted adding Professor Rowland's name to the committee, the chairman named as the committee Professors Rogers, Newcomb, and Wead.

The Congress then adjourned its third sitting till the following day.

From London to Brighton.—It is stated that the United Telephone Company have arranged to lay a tenth line between London and Brighton, which is to be at work in a week or two. Similar communications will be opened between London and the principal commercial centres.

Western and Brazilian Telegraph Company.—The traffic receipts of this company for the week ending 19th September were £2,875, after deducting the "fifth" of the gross receipts payable to the London Platino-Brazilian Telegraph Company.

Brazilian Submarine Telegraph Company.—The traffic receipts of this company for the week ended 15th inst., amounted to £3,275.

A MAGNETO-ELECTRIC PHENOMENON.

By C. V. BOYS, A.R.S.M., Demonstrator of Physics at the Science Schools, South Kensington*.

Every one is familiar with the effect produced when a copper disc is set to spin in a powerful magnetic field; the currents induced by the motion of the disc act in such a direction as to oppose the motion, which therefore speedily ceases. Faraday observed that if, instead of being set to spin, a disc is merely suspended between the poles of an electro-magnet, it will in general be disturbed whenever the current in the coils of the electro-magnet is made or broken. If it lie with its plane parallel or at right angles to the lines of force, no disturbance will be apparent if the lines of force where they are included by the disc are parallel. But if the plane of the disc makes an angle α with the parallel lines of force, then on making the current in the electro-magnet an impulse is given tending to diminish the angle α, while breaking the current gives an impulse tending to increase the angle α.

Again, if the angle α be 90°, so as to eliminate this twisting effect, no movement will be visible at the making or the breaking in a parallel field; but if the disc be placed in a field with diverging lines of force, in which, of course, the strength diminishes as the lines separate, and if it be placed symmetrically so as to include the greatest number (*i.e.*, with its plane at right angles to those lines passing through its centre), then, on making the current, it will receive an impulse causing it to move parallel to itself along the lines of force towards the weaker part of the field, and at the breaking it will receive an impulse more evident in the opposite direction. If this radiating field is produced between a pointed and a flat pole, the disc will, on making the current, appear to be repelled from, and, on breaking, to be attracted by, the pointed pole. So powerful is this effect that a piece of impure copper, which is strongly magnetic, is repelled from the pointed pole on making, and attracted on breaking, the current, thus appearing at first sight strongly diamagnetic.

Though these impulses must have been observed by most experimentalists, their amount has not been, so far as I am aware, determined in absolute units, nor have they been turned to account for making any measurements. As they seem to afford one of the most convenient methods of determining conductivity and field-intensity, perhaps a short paper on the subject, even though it be incomplete, may be of interest to this society.

The explanation of the motions described will be obvious, but it may be well to give it at length for the sake of arriving at quantitative results. In the first place, let the lines of force be parallel, so that the field is of uniform strength. Let a ring of (small) section s, of specific resistance ρ, and of radius r, be placed in the field, with its plane making an angle α with the lines of force. Let the strength of the field be H units. Then during a small increment of field-intensity dH, in the time dt, a current will be induced in the ring of the strength

$$\frac{rs\sin\alpha}{2\rho}\frac{dH}{dt}.$$

This current in the field H will produce a twisting tendency to increase α with a diminishing, or to diminish α with an increasing field, represented by the couple

$$-\frac{\pi r^3 sH\sin 2\alpha}{4\rho}\frac{dH}{dt}.$$

From this it is clear that the couple varies inversely as the time dt occupied in making any small change of field-intensity dH, but it lasts for the time dt; therefore the momentum acquired by the suspended disc, if free to move, will be independent of the rate at which any small change in the magnetic field may be made, but will depend only on its amount, provided that the time is is not sufficient for the angle α to have perceptibly altered during the change. Since this is true of any element, it is true of all; so the momentum acquired by the ring is a direct measure of any total change in the strength of the field in which it lies, no matter by what law it changes in strength. If at the end of any rapid change the field remains of any strength, the motion of the ring will be rapidly stopped by the well-known damping action, of which I shall have more to say later. If, however, the field sinks to zero, or nearly so, the momentum acquired can be measured and the original intensity determined.

The current induced in the ring will of course react on the field and bend the lines of force in such a manner as to hinder their passing through its edge, that is to delay the change of included field intensity; but the impulse is independent of the time or the manner in which the field changes, so it cannot be effected to any extent by this cause.

Since the impulse given to the disc during any element of time is

$$-\frac{\pi r^3 s\,H\sin 2\alpha}{4\rho}\frac{dH}{dt},$$

the total impulse while H changes between 0 and H will be

$$-\frac{\pi r^3 s\,H^2\sin 2\alpha}{8\rho}.$$

If the moment of inertia of the disc be M, and the torsional value of the supporting wire be T, the angular velocity ω generated will be

$$\omega=-\frac{\pi r^3 s\,H^2\sin 2\alpha}{8\rho M},$$

and the throw of the ring θ will be

$$\theta=-\frac{\pi r^3 s\,H\sin 2\alpha}{8\rho\sqrt{MT}}.$$

The action on a disc may be considered as the sum of the actions on the several elementary rings of which it is composed, for there cannot be any tendency for any part of the currents to cross over the elementary circles. The impulse therefore on a disc of radius r and thickness s will be

$$-\frac{\pi r^4 s\,H^2\sin 2\alpha}{32\rho};$$

and the impulse on a disc of radius r_2 with a concentric hole of radius r_1 will be

$$-\frac{\pi s\,H^2\sin 2\alpha}{32\rho}(r_2^4-r_1^4).$$

Since the moment of inertia of a disc is also proportional to the fourth power and to the thickness, so long as the thickness is small, it will appear that the velocity imparted to a disc of any size or thickness, or to a ring, during a change in a magnetic field will be the same. To what extent a correction should be applied to these results for self-induction between different parts of the disc I am not prepared to say; their calculation would give trouble.

For comparing one field with another, discs or rings of metal may be used; but for absolute measurements, as it would be impossible to measure the exact conductivity of a disc, a coil is preferable. By employing discs of different metals their conductivities can be compared without the trouble of drawing into wire or cutting into long strips.

It will be found that a coil of area A and resistance R will, under a torsion T, experience a throw

$$\theta=-\frac{A^2 H^2\sin 2\alpha}{4R\sqrt{MT}}.$$

If, instead of a disc, a sphere be used, no twisting should be experienced if the conductivity in different directions is the same. If, however, there is a plane of greatest or least conductivity, it should be possible to discover it. Crystallisation or mechanical treatment might give rise to such planes in metals; no definite results could be expected in anything else.

I have referred to the apparent repulsion and attraction of a disc of metal by a pointed pole at the making and breaking of the magnetising current. As the lines from such a pole radiate outwards, they are not normal to the metal except in the middle. On their passage inwards or outwards they give rise to circular currents tending to move each part of the disc

* From the *Philosophical Magazine* for September.

Digitized by Google

normally to the lines of force. There is therefore a longitudinal component away from the point of radiation during an increase in the field, and towards it during a diminution of the field. A closed coil of wire is subject to the same forces. If a coil be made of uncovered copper wire in the form of a double helix with the ends joined together, and if the convolutions are separate so as nowhere to touch one another, the growth of the magnetic field can be watched by placing the coil nearly over one pole. On making the current the field begins to grow, at first quickly and afterwards more slowly. The coil will receive a push and will extend itself. As the push diminishes in amount, owing to the diminishing rate of growth of the magnetic field, the coil will gradually regain its former shape. It might be thought that the slow recoil is simply due to the damping action of the field: but this is not sufficient to account for it, as when the field is fully grown the coil will, on being forcibly drawn out, recover its shape much more quickly. On breaking the magnetising current, the impulse in the opposite direction, being the same as before but lasting for so much shorter a time, is far more evident.

My first experiments were made with a view to determine whether the impulse was proportional to sin 2α when other things remained the same. I therefore cemented a disc of metal (a half-crown) to an ebonite rod carrying a glass index and hung by a torsion-wire of platinum. The glass index travelled over a card divided into degrees; and the wire to which the upper end of the torsion-wire was soldered also carried a pointer, the position of which could, if desired, be read on a divided card. The disc was suspended between two parallel polar faces of iron. The upper index was turned until, on making and breaking the current, the lower index showed no sign of motion. It could thus be placed within a small fraction of a degree, so that α was either 90° or 0°. The lower card was then adjusted, and the upper index turned so that the lower rested successively at 5°, 10°, 15°, &c., up to 90°. The negative impulse on making, and the positive impulse on breaking, the current were observed by the throw of the lower index. These are given in the second and third columns of the following table. In the fourth column is a series of numbers in the proportion of sin 2α, the largest number being made to agree with the observed positive throw.

TABLE I.

Position of rest.	Negative throw.	Positive throw.	Calculated positive throw.
5	1	4·5	4·6
10	2	9	9·1
15	3	13	13·2
20	4·5	17	17·1
25	5	20	20·3
30	6	22·5	23
35	7	24·5	25
40	7·8	26·2	26·2
45	8·8	26·5	26·5
50	8·5	26·2	26·2
55	8·2	24·5	25
60	7·8	22	23
65	7·5	20	20·3
70	6·5	16	17·1
75	5·5	12·5	13·2
80	3·5	9	9·1
85	2	4	4·6

The close agreement of the other numbers shows clearly that, on breaking the circuit, the impulse is truly proportional to sin 2α. Examination shows that the negative impulses, though in reality equal to the others, are apparently much less in amount, that they are not even in proportion, and not only this, but that the corresponding values on either side of 45° are not the same. This want of symmetry is clearly shown by Fig. 1. The discrepancy is due to the fact that the disc is brought to rest by the damping action of the field as well as by the torsion of the wire, and that the damping action is greater as the angle is less, being $::\cos^2 \alpha$.

I thought it would be interesting to determine to what angle the disc would be thrown if the torsion of the wire did not act. I therefore suspended, instead of the disc, the coil used in the absolute experiments by a silk thread, adjusted the lower card by the method of no throw, and brought the index to rest successively over 10°, 20°, 30°, &c., up to 90°. The

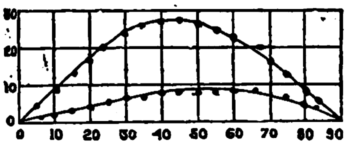

FIG. 1.

index came to rest at the series of positions shown in column 2 of the following table:—

TABLE II.

Pointer fell		Pointer fell	
From	To	From	To
10	3·6	50	18
20	6	60	22
30	10	70	29
40	13	80	39
45	16		

The same results are shown graphically in Fig. 2. It is interesting to note that the curve shown is a natural curve depending on circular functions only. It is independent of the nature of material, such as conductivity, moment of inertia, or of the strength to which the field is made to grow from zero. It is subject to a small error, for I did not destroy the residual magnetism. That the effect of this is appreciable is evident, for in one series of experiments with a disc the throw on making was always from 45° to 33°; but the first time that the direction of the magnetising current was changed the throw was from 45° to 35°, after which it was from 45° to 33°, as before. This diminution at the first reversal was always the same. I found almost the same fall with the half-crown as with the coil, and with one cell as with ten cells. There were slight differences, but not more than draughts from which I did not shield the needle would have accounted for. The lower angle can be read with precision, but the higher angles become difficult to observe as the damping influence diminishes. The position $\alpha = 90°$ is one of instability; for however slight a velocity is given to the disc, it will not be brought to rest for a considerable time, owing to the very minute nature of the squares of the cosines of angles, nearly equal to 90°.

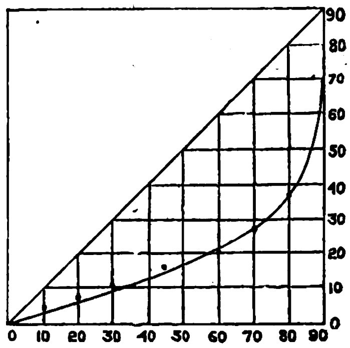

FIG. 2.

The last series of experiments was made with a view to determine whether the strength of field determined by observation of the throw of the disc at breaking agreed with the strength determined by some recognised method. I therefore made a small coil of twelve turns of copper wire of 1·45 centim. radius and with a resistance of 0·085 ohm. The area of the coil was 79·4 square centim. The moment of inertia of coil and index was found by comparison with a cylinder to be 58·1 units, and the torsional value of the sup porting wire to be 17,000 units. The plane of the coil was

Digitized by Google

adjusted by the usual method to zero, and then set to 45deg. The currents from 10, 9, 8, &c., to 1 Grove cells were sent in succession through the coils of the electro-magnet and through a Siemens electro-dynamometer. The following table shows the amounts of the positive and negative impulses, the strengths of the magnetising currents in amperes, and the field-intensities calculated from the positive throws by the formula

$$H^2 = 9311000 \times \text{Throw measured in degrees.}$$

TABLE III.

Number of cells.	Magnetising current in amperes.	Negative throw.	Positive throw.	Calculated field in absolute units.
10	11·85	10·5	27·5	16,000
9	11·2	9	26	15,600
8	10·44	8·2	24·5	15,100
7	9·47	7	22·5	14,500
6	8·63	6	21·3	14,100
5	7·60	4·8	19·2	13,400
4	6·53	3·3	16·5	12,400
3	5·18	2·2	13	11,000
2	3·67	1	8	8,630
1	1·83	0·2	2·8	5,070

The ends of the coil which were soldered together were then unsoldered without disturbing the soldered connection between the torsion wire and one end. The other end was bent so as to dip into a small mercury cup in the axial line, so that a known current, measured by a second electro-dynamometer, could be sent through the coil. During this change no part of the apparatus was moved at all; it was, however, necessary to redetermine the zero position, which was now rather more difficult, for the resistance of the torsion wire was so great in comparison with that of the coil alone, that the throw at any angle was only about one-tenth of what it was before. As before, the current from 10 to 1 cells was sent successively through the coils of the electro-magnet and an electro-dynamometer. The current from a Daniell cell was sent through the suspended coil and measured. In the fourth column of the following table will be found the deflection of the coil due to currents tabulated in columns 2 and 3. In the fifth column is the deflection due to the residual magnetism; and in the sixth column the strength of field in absolute units, calculated from the formula

$$H = \frac{3{\cdot}73 \times \text{deflection in degrees}}{\text{deflecting current in absolute units} \times \cos \delta}.$$

TABLE IV.

Number of cells.	Magnetising current in amperes.	Deflecting current in amperes.	Deflection = δ.	Deflection due to residual magnetism.	Calculated field in absolute units.
10	11·92	·514	65	4	11,200
9	11·05	·530*	64	4	10,260
8	10·52	·502	63	4	10,320
7	9·48	·496	62·5	4	10,150
6	8·63	·480	61·5	4	10,050
5	7·60	·480	60·3	4	9,470
4	6·45	·480	59	4	8,930
3	5·14	·480	57	4	8,120
2	3·67	·480	51·5	4	6,470
1	1·98	·480	40·5	4·5	4,140

* Obviously over-estimated, hence small results.

The residual magnetism was always the same till one cell only had been employed to excite the electro-magnet, when the deflection was clearly greater. This I repeated several times with one and with more than one cell. A deflection of $4\frac{1}{2}°$ was always obtained from one cell, and of 4° from more than one cell. To obtain a still higher residual magnetic effect, I drew the terminal along a fine wire, and gradually diminished the field; by this means I obtained a residual field giving a deflection of 5°·4. The magnetic fields corresponding to the deflections 4, $4\frac{1}{2}$, and 5·4 are 312, 352, and 422 absolute units.

Fig. 3 shows the field intensity measured by the two methods. They do not agree, nor are they quite proportional, nevertheless they are of the same order of magnitude. The discrepancy is greater than would be expected from errors of an experimental kind, even though the apparatus was hastily improvised. Nevertheless the agreement, such as it is, shows that it will be worth while to carry out a series of experiments with the accuracy and care that are needed in physical investigations. This I intend to do as soon as I am able. It will

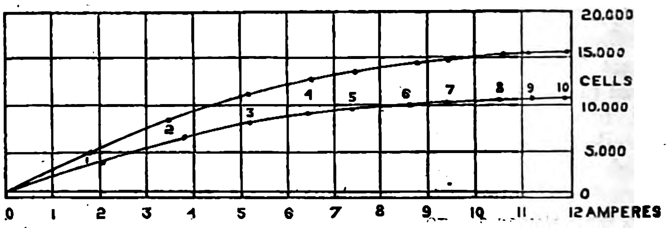

FIG. 3.

then, perhaps, be possible to tell whether this method of determining conductivity or field-intensity is to be relied upon; it certainly, in convenience and simplicity, compares very favourably with any of the usual methods.

NOTES.

THE JABLOCHKOFF COMPANY.—This company's offices are now removed to the factory, No. 36, Albert Embankment, Lambeth, London, S.E.

BRAZILIAN SUBMARINE TELEGRAPH COMPANY.—The traffic receipts of this company for the week ended 26th ult. amounted to £3,356.

ELECTRIC LIGHT AT ROTTERDAM.—It is proposed to install the electric light at the Dutch port of Rotterdam, and maintain it by means of accumulators.

KING'S COLLEGE.—We understand that an evening class in practical physics is to be conducted by Mr. A. P. Trotter during the forthcoming winter session.

ELECTRIC LIGHT ON BOARD STEAMERS.—The Cunard Company's new liners, the "Umbria" and "Etruria," are provided throughout with the incandescent form of the electric light.

ELECTRIC LIFTS.—Electricity is now being largely used in the great towns of America for working lifts, the current being either supplied from a central station, or from a dynamo on the premises.

TELEGRAPH REVENUE.—The telegraph is one of the only three items of revenue which have yielded an increase during the financial half year just ended; but the sum is very small, being only £5,000.

COMMUNICATION WITH CHINA.—Owing to the stoppage of the Saigon and Hong Kong cable, the lines of the Eastern Telegraph Company and of the Indo-European Telegraph Company to China are interrupted.

ANTWERP EXHIBITION, 1885.—The cost of motive power for driving machinery has been fixed at 20 centimes per French horse-power (0·986 horse-power), which is as nearly as possible 2d. per horse-power per hour.

ELECTRIC LIGHT AT THE ODESSA EXHIBITION.—An exhibition of Russian and foreign products was opened at Odessa last week. In the evening, the numerous pavilions and *parterres* are illuminated by the electric light.

FOOCHOW.—The Post Office notify that telegrams may be again accepted for Foochow, at the sender's risk, to be forwarded from Sharp Peak, the place where the cable lands, by steam launch which runs daily to Foochow.

ELECTRIC LIGHT AT DUNDEE.—The rooms in which the Fine-Arts Society of Dundee is to hold its Exhibition are to be illuminated electrically by the Anglo-American Brush Electric Light Company, with a No. 8 Brush arc machine and lamps.

WESTERN AND BRAZILIAN TELEGRAPH COMPANY.—The traffic receipts of this company for the week ending 26th September, were £2,688, after deducting the "fifth" of the gross receipts payable to the London Platino-Brazilian Telegraph Company.

ELECTRIC LIGHT IN HUNGARY.—Last night, says the *Standard's* Pesth correspondent of Tuesday, the town of Temesvár was, for the first time, lighted with the electric light. A complete installation on the Brush system has been laid down for the permanent illumination of the place.

THE DISCOVERERS OF ELECTRO-MAGNETISM.—Our contemporary *Cosmos*, a new and enlarged series of which has just been commenced, complains that Lord Rayleigh, President of the Montreal Congress of the British Association, omitted the name of Ampère from the discoverers of electro-magnetism.

ELECTRIC LIGHT IN THE EAST RIDING.—The Brush Company have received instructions from the Driffield and East Riding Oil Cake Company to light their oil works. The plant to be employed consists of a D2 Victoria incandescent dynamo, 130 Victoria incandescent lamps, and all the necessary cable, switches, and other plant.

THE CUBA SUBMARINE TELEGRAPH COMPANY.—The number of messages passing over the lines of this company during the month of September was 2,644, estimated to produce £2,150, against 2,656 messages, producing £2,515 in the corresponding month of last year. The traffic receipts for the month of June, estimated at £3,150, realised £3,168.

ELECTRIC LIGHT IN FINLAND.—The Anglo-American Brush Company has received an order from Finland for the necessary plant to light the theatre at the town of Bjorneborg. The plant to be employed will consist of a D 2 Victoria compound-wound machine, 130 Victoria incandescent lamps, and the necessary cable, switches, cut-outs, and fittings.

THE ELECTRICAL RESISTANCE OF ALUMINIUM.—The electrical resistance of aluminium commercially pure is 1·96 that of pure copper, while the addition of a small quantity of aluminium to copper greatly increases its resistance, both electrical and mechanical. For wires of equal length and weight, the resistance of aluminium is a little less than that of copper.

UNIFORM MERIDIAN.—The International Prime Meridian Conference was opened at Washington on Wednesday. Forty delegates were present, representing twenty-two countries, and were welcomed by Mr. Frelinghuysen. Count Lewenhaupt, the Swedish Minister, acted as temporary chairman. Admiral Rodgers, of the United States navy, was elected permanent chairman.

FRENCH POSTAL TELEGRAPH REVENUE.—The receipts from the telegraphic service during the first six months of the present year were 13,150,600f., or 907,400f. less than the estimate for that period. A similar and larger falling off has occurred in the French Post Office receipts. This coincides with the state of things in Lower Austria, which we recorded last week.

REVOLUTION CAUSED BY THE ELECTRIC TELEGRAPH.—In a recent article on scientific discoveries, *The Times*, after commenting on the change in trade brought about by railways, says that a revolution has followed, much more quickly, through the extension of the electric telegraph to every capital of importance in the world, and to nearly all the minor centres of trade and production.

THE BENNETT-MACKAY CABLE.—The "Faraday" is reported to have commenced laying the last section of the second Bennett-Mackay cable, making steady progress in face of unfavourable weather, and being likely to finish her task very shortly if all goes well. We learn that, after completing this work, the "Faraday" will proceed to lay the connecting cable from Canso, Nova Scotia, to New York City.

ELECTRIC LIGHT IN PARIS.—Hachette et Cie, the large firm of publishers and booksellers in Paris, with branch in London, have had their folding and binding departments in the Rue Stanislas lighted by incandescent lamps for two years

Digitized by Google

past. So satisfied are they with the results, that they have now arranged to extend the electric light to the whole of their establishment, and have ordered 350 Edison lamps.

ELECTRIC LIGHT REGULATOR.—M. Roussy, proprietor of the Gilamont Mills, near Vevey, which have been illuminated by the electric light on the Edison system upwards of two years, has invented a governor, which permits of regulating, at pleasure, the intensity of incandescent lamps. The contrivance, which is attached to the lamp holder, is said to be remarkably simple and easy to work, while scarcely increasing the first cost of the lamp.

POPULAR LECTURES.—A course of weekly lectures, accompanied by class teaching, will he held during the coming session (October-December, 1884) in connection with the London Society for the Extension of University Teaching, as under:—Electricity, at Highbury; Some Physical Properties of Air and Water, at Whitechapel. The lecturer will be J. W. Waghorn, D.Sc., R.N., Instructor in Physics at the Royal Naval College, Greenwich.

VOLUNTEER TELEGRAPHISTS FOR EGYPT.—We are informed that every one of the 50 Post Office telegraphists incorporated in the Army Reser ve volunteered their services for Egypt—a fact which is highly creditable to the spirit of the men and to the corps they honourably represent. The twelve men finally selected sailed in the "Deccan" last week. Five came from the Central Station, one from the Metropolitan District, one from the London Telegraph School, and the remaining five from provincial offices.

DIRECT UNITED STATES CABLE COMPANY.—This company notifies that the £100,000 six per cent. debenture loan of the company, falling due on the 15th October next, will be repaid on and after that date at the Consolidated Bank (Limited), 52, Threadneedle-street, London, E.C., together with the interest then due. The debentures, which will cease to carry interest from 15th October next, must, with coupons attached, be left for examination at the Consolidated Bank three clear days prior to application for payment.

THE DOVER-CALAIS CABLE.—In the splendid armoury of Turin, amongst war-like implements of all sorts and of all ages, surrounded by warriors armed *cap-à-pie* on prancing steeds (stuffed), there is to be seen, in a glass case, a piece of the old Dover-Calais cable which had been presented to the King of Italy years ago. It is carefully labelled, and its weight is recorded in a corner of the label. Probably the donor or the museum authorities thought that the merits of the sample, about a foot long, were commensurate with its weight.

MORE BALLOON STEERING TRIALS.—The *St. Petersburg Herald* states that a formidable Russian rival to the experimental balloon at Meudon is in the field. Captain Kasztowitz is building at Okhta a large cigar-shaped balloon, 200ft. in length and 80ft. in height, including the car, which he has furnished with a screw and also with wings. He considers that he will be able to take a crew of 16 men and 250lb. of ballast at the rate of 40 German miles an hour. The experimental trip is expected to take place early next month.

CHESS BY TELEPHONE.—There have already been international chess matches played by means of the telegraph; and it is probable that the moves were communicated by a concealed player to the famous chess-playing automaton, Ajeeb, by means of the electric current. Now, however, we learn that an eight-board chess match was played on Monday night between the Bradford and Wakefield clubs. The games were completed without delay, in four hours, by sixteen players, the moves being transmitted by telephone along twenty-five miles of wire.

WEST INDIA AND PANAMA TELEGRAPH COMPANY.—At a meeting of the directors held on Wednesday last it was decided, subject to final audit, to place £10,000 to reserve, and to recommend to the shareholders at the approaching meeting that a dividend of 6s. per share be declared on account of arrears of dividends on the first preference shares. The estimated traffic receipts of this company for the half month ended the 30th September were £1,987, as compared with £2,299 during the corresponding period of 1883. The June receipts, estimated at £6,066, realised £6,196.

DEAL.—The Mayor and Corporation of Deal, a small but growing seaside resort on the east coast of Kent, have wisely decided to adopt the electric light both for public and private lighting. The Deal and Walmer Electric Light Company (Limited) have decided on working the light on very economic principles to ensure its being a success. Two of the principal items in the cost are eliminated, for the manager, Mr. H. G. Frost, and the secretary, Mr. Carterfield, have decided not to accept any remuneration for the offices they fill for the first twelve months at least; and, as the manager is a thoroughly practical man, we feel sure that nothing but success can ensue.

A NEW FORM OF MAGNET.—A fairly powerful magnet is credited to Signor B. Ricco, of Palermo, who surrounds a soft iron core with a long band of sheet iron, having oiled paper between the coils for insulation. One pole is put in connection with the core, to which the internal extremity of the sheet iron band is soldered; and the other pole with the external extremity of the band. The electric current magnetises not only the core, but also each coil of the band, which thus acts both as conductor and as magnetic substance, thereby condensing the lines of force and causing a great concentration of power. Magnets of this form have been used to our knowledge for several years past in this country.

ELECTRIC LIGHT IN THE NAVY.—We learn that the Anglo-American Brush Corporation have received an order from the Admiralty to fit out H.M. ss. "Reindeer," "Cleopatra," and "Linnet," with electric light apparatus. The plant to be employed on each vessel will consist of a D2 Victoria compound-wound incandescent machine, capable of producing a search light of 25,000 actual candles, one of Brotherhood's new and improved 3-cylinder direct-acting engines, and a 60 cm. projector, fitted with inclined hand lamp. The dynamos are of the special slow-speed type designed by the corporation for ship lighting, and will be driven at a speed of 600 revolutions per minute.

POWERFUL LIGHTS IN FOGS.—It has been stated, upon reasonably good authority, in connection with the South Foreland Lighthouse experiments, that, whereas in clear weather the powerful electric light has proved incomparably more brilliant than the oil and gas burners tried with it, it does not hold its own in foggy weather, when the gas-lamp becomes the most visible of the three lights. This statement, of course, proceeds from unofficial observers; but it agrees with common experience. So says the *Journal of Gas Lighting*. But we may venture to ask if the electric light has really been tested in foggy weather? In the experiments, have any specially prepared carbons been used to obtain effective fog penetration? Let us assume that rays at a certain part of the spectrum pass more easily through

Digitized by Google

fog, yellow rays for example. Have carbons treated with sodium been tried? Have incandescent lamps been tried? And so on. Till such trials have been made we maintain that the whole series of tests are of little real value.

METAL DEPOSITS.—By modifications in detail, introduced into his electro-chemical processes, M. Weill has succeeded in coating, instantaneously, at the ordinary temperature, and by means of a single battery, all the ordinary metals and their alloys with a thin adhesive coating of brass, which presents at will the brightest and most varied colours. The operator, by modifying an electric action produced without separate battery, obtains at pleasure, on the same object, solid deposits of various hues and extreme brilliancy. It appears that the varied tints are due to the formation of several copper oxides, the composition of which is not yet determined. The coating is of such slight thickness that it can be applied to all metals, and in no way detracts from the sharpness of outline of the most delicate jewellery, to which it gives curious and often very appropriate hues. Ornaments cast in iron or stamped out in sheet iron may also be treated by this process.—*Bulletin de la Compagnie Internationale des Téléphones.*

ELECTRIC LIGHT IN THE BALL ROOM.—The American Crœsus, George Gordon Bennett, lately gave a big masquerade ball at his Newport villa, in honour of President Arthur, who was his most honoured guest. Rare Ben Jonson's masques in the Elizabethan age must have been considerably thrown into the shade, for we learn that electric lamps were profusely distributed about the grounds, and within a large ball room improvised of canvas for the occasion. At one end, from out of a mimic iceberg, composed of twenty tons of ice, issued tiny streams, led by concealed pipes, and falling into "a clear lake," which, if not "margined by fruits of gold," was artfully and artistically illuminated by masked electric lights. At the other end, a huge pyramid of maiden hair was surmounted by the flags of the "Namouna," the host's large steam yacht. The reduction of temperature by the iceberg is said to have rendered dancing enjoyable by the 600 guests, although the thermometer in the rest of the grounds stood at 80°F.

ELECTRIC CURRENT GENERATED BY DRIVING BELTS.—From time to time this one phase of frictional electricity crops up like the big gooseberry during the dull season. It is now reported that Herr Bacher, lighting inspector at the Dresden Opera House, has, in a few seconds, charged a Leyden jar with the electricity generated by a machine belt, and that its discharge produced sparks nearly three-sixteenths of an inch long; and, further, that a person, standing on a stool insulated with glass legs, drew powerful sparks from the belt by bringing his finger-top within a distance of about half an inch. After all, this is but one of the countless manifestations of the generation of electricity by friction with which we were made familiar in childhood by rubbing a piece of sealing wax on blotting paper, and finding it would attract light substances; and also by eliciting sparks on rubbing a cat's back the wrong way in the dark. Darkness was a condition of occular demonstration, and therefore of belief. If we had been told that the sparks were produced with equal intensity in the daytime we should not have believed it.

LONG DISTANCE TELEPHONING.—Last week some experiments were made, under the auspices of the United Telephone Company, in telephoning from the Grosvenor Hotel, near the Victoria Station, to Dover. We learn that messages from this town were distinctly heard in London, but the attempt to hear messages sent from London to Dover and back was not successful. The experiments were much interfered with, owing to the wire used being that on which the London, Chatham, and Dover Railway Company send their block-system service messages between London and Dover, which interrupted the telephonic communications. But why does not the company adopt the Van Rysselberghe system, as now being applied in Belgium, which permits of telegraphic and telephonic messages being sent simultaneously along the same wire? Intelligence has since reached us that on Monday last messages were spoken from Reading to Weymouth, a distance of 141 miles; and on Wednesday, by special arrangement with the Post Office, a G.P.O. wire from St. Martin's-le-Grand to Liverpool was connected with telephones, when messages were thus sent over 200 miles.

ELECTRIC LIGHTING AT HYDE PARK, BELFAST.—A most successful installation has just been carried out at Hyde Park, the well-known bleach green of Messrs. Fenton and Connor, Belfast. The installation has been effected in the upper works, and by means of some 130 20 candle-power incandescent lamps, the main portion being distributed in the stoves, finishing, old beetle and patent beetle rooms; but, in addition, lamps have also been introduced into the engine room, boiler house, circular saws, turning, and carpenter's shops, as also into the stores and offices. The first trial was made on Monday night, with such success that extensions were ordered the same evening into the browning rooms, situated in the lower or wet works some little distance off, and the question of the introduction of the light into every portion of the building is under consideration. The cables and wires are from Messrs. Callender and are encased almost throughout, while the lamps and dynamo are Brush Victoria. The installation has been carried out by the Belfast Electric Appliances Company (Limited), under the supervision and arrangement of Mr. G. Annesley Grindle, their engineer and manager.

THE TELEPHONE IN THE POTTERIES.—A meeting, presided over by Mr. J. N. Peake, chief bailiff, was lately held at Tunstall, to consider some proposals for establishing a telephone exchange, emanating from the North Staffordshire Chamber of Commerce. Mr. F. W. Neale, telegraph engineer, said that, if he undertook the work, each town would be provided with a centre, with which any subscriber of £12 per annum in the parliamentary boroughs of Stoke and Newcastle, without distinction as to distance, could be placed in communication; and, should he have two or more places of business in the several towns comprised in the said boroughs, the subscription for each would be reduced to £9. With respect to existing contracts with different firms, special arrangements would be made, so that they would not have to pay more than the above-named amounts. It would not be necessary to wait until a certain number of subscribers was guaranteed, as they were sure to increase on the public seeing its interest in the matter. Mr. Neale also proposed that, as soon as the project was fairly at work, the police stations should be put in communication at cost price, and that, when the exchange was closed at night, communication between each town should remain established, in case of fire or other emergency. The chairman expressed himself satisfied with Mr. Neale's statement, for which he proposed a vote of thanks; and the meeting was adjourned for a month to see what course other towns would take in the meantime.

THE S.S. "SAN MARTIN."—INSTALLATION OF THE ELECTRIC LIGHT.—The new screw-steamer "San Martin," built by Messrs. Napier, Shanks, and Bell, the well-known Clyde firm

Digitized by Google

for the Lloyd-Argentino Steamship Co., and now lying in the Queen's Dock, has been lighted throughout with the electric light, the installation being made by the Edison and Swan United Electric Light Company. The electric light is now comparatively common on board ships, all first-class vessels being fitted with it. The Edison-Swan Company alone have fitted out 50 passenger ships, and by the experience thus gained they have been enabled to perfect their system, and overcome many difficulties which beset them in the earlier days of electric lighting. In the "San Martin" the motive power is supplied by a 10 h.p. Tangye engine, which, by means of a cotton rope, drives a 200-light Edison-Hopkinson dynamo. The wires which convey the current from the dynamo room to all points of the ship are placed behind mouldings, suitably combined in harmony with the general decorations of the ship. The total number of lights is 157. Each state room is furnished with a light, and provided with a switch by which the passengers will have control over it. The dining saloon is well lighted by two-light pendants supplied by Messrs. M'Geoch and Co. The whole of the work has been completed under the inspection and to the satisfaction of Señor Brugo, president of the Argentine Company, by members of the Edison-Swan staff.

Electric Light at Brighton.—We learn that the Executive Committee of the Art Loan Exhibition to be held in the Corn Exchange, Brighton, are desirous that that building be lighted by electricity during the exhibition. Hearing that the motive power on the premises is not sufficient to permit of the efficient illumination of the whole of the property, they applied to the Pavilion Committee for authority to obtain current from some other source. This committee has authorised the Exhibition Committee to make arrangements for obtaining current from a source outside the Pavilion, stipulating, however, that all the wires and apparatus on the Pavilion estate be fixed to the satisfaction of the borough surveyor and of the insurance companies. The committee made a strong recommendation in favour of the arrangement for the extra amount of current being entrusted to Mr. Magnus Volk, electrical engineer, of Brighton. On 22nd ult. the Gas Committee took in hand the question of an improved lighting for the front of the town, and passed the following resolution:—"That the Electrical Sub-Committee be requested to visit Colchester for the purpose of inspecting and reporting upon the system of electric lighting in operation in that borough; that they be also authorised to visit other towns where systems of electric lighting are in operation; and that a sum not exceeding £50 be set apart to defray the expenses of the deputation." We learn that the sub-committee have secured the services of Mr. Volk to aid them in their inspection.

On Unequal Electric Conduction Resistance at Cathodes.—Dr. G. Gore, F.R.S., in the *Proceedings* of the Royal Society, says:—"During some experiments which I have been making on the unequal resistance to the deposition of a metal upon cathodes of different metals in the same solution by the same current (*see* "Some New Phenomena of Electrolysis," vide *Electrician*, May 31, 1884), I have been led to investigate the resistance of cathodes of different metals to the passage of the current into them. I have found that by taking a good conducting electrolyte, immersing in it a positive sheet of zinc, and a smaller negative one of another metal, connecting the plates with a galvanometer of low resistance, reducing all the other resistances in the circuit to the minimum except that of the negative plate; then making a series of measurements of strengths of current of different couples formed by the zinc and about 12 other metals, during removal of polarisation by stirring the liquid; also making another series of measurements of the electromotive forces of the same couples during stirring; calculating from these data the total resistance in each case, then deducting the portion of resistance due to the galvanometer, also that due to the liquid itself, and to opposing contact-potential, and thermo-electric and voltaic action at the cathode and external junction, very different amounts of resistance, large in some cases, remain, and are exercised by different metals as cathodes, and those differences of resistance are only to a small extent due to heat and current absorbed in liberating hydrogen, and can only in a few cases be partly accounted for by chemical action, films, or absorption of gases at the cathode. I am now investigating the nature of this resistance, and the relations of the resistance to various circumstances."

Franks' "Granule Carbon" Battery.—In a paper on the application of electricity to illumination in astronomical observations, Mr. W. S. Franks, of Leicester, records in the *Journal of the Franklin Institute* experiences with incandescent lighting by battery power. His requirements in the matter of lamps were not large, as he only used two of Swan's 2½-candle type, supplied at first by a 4-cell bichromate battery of the usual kind. Ultimately, however, Mr. Franks decided upon a type of home-made battery, which may readily be made by any one connected with gasworks wishing to make a private trial of incandescent lighting on a small scale. The outer cell is a wide mouthed, two-gallon salt-glazed stoneware jar, in which is placed a carbon plate, sawn out of the raw material as obtained at gasworks, its rough edges being merely cut true. There is also a porous cell containing a zinc plate; and both cell and carbon plate are packed into the jar with pieces of carbon broken to the size of a small nut. The jar is then charged with 1lb. of bichromate of potash, dissolved in 1 gallon of hot water, with 1lb. of sulphuric acid afterwards added, while the porous cell is charged with dilute sulphuric acid, in the proportion of 1 to 10. The three cells are coupled for intensity. When not in use, the zincs are lifted out of the liquid and suspended, by loops in the insulated wire connections, upon small nails. The only preparation of the carbon plate was to thoroughly paraffin the exposed end, and place a small clip of platinum foil on it, under the brass clamp, which effectually prevented the destruction of the clamp by acid creeping up the pores of the carbon. It is stated that, for the usual intermittent observatory work, the cells will last for three months without recharging; though, when required, the lamps can be kept up to full incandescence for hours together. In the ordinary way Mr. Franks puts down the expense at about 3d. per week on an average.

The Woolley Electric Headlight for Locomotives.—We have already referred, on two occasions, to the Woolley electric headlight for locomotives, in use on the Chicago, Milwaukee, and St. Paul Railway; and the following particulars, furnished by Mr. Lowry, general master mechanic of that line, will be read with interest:—"We are experimenting with what is known as 'Woolley's' patent electric headlight, and for your information I will add, the engine and dynamo are placed on the running board on the left-hand side of the locomotive, opposite the air-brake pump, which is located on the right-hand side. They (engine and dynamo) occupy a space 34in. in length by 10in. in width. The dynamo is 18in. square by 10in. high. The armature is made up of discs, and is 12in. long by 6in. in diameter. The power is furnished by a small rotary engine, built by the Noteman Engine Company, of Toledo, Ohio, which runs six hundred revolutions per minute. The engine is connected to the

Digitized by Google

shaft of the armature direct, the governor being on the opposite end of the shaft. There are no belts or gears of any kind. The dynamo is closed, so that it cannot be injured by the weather, &c. The lamp used is a focusing arc lamp with an ordinary locomotive reflector. The lamp is made so that it can be regulated from the cab of the locomotive. The light is a good one; it is claimed it will penetrate so far into darkness that, should the track be obstructed from any cause and a locomotive with the light on it be running at the rate of 50 miles per hour, an obstacle can be discovered sufficiently ahead that the locomotive can be stopped in time to avert a disaster. I might add furtherthe machines are built by the Woolley Locomotive Headlight Company, Indianapolis, Ind. The power of the lamp I have referred to is 2,000 candle-power. It has an attachment to counteract any quick movement, so that any sudden jar of the locomotive does not affect the light in the least."

ELECTRIC SYNCHRONISM.—In the current number of the Society of Telegraph Engineers' *Journal* is the following abstract of a paper by M. Deprez:—"The apparatus proposed by the author consists of two parts, the so-called 'annular comparative instrument' and a special form of magneto-machine. The latter has a ring of the Paccinotti type arranged between the poles of the magnet, which is free to rotate as well as the ring. Four brushes are used, arranged at right angles, and thus dividing the commutator into four quadrants; two brushes at opposite ends of the same diameter are joined up to the comparative instrument, which consists of a fixed iron ring with two windings of wire, split up in such a way that the successive sections alternately form part of one or the other winding. If two electric currents of different strength are passed through this instrument, four poles will be formed on the circumference of the ring, the lines joining which will be at right angles; but the magnetic forces exerted in their direction will combine to form a resultant, the position of which will depend on the proportion of the two currents, and not on their absolute strength. A magnetic needle suspended at the centre of the apparatus will place itself along this polar line. If now this 'annular comparative instrument' be joined up to the Paccinotti ring, and the ring rotated while the magnet remains fixed, the same result will be attained as though the ring rotated inside two distinct magnetic fields. Now each pair of brushes will collect separately the current due to the magnetic influence of the perpendicular component at its line of contact, and the comparative instrument will be traversed by two currents of different strength, which will cause the magnet needle to take up a definite position. Suppose this the initial position, now rotate the magnet, leaving the brushes fixed; then to every angle described by the polar line will correspond a definite value of the ratio of the two components of the magnetic field, and therefore of the two currents produced. It may be concluded that if the brushes and the magnet are rotated at different rates, the comparative instrument, which may be placed anywhere, will show the relative displacement of the two. To adapt such an apparatus for use as a compass, the axis of the rotating ring is placed vertically, and the inducing magnet is done away with, being replaced by the natural magnetic field of the earth. The resultant of the earth's magnetic force at a point can be resolved into two components, the one being a horizontal projection of the resultant, and coinciding with the magnetic meridian—this force replaces the permanent magnet; the second is vertical to the former, and therefore without action on the ring. If, then, the brushes remain fixed, any change, however small, in the magnetic meridian will produce a corresponding change in the comparative instrument. This latter may be placed in any convenient position, while the ring may be placed at the mast-head of a ship, out of the way of all influence due to the presence of masses of iron."

STEAM SHIP ELECTRIC LIGHTING ON THE WEAR.—The Hammond Electric Light and Power Supply Company have fitted one of Mr. James Laing's new vessels (No. 295) with a most complete system of incandescent electric lighting, consisting of a duplicate plant for 150 20 candle-power lights. Each plant consists of a Westinghouse high-speed single-acting engine and a new pattern slow-speed Ferranti dynamo and exciter, coupled together and mounted on one base plate, and running at 600 revolutions per minute. The Westinghouse is one of the most practical forms of high speed engines. Those used have two cylinders, 9in. bore and 6in. stroke, steam acting on one side of the piston only. All wearing parts are kept constantly in compression, and knocking therefore cannot occur. The generators have been specially designed for ship lighting, the slow speed making it practicable to couple direct to engine, all risks due to intermediate gear being dispensed with and the space required brought down to a minimum. All parts are to gauge and be interchangeable, the wearing parts being arranged so that they can be replaced by any ordinary mechanic, as the electrical parts of the machine have been made permanent and free from wear. Another feature is the extreme lightness of the revolving parts of the machine, which is of first consequence in ship lighting plant, on account of the roll of the vessel at sea. The engines are coupled to the dynamos by means of new flexible couplings, so that none of the vibration on the crank shaft is communicated to the dynamo. The oiling arrangements have been very carefully worked out, so as to reduce the attendance to a minimum. From one elevated oil vessel all the parts are oiled through a system of pipes, a small valve being placed at each bearing to regulate the supply to each part. After passing the valve, the oil is visible as it enters the bearings. In case of heating, the valve can be fully opened; and the pressure due to the elevation of oil vessel will force oil through and cool down very quickly. The wires have been specially prepared for the company to suit this class of work, and are well protected throughout from all external injury. A great source of trouble has hitherto arisen in ship-lighting from the lamps shaking loose in their holders, through the vibration of the vessel. This is obviated by a new type of holder, which is fitted to all the lamps, and is self-locking. This holder is mechanically very strong, and does away with the breakage of the platinum loops so common to the ordinary method of fixing incandescent lamps. The lamps are run in parallel arc, the E.M.F. being 100 volts. The current to all parts of the vessel is controlled by switches fitted to each lamp or group. These switches are efficient, elegant, and simple. The special feature is that the contact surfaces, when making or breaking, neverleave each other, but wear smoothly together, keeping the surfaces bright and clean; they break simultaneously at two points, without any jerking action caused by the surfaces separating. All the parts are made by special tools, and are exact duplicates of each other. Each lamp or group is also fitted with a safety fuse, to protect the wires in case of accident to any branch. The two plants are set side by side in a small recess of the engine room, measuring 12ft. 6in. by 7ft. 6in. by 6ft. only, open to the engine room, and allowing a passage round the back to get at any part of the plants. The stop valves are placed together and close to a switch-board, so that the engineer standing in one place can start and stop the engines or put either plant on to part or the whole of the circuit.

THE BRITISH ASSOCIATION MEETING AT MONTREAL.

The meeting at Montreal is over, and every one is pleased with the result. There were 1,773 members, and £1,800 was added to the funds of the Association. £1,500 was distributed in small sums to carry out the object of the Association, viz., the advancement of science. Six hundred old members turned up, a number that compares very favourably with the average attendance. The hospitality of the inhabitants of Montreal was unbounded, and nothing whatever occurred to mar the relation between guests and hosts, though several members in England had accepted invitations to stay with people, but did not turn up, nor wrote, nor telegraphed, so deprived their colleagues of comfortable quarters, and were guilty of rudeness themselves.

The environs of the town were well explored, and the excursions to Quebec, Ottawa, Toronto, &c., filled to overflowing. Altogether the trip across the Atlantic was very enjoyable, and those who went have been amply repaid for their expenditure and trouble.

The character of the papers read has been above the average, but much disappointment has been experienced at the few contributions received from Canada and from the States. Doubtless the Americans were mindful of their own forthcoming meeting, and probably the Canadians were too busy with their preparations for welcoming and preparing for their guests.

It was scarcely an electricians' meeting. No striking facts of novelty were introduced, nor was there any paper of peculiar value or merit. Lord Rayleigh was the prominent figure of the meeting. The manner and matter of his remarks on all occasions were very impressive. The portion of his address dealing with electricity was very exhaustive and instructive. He gave four short papers, one describing an interesting lecture experiment on induction, the other describing a galvanometer he uses to measure powerful currents of electricity, the third describing some experiments made to verify Clark's cell, and the fourth a formula and calculation to determine the distance along a cable that it is possible to speak by telephone with a cable of the Atlantic type. The theoretic limit was about twenty miles. His formula was based on the influence of inductive capacity in lowering the intensity and the number of the vibrations per second. Professor Graham Bell was present during the discussion that followed the last paper, and Mr. Preece gave some experimental facts that tended to confirm Lord Rayleigh's deductions. He showed that the distance through which one could speak was a question of induction and not of resistance, and if a small wire were carried to the moon we should be able to speak, though the distance was 240,000 miles. The chief difficulty in working long distances was overcome by using metallic circuits, the two wires forming the circuit twisting around each other with a very long lay, so as to neutralise all disturbances from neighbouring wires.

Sir William Thomson was not so ubiquitous or communicative as usual. His duties as president confined him to Section A. He brought forward very few papers, and nothing electrical. Of course he took an active part in the discussion in his own section, and he patronised Section G on its electrical day. It is generally arranged to make Friday the electrical day in Section A and Monday in Section G. The most interesting feature of the meeting was the discussion in Section A, on the seat of electromotive force in the voltaic cell. This was experimental, and the experiment was so successful that this mode of dealing with questions of moment will probably now become annual. For instance, it has been suggested that next year shall be taken on standards of light. Professor Oliver Lodge opened the discussion with remarks which, though written, were so fresh, original, and interesting, that they were ordered to be printed *in extenso*, and we shall have the pleasure of giving them to our readers. The discussion, which, though well maintained, was all on one side. The supporters of the chemical theory were nowhere. If electricity flowed through the seat of electromotive force, energy was evolved or absorbed there, and wherever energy was absorbed or evolved there was the seat of electromotive force. This was the surface of the metal and acid, and the primary cause of the disturbance that lead to the production of currents was contact. Professors Fitzgerald, Silvanus Thompson, Willard Gibbs, Schuster, and MacAlister, and of course Sir William Thomson, took part in the discussion.

In Section B there was an extremely interesting discussion on the constitution of elementary bodies, which was led off by Professor Dewar, who maintained the atomic theory now so universal, and narrated the present condition of our knowledge on this point. Is the atom decomposable, as is the molecule? What is the difference between an elementary and a compound body? It is a question of syndethes, says Professor Dewar. Oxygen is $O + O$, and is therefore a molecule, and not an atom. Peroxide of manganese and peroxide of hydrogen mixed give out oxygen in those molecules. CH_3 in simple molecules is methyl, but $2(CH_3)$ makes a different molecule, and a different substance called ethyl. Professors Frankland, Lyon Playfair, Walcot Gibbs, Gladstone, Roscoe, and Liveing, took part in the discussion, which was very well maintained.

A second discussion took place in Section A, inaugurated by Professor Schuster, on the connection between sun-spots and terrestrial phenomena. There was no difference of opinion as to the connection between the phenomena of terrestrial magnetism, auroras, and earth currents with disturbances in the sun, but doubts were expressed as to any connection with rainfall, famines, and other abnormal phenomena. The discussion was not so well maintained as on the other subjects, for it did not involve so much a question of personal opinion or individual theorising as it did a comparison of facts. Professors Perry (of Stonyhurst), Douglas Archibald, and Lant Carpenter were the only speakers.

Mr. Preece's communications were four—one in Section A on the Law Determining the Connection between Current and Light Emitted in the Incandescent Filaments of Glow Lamps. He pointed out that the light emitted from an incandescent carbon filament varied as the sixth power of the current, but that this law was followed only between the limits embracing the ordinary range of a glow lamp when used for artificial illumination. At the point where the law commenced to be departed from disintegration probably commenced, and this point ought to be determined for all lamps, so that their state of incandescence might be limited. His second paper, read in Section G, dealt with the watt, which he desires to be legalised like the ohm and ampere; and he suggested that the horse-power should be increased in value 34 per cent., so as to make it equivalent to 1,000 watts and to bring it into the C.-G.-S. system of absolute measurement. The third paper dealt with some experiments with secondary batteries for telegraphic purposes, and the fourth paper was on Domestic Electric Lighting, in which he described the fitting up of his own house.

The sole electrical paper of Sir William Thomson was on Safety Fuses for Electric Circuits, which he considered highly essential, but he objected to the use of lead and other soft metals. He used fine copper wire about ¾in. long.

Professor Frankland gave an interesting paper on Secondary Batteries, the results of his own long-continued experiments. He divides the discharge into two portions, one of which he calls the useful, and the other the useless electricity, and these are due to two distinct chemical changes. The paper was read in Section B. It was beyond the chemists, and was not, therefore, much discussed.

Electrical tramways, and the transmission of power, were brought forward by Dr. Traill and Mr. Holroyd Smith. The former gentleman illustrated his paper by an admirable working model that was manipulated by Professor Fitzgerald. Dr. Traill said that the working expenses are about one-fourth those of horse-power.

Professor George Forbes read a paper on the Heating of Conductors by Electric Currents, reiterating the views given by him before the Society of Telegraph Engineers last session, and Professor Silvanus Thompson discussed ~~Some Points~~ in Dynamo-electrical Machines, with special reference to the

Digitized by Google

direction of the leads of the brushes on the commutator. His views on dynamos are well known from his papers read before the Society of Arts. They are also published in book form by Messrs. Spon.

In Section A, Professor Fitzgerald gave an interesting paper on the analogy between electricity and heat, and Professors Reinold and Rucker one on the Thinning of Liquid Films by Electric Currents, in which they showed that a coloured film of a soap solution turned black, becoming about half its former thickness, when an electric current was passed through it, returning to its original colour when the current ceased.

Professor Oliver Lodge threw out a curious suggestion in his lecture on "Dust," which was to utilise the steam-power on board our ocean steamships to work large Holtz machines, so as to discharge copious sparks from the mastheads to dissipate fogs. He showed on a small scale how this could be done.

The meetings of the sections were unusually well attended, and both Canadians and Americans showed a lively interest in the way in which business was conducted. The Americans seemed to reserve their forces for their own meeting in Philadelphia. They did not often take part in the discussions, but when they did they spoke with force and power. Professors Willard Gibbs and Newcomb came most to the front, though Professors Rowland, Barker, Canhart, and others carried on with great spirit that friendly intimacy and contact that makes science such a true republic.

The meeting will not be memorable for any novelty, but it will never be forgotten as a gigantic experiment and a very pleasant outing.

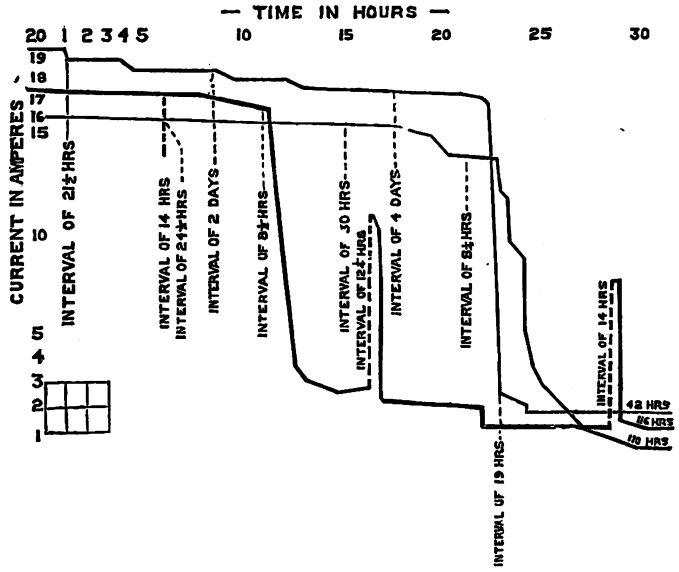
The death of Mr. Walter R. Browne, the late secretary of the Mechanical Engineers, was a sad event that marred the pleasure of many, for he had many friends in Montreal.

On the Discharge of Electrical Accumulators.*

BY E. FRANKLAND, F.R.S.

In a communication to the Royal Society on this subject (*Proc. Roy. Soc.*, Vol. XXXV., p. 67) I described certain experiments which went to prove that the active material in an uncharged accumulator (in which, when charged, spongy lead and lead peroxide are the opposing plates) is lead sulphate; that, in charging, this lead sulphate is decomposed on the positive electrode, the formation in both cases of hexabastic sulphuric acid, and that in the discharge these chemical changes are reversed, lead sulphate being reproduced on both electrodes and plates. These results are in the main confirmatory of previous experiments made by Gladstone and Tribe. I also stated that the sulphuric acid thus added to or withdrawn from the liquid contents of the cell can be made to indicate by change in specific gravity the degree of charge in the cell at any given moment. At the conclusion of the paper I expressed a hope that further experiments would enable me to denote in terms of current from the cell the definite relation between the amount of energy stored and the weight of sulphuric acid liberated. I have not as yet, however, obtained results which would justify me in announcing this equivalent, but I venture to think that the details of some experiments which I have made with this object may not be altogether uninteresting at a moment when the storage of energy is attracting so much attention.

The storage cell employed contained ten plates, each having two active surfaces of 11in. by 9in. Rejecting the free sides of the two endmost plates, the total effective surface was 12·3 sq. ft. These plates were completely immersed in dilute sulphuric acid, of which the cell contained about 14 imperial pints. The cell was fully charged in series with several others by a current from a Siemens shunt machine, varying usually from 15 to 20 amperes, and it was then allowed to rest for three days. The discharge was made through a piece of platinum wire, 1·035 mm. in diameter and about 10in. long. Carefully sheltered from drafts, this wire was maintained at a red heat just visible in the dark so long as the current did not sink below 17 amperes. The current was measured by a Siemens electro-dynamometer constantly included in the circuit. As the complete discharge occupied 73 hours, it had to be frequently interrupted. These interruptions are not mentioned in the following tabulated results, but they are noted in the accompanying diagram, which shows these results in the form of a curve. The current maintained itself at between 19·61 and 18·09 amperes for nearly 22 hours, and then fell very suddenly in the course of about an hour to less than three amperes, at which rate it continued for upwards of 50 hours. At the end of this time the current was still 2·57 amperes, when it was stopped at 10:30 p.m. At 6:30 the



following morning, on re-establishing the circuit, no perceptible current passed.

The following are the tabulated results of the discharge :—

Date. April.	Duration of discharge. H.	M.	Currents in amperes.	Ampere hours.
7	1	0	19·61	19·61
8	2	30	19·24	48·11
8	5	6	18·81	95·98
10	3	0	18·61	55·88

20	2	22	2·78	6·46
20	3	0	2·57	7·71
	73	5		545·81

The cell therefore kept up a current for 73h. 5m., and delivered an aggregate charge of 545·81 ampere hours. Of this charge 404·18 ampere hours were delivered with an electromotive force of about two volts, whilst 141·63 ampere

* A paper read before the British Association at Montreal.

Digitized by Google

hours were delivered with an E.M.F. of only about three volts. This result may be tabulated as follows:—

	Ampere hours.
Useful electricity or electricity of high E.M.F. (two volts or upwards)	404·18
Useless electricity of low E.M.F.	141·63
	545·81

In the experiment just described the discharge at high electromotive forces was rapid, but the cell had many intervals of rest, several of them long ones. Thus, after the first hour's discharge at the rate of 19·61 amperes, there was a rest of 21½ hours. Then the discharge was continued at the rate of about 19 amperes for 7 hours 36 minutes, followed by a rest of two days, when the discharge was maintained at nearly the same rate through the same resistance for 8 hours 23 minutes. Then came another rest of four days, at the end of which time the discharge started at exactly the same rate as that at which it had previously left off, and continued at very nearly the same rate for 4 hours 45 minutes longer, when it suddenly fell off to about 2¾ amperes.

In the next experiment, which was made with a cell similar in all respects, the heavy current was taken continuously up and down the fall, with the exception of one break of fourteen hours at the end of six hours. The following are the numbers noted during the discharge:—

Date. June.	Duration of discharge. H.	M.	Currents in amperes.	Ampere hours.
9	6	5	17·47	106·23
10	1	40	17·47	29·11

18	0	30	·91	·45
	147	39		457·26

The current maintained a nearly uniform rate of between 16½ and 17½ amperes for eleven and a quarter hours, or only for about one half the time in the previous experiment. It then suddenly sank to little more than 3 amperes, but rose again for a few minutes to over 11 amperes after a rest of twelve hours. It then sank to 3 amperes, and finally to less than 2, after nearly twelve hours continuous discharge; but after fourteen hours' rest it again rose for a few minutes to nearly 10 amperes, to sink in fifteen minutes to 2·57, and in another hour and forty minutes to 1·82 ampere, at which rate it remained for forty-seven hours continuously.

Under perfectly constant conditions of discharge it was interesting to try the effect of interpolating a fresh charge from the dynamo. Accordingly the discharge was interrupted, and immediately a steady current of 22·16 amperes was sent through the cell for exactly one hour, and the cell was then allowed to rest for three hours. On recommencing the discharge through the same resistance as before, a current of 9·96 amperes was obtained; but this was maintained for three minutes only, and at the end of an hour it had sunk to 2·87 amperes. It was only, however, after the lapse of eight hours that the rate of 1·82 ampere was resumed, and this was afterwards continuously maintained for fifty-two hours. Thus, of the twenty-two ampere hours with an E.M.F. of about 25 volts put into the cell, only 8·94 ampere hours came out again with a higher E.M.F. than that possessed by the previously constant current of 1·82 ampere. Moreover, the E.M.F. of the augmented current never exceeded 1·09 volt, whilst in 20 minutes it sank to ·49 volt. This result shows how wasteful it is to keep a storage cell in circuit after the high E.M.F. portion of its charge has been extracted. Altogether the complete discharge of this cell occupied 147 hours 39 minutes, and there was obtained:—

	Ampere hr.
Useful electricity or electricity of high E.M.F. (two volts or upwards)	194·38
Useless electricity or electricity of low E.M.F. omitting the 22·15 amperes hr. interpolated	240·78
Total......................	435·11

The cell, therefore, contained a smaller aggregate charge than the previous one, but what is of much more importance the proportion of useful electricity was greatly diminished, for whilst, in the first experiment, the proportion of useful or useless electricity was 5:7::2, in the second it was only 1:6::2. It can scarcely be doubted that this diminished proportion was due to the much more continuous nature of the discharge in the second case.

In order to test this conclusion, however, a third cell was submitted to experiment. This cell contained 13 pints of diluted acid, but only eight plates 8·5in. × 11in., or an aggregate effective surface of only 9·09 square feet, as compared with 12·3 square feet in each of the former cells. On this account the cell was discharged through a somewhat higher resistance, so as to obtain a lower rate of discharge.

Duration of Discharge. H.	M.	Current in amperes.	Ampere hours.

The cell maintained a nearly uniform current, averaging 15·8 amperes for almost the same time (22 hours) as the first cell. The current then sank, not quite so suddenly, to 91 amperes, at which rate it continued steadily for 111½ hours. During the course of this discharge the cell had the following period of rest:—Discharge, 6h. 5m.; *rest*, 25h. 35m.; discharge, 5h.; *rest*, 8h. 30m.; discharge, 4h. 20m.; *rest*, 6h. 10m.; discharge, 4h. 40m.; *rest*, 8h. 15m.; discharge, 121h. 15m.

These periods of repose had a most beneficial effect on the economic value of the charge. For whilst the cell, discharged with but little rest, gave a proportion of useful to useless electricity of only 1 : 6 : : 2, this cell, with intermittent discharge, yielded a result expressed by the proportion 6 : 5 : : 1, which is even higher than that obtained from the cell used in the first experiment. The complete discharge of this cell occupied (exclusive of the periods of rest) 141 hours 20 minutes, and there were obtained:—Useful electricity, 371·9 amperes; useless electricity, 114·9 amperes—total, 486·8 amperes.

In all these experiments moderate currents only were drawn from the cells, such as would be used for the supply for 14 or 15 Swan lamps of 20 candle-power; but much heavier currents can be obtained if desired, for Messrs. R. E. Crompton inform me that they have obtained from a cell of 12 plates of the same construction a steady current of 250 amperes. It would thus be possible, by coupling in parallel only 30 such cells, to obtain for a short time a steady current of no less than 7,500 amperes. The results of these experiments permit the following conclusions to be drawn:—

1. The energy of a charged storage cell is delivered in two separate portions, one having an E.M.F. of 2 volts and upwards, the other an E.M.F. of 5 volts or under; one of these may be termed useful electricity, the other useless electricity.

2. The proportion of useful electricity obtainable is greatest when the cell is discharged intermittently and least when the discharge is continuous.

3. Neither in the intermittent nor continuous discharge at high E.M.F. is the current, through uniform resistance, augmented by rest. At low E.M.F., however, the current, after continuous discharge of the high E.M.F. is greatly augmented, but only for a few minutes. This augmentation of current at low E.M.F. after rest is barely perceptible when the high E.M.F. discharge has been taken intermittently.

4. The suddenness of fall in potential indicates two entirely distinct chemical changes, the one resulting in an E.M.F. of about 2·5 volts, the other in one of eight volts.

5. The chemical change producing low E.M.F. is the first to occur in charging, and the last to take place in discharging a cell. It is the change which occurs during what is called the formation of a cell, and in the interest of economy, a reversal of this change should never be allowed to take place.

6. It would be difficult to suggest an explanation of the nature of these two chemical changes; but I refrain pending their actual investigation in which I am now engaged.

7. Currents of enormous strength may be obtained from storage batteries coupled up in parallel. For instance, a current of 25,000 amperes is quite feasible from only 100 cells. Such a current reduces to insignificance the output of the largest dynamo ever built. It is to be hoped that currents of this magnitude will open up new possibilities of research into the constitution of matter.

The Watt and Horse-power.*

BY W. H. PREECE, F.R.S.

The most practical unit in use among electricians that has been derived from the C.-G.-S. system of absolute measurement is probably the watt, or the rate of doing work when a current of one ampere is maintained through a resistance of one ohm. The work done by an electric current is thus brought into intimate relation with all other kinds of work. The common gravitation unit rate of working is the horse-power, which is 550 foot-pounds per second. The absolute C.-G.-S. unit is the erg per second, or the work done in one second in overcoming the force of one dyne through a distance of one centimetre. In any electrical measurement the electromotive force (E) in volts multiplied by the current (C) in amperes gives a product (E C) equivalent to so many 10^7 ergs per second, which is the watt. There are 746 watts in a horse-power, and E C is reduced to horse-power by dividing it by 746. The rate at which electrical energy is developed or expended in any part of any circuit is given in watts when we multiply by the number of volts by the number of amperes. Strange mistakes are made in confusing the unit of power with the unit of work. No less an authority than Professor Adams, in his inaugural address as president of the Telegraph Engineers and Electricians, spoke of the watt as the unit of work, and gave its value in kilogrammetres as kilogrammetres = watts × 10192. It is evident that as the watt is the unit of power it is equal to 10192 kilogrammetres per second, or, in other words, work done at the rate of a kilogrammetre per second = 981 watts = g watts.

I cannot help thinking that the good work of the British Association Committee will not be complete until the C.-G.-S. system is authoritatively applied to work and power. The following table brings together nearly, if not all, the units in common use:—

Unit.		Equivalent.
Horse-power	33,000	foot-pounds per minute.
,, ...	550	foot-pounds per second.
,, ...	746	× 10^7 ergs per second.
,, ...	7460	megergs per second.
,, ...	75·9	kilogrammetres per second.
,, ...	1·01385	force de cheval.
,, ...	746	watts.
Force de cheval............	75	kilogrammetres per second.
,, ...	542·48	foot-pounds.
,, ...	0·9863	horse-power.
,, ...	736	watts.
Watt	·0013405	horse-power.
,, ...	10^7	ergs.
,, ...	10	megergs.
,, ...	$\frac{1}{9·81}$	kilogrammetres per second.
,, ...	·1029	kilogrammetres per second.
B. of T. unit	1000	watts per hour.
C.-G.-S. unit...............	erg	per second.
Megerg	10^6	ergs per second.
Watt	10^7	ergs per second.

According to Professor Dewar a standard sperm candle develops 240,000 foot-pounds per hour, or 4,000 foot-pounds per minute. Now, since a watt is equivalent to 44·2 foot-pounds per minute, it follows that a standard candle develops 90 watts per minute. Again, according to the same authority, 5 cubic feet of coal gas in London develops 2,500,000 foot-pounds per hour, or 4,666 foot-pounds per minute, or 2,976 foot-pounds per candle per minute, which is equivalent to 67 watts per minute. A good glow lamp absorbs 2·5 watts per candle per minute; hence a glow lamp has an economy in energy of about 1-30th of a gas lamp and 1-40th of a standard sperm candle. A man working very hard expends about 100 watts per minute, and if a man-power is equal to, say, one standard candle, it is equal to 1·34 gas candles and 36 electric candles. What a field for economy in lighting, and how essential it is that gas should be applied to the production of power rather than to the production of light.

The horse-power as a unit has all the defects of an arbitrary unscientific standard. It involves the use of coefficients, and it is not connected directly with the absolute system of measurement. It differs in different parts of the world, and its name is misleading. It could be changed both in value and name without any inconvenience, except to those who are too familiar with the existing coefficients and formulæ. If its value were raised 34 per cent. it would become the kilowatt, and be connected directly with the C.-G.-S. system. It would thus become a scientific system, and diminish the use of coefficients. Even the present name could be retained, and its value altered from 746 to 1,000 watts, or from 33,000 foot-pounds to 44,233 foot-pounds per minute without any serious inconvenience. Existing numbers expressing horse-power would simply have to be multiplied by 746 to bring them to the value of the new unit, or numbers in the new unit would have to be multiplied by 1·34 to express their value in the old system.

I cannot help thinking that the good work of the B.A. Committee will not be complete until the C.-G.-S. system is authoritatively applied to work and power.

THE ELECTRIC LIGHT AT COLCHESTER.

The vestry of the parish of Chelsea is to be congratulated on having for its surveyor a gentleman who is at once free from the prejudices of his profession, cautious enough to guard his clients from going too fast, yet sufficiently alert to insure them against the reproach of being too slow. We have on one or two former occasions commented upon Mr. G. H. Stayton's reports relating to electric lighting, and we have before us now, dealing exclusively with the installation at Colchester, a document in which the brevity and directness of his remarks are as conspicuous as ever. At the conclusion of his paper, after a personal visit to that town, and a careful inspection of what has been done there in the interval between June last and the present time, he expresses his opinion that the time has now arrived when the question might be considered by the Chelsea Electric Lighting Committee for their report upon the desirability or otherwise of taking any steps under the powers of The Electric Lighting Act, with a view to the introduction of electricity for the purposes of illumination in that parish. Mr. Stayton's report, we understand, has been accordingly referred to the committee, and in due course we may expect to hear their decision.

Now, without in the least attempting to influence the deliberations of this committee, much less to predict what their recommendations may be, we feel ourselves at liberty to express a general satisfaction with the Chelsea surveyor's report. From correspondence which has appeared in our columns, and from other sources of information, we have not been free from misgivings as to the character of the work, or the system employed in carrying out the Colchester installation; and even after a perusal of Mr. Stayton's report we are by no means sure that the best has been done that might have been practicable under more favourable circumstances and a greater amount of capital expenditure. We are, perhaps, not disinclined to endorse the opinion of an unfriendly criticism in the *Journal of Gas Lighting* of last Tuesday, the writer of which is "struck with the paltry practical outcome of a movement that has commanded millions of capital;" for, at the first glance, it does seem disheartening that of all the big schemes that have been floated the one that has contrived to avoid partial or complete submersion is an obscure company, in a comparatively insignificant locality, provided with very inadequate means. But, on the whole, these disadvantageous conditions speak well for the general results, which Mr. Stayton assures us have given great satisfaction on the spot. The gas journal just quoted asserts that a large hotel in Colchester has withdrawn its custom; a statement which is not confirmed in the Chelsea surveyor's report, and which in any case is not explained, and may therefore, even if it is true, be accounted for by reasons other than dissatisfaction with the light itself, or the price demanded for its use.

As regards the price, Mr. Stayton frankly admits that it is, light for light as compared with gas, 33 per cent. dearer; and that thus it may be regarded as a luxury. But he is not so precise as we could have wished in respect to the illuminating power of the electric lamps; in other words, as to the number of lamps required in place of the gas burners giving an equivalent amount of light. In one portion of his report, indeed, we notice that the necessity for outside gas lamps with reflectors has been done away with by the introduction of electric lights inside the shop windows; and if this is generally the case a considerable saving of argand gas burning must have been effected. Such comparisons of price, like similar comparisons of light, are, as we have over and over again pointed out, altogether untrustworthy; the only comparison the customer will care about is between the bills he formerly paid and those he has now to pay for lighting his premises in an effective way. But should the balance at Colchester turn in favour of gas, there is still apparently a large margin left for reduction to the consumers, the profit of the 14½ per cent. which the managing director states he would realise if his customers were appreciably increased being larger probably than the company would think it expedient to continue demanding. It is to the interests of the inhabitants of Colchester, therefore, to encourage the extension of the electric light throughout the assigned area; and if, as is alleged, the advantages of the light are greatly appreciated by the present users, there is reason to hope that the demand for it will greatly increase. Meanwhile, as a matter of business, we should advise the adoption of rates as low as possible, based on the well-founded assumption that the area of demand will be covered in due time so as to yield a good profit.

One of the chief merits of the electric light for shop interiors is dwelt upon in Mr. Stayton's report with an emphasis it well deserves. Not only is the contrast between shops illuminated by gas and those where electricity alone is employed extremely unfavourable to the former in general splendour of effect, but the colours of the goods show up with perfect truthfulness, and their texture is not affected by heat or noxious fumes. This, to our thinking, is a most important feature of the electric light. The *Journal of Gas Lighting* makes fun of somebody who has mistaken Lewis's incandescent gas burners for incandescent electric lamps, and reported that the air of Gower-street Railway Station is greatly purified by their use. But the

Digitized by Google

mistake is only laughable if the air is really no purer; that is the main question, and it is one which the gas interest has taken very little pains to solve. Meanwhile, we are justified in asserting that the electric lamp is the only pure and harmless light in existence; and if the damage done to the shopkeeper's material goods, to say nothing of his human assistants, by the use of gas is set against the perfect immunity from this source of deterioration when electricity is employed, the difference in actual cost will not be so great as it seems. In a large number of instances, we are persuaded, the electric light might supersede gas with profit, even if their respective prices differed more than they do. This fact is better known probably in London than it is in Colchester, and should the effect of Mr. Stayton's report be to induce the Chelsea Vestry to give London a trial on a larger scale and under better auspices than the experiment at Colchester has enjoyed, we entertain no doubt that it would be a commercial success as well as a great social boon. Some of the vestrymen object to the employment for this purpose of capital obtained from the ratepayers' pockets. We can sympathise with the objectors, and hope they may see their way to the employment of private enterprise independent of the now discredited Electric Lighting Act.

CORRESPONDENCE.

SPEED OF THE WHEATSTONE INSTRUMENT.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: In reply to the question of "X," in *The Electrician* of 27th inst., I would observe that the speed mentioned for the Wheatstone in the *Formulaire Pratique de l'Electrician* refers to a line of from 600 to 700 kilometres (372 to 435 miles) long. If "X" will refer to a passage a few lines higher up, he will see that, *on a short line*, the Wheatstone is capable of transmitting as many as 130 words a minute. Moreover, these figures agree with those given by Messrs. Preece and Sivewright in their "Text Book on Telegraphy," second edition, sections 126 and 127.—Yours, &c.,

Paris, 29th September, 1884. E. HOSPITALIER.

INTERNATIONAL EXHIBITION OF INVENTIONS.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: The International Exhibition of Inventions, 1885, will bring together the inventors and patentees of all nations, and an opportunity will be afforded, which will not again occur for many years, of developing an international patent law.

The International Convention for the Protection of Industrial Property, which by an Order in Council came into effect on the 7th July last, has not been signed by Germany, Russia, Austria, or America. These countries therefore were, for different reasons, not satisfied with the terms of the convention. All our attempts at patent-law legislation, whether international or on our own account, have proved failures for the same reason, namely, because the actual requirements of inventors have not been ascertained. The interests of inventors are identical with those of the public; encourage invention and you create trade.

One of our leading statesmen has said, "Inventors are the creators of trade." If this is so, on what possible principle can any tax whatever be levied on letters patent? Such a tax must of necessity hinder the "creation of trade," must throw obstacles in the way of development of new inventions, must deprive the Treasury of large sums which would flow into it in the way of income-tax, and, worst of all, must deprive the operatives of this country of numerous sources of employment. If inventors as a body could only realise the extent of their numbers, the talent, influence, and even wealth of their individual members, they would lose no time in exerting such a combined and irresistible pressure on the Government as would result in a complete revision of the Patent Laws, and would lead to a revival of the trade of the country. —Yours, &c., H. P. DEANE, Secretary.

Inventors' Institute, 27, Chancery-lane,
29th September, 1884.

DIMENSIONS OF DYNAMOS.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: I am making a Schukert dynamo for incandescent lighting, and should feel much obliged if you could give me information through the medium of your paper as to the wire I ought to use to make it shunt wound, and to give an E.M.F. of 100 volts.

The dimensions (unwound) are:—External diameter of armature, 6in.; internal diameter of armature, 3in.; thickness of armature, ½in.; number of sections, 16; length of magnet cores, 2½in.; diameter of magnet cores, ⅞in.

Will you inform me:—1st. Length and B.W.G. of wire on each of the four magnet cores; 2nd. Length and B.W.G. of wire on each section of armature.

The dimensions are one quarter those of a four-arc light machine, so that I ought to be able to light 10 sixteen candle-power lamps.—Yours, &c., F. J. SHAW.

7, Stanton-villas, New Southgate.
October 1, 1884.

NON-MAGNETISABLE WATCHES.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: In reply to Mr. Grundy's letter in your last issue, I write to say that it is not necessary to go to America to obtain non-magnetisable watches, as I have made them since 1880. They were exhibited at the Electrical Exhibition at the Crystal Palace in 1882, and were awarded a medal.—Yours, &c.,

5, Queen Victoria-street, E.C., R. WEBSTER.
29th September, 1884.

DUNDEE TELEPHONE.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: I should feel much obliged if any of your correspondents would give me any information *re* the Dundee Telephone Company, such as the system used, number of subscribers to the exchange, number of private renters, mileage of wire used, &c. I hear that the subscription is only £5 per annum; if so, please state, and oblige—Yours, &c.,

CURIOSITY.

29th September, 1884.

THE PHILADELPHIA EXHIBITION.—II.

(FROM OUR SPECIAL CORRESPONDENT.)

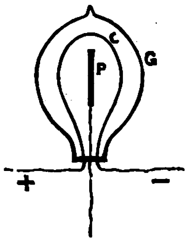
PHILADELPHIA, SEPT. 19.

This week has witnessed a great improvement in the Electrical Exhibition. The exhibits are all in order, the lights are all ablaze, and the hall is crowded nightly. Many additions have been made to the exhibits, among them an electric railway car running on a short track. This, although a very bad sample in itself, serves to complete the exhibits of practical applications of electricity. The Conference having adjourned, a course of lectures on electrical subjects is being delivered in the annexe to the Exhibition hall. They attract large audiences, the lecturers being famous professors (here on other business), and the Exhibition affording them a great wealth of illustrative apparatus.

One of the chief objects of curiosity for the last few days is a nameless piece of apparatus in the Edison exhibit. All the electricians have examined it, and countless theories have been offered to explain the observed phenomena, but none are wholly satisfactory. Fortunately the apparatus is so simple as to be easily described and readily understood. An ordinary Edison lamp has introduced within the loop a small ribbon of platinum. This is in no

Digitized by Google

place nearer to the loop than, say, a quarter of an inch, and terminates about that distance from the turn of the loop. It is connected with a separate conductor, carried out to a binding post, and is sealed in the glass like the other conducting wires. The bulb is exhausted of air, so as to produce as high a vacuum as possible. For experimental purposes a resistance box is put in the circuit to regulate the current. Let us suppose a conductor to be led from the positive pole of the lamp filament to a galvanometer, the other conductor from the galvanometer being carried to the central strip of platinum which terminates in the vacuum. The galvanometer stands at zero. On turning on the current through the carbon filament the deflection of the galvanometer shows that a current is also passing through the strip of platinum, or, in other words, that the circuit is completed in some way through the vacuum. As the lamp is raised to a higher degree of incandescence the deflection becomes greater, the action being precisely the same as though the circuit including the galvanometer was metallic throughout. This, it must be remembered, is while the positive pole of the lamp is connected with the galvanometer, and the deflection generally reaches about 75 or 80 degrees. The current is, in fact, sufficiently powerful to work a telegraphic relay, which is sometimes put in circuit in place of the galva nometer. This in itself is a pretty hard nut to crack, but the phenomenon that upsets most of the theories brought to explain the action is observed when connection is made with the negative instead of the positive pole. The needle ought then apparently to be deflected in the opposite direction, and it is, but only to the amount of a single degree or a fraction thereof. All other known conditions being precisely the same, the deflection when the positive pole is in the galvanometer circuit is, say, 75 degrees, while with the negative pole it is only half a degree the other way. Edison does not explain the observed facts, he merely presents them, but he says that the apparatus may some day be the germ of a new theory of electrical action.



He has another very curious apparatus with an incomplete circuit, if there can be such a thing. For want of something else by which to call it, the attendants say that it is devised to make visible the "etheric force." A conductor is carried through a closed box under a microscope. In the field of the microscope there are two carbon points forming part of the conductor, and (I presume) presenting a point of imperfect contact.

One end of the conductor outside the microscope is connected with an automatic current breaker, the other end is carried to an insulated support; in other words, there is no circuit formed. Nevertheless, upon turning on the current the carbon points under the microscope are seen to glow. The most delicate testing apparatus fails to show the presence of electricity, but some form of energy is evidently at work in the conductor. This description of the apparatus and its effects I derive from one of the attendants, having had no opportunity to examine it. No explanation of the phenomena is offered.

The passage of the current through vacuo in the manner described above I examined for some time. The galvanometer deflection remained constant while I was looking at it, but I am told that it is sometimes subject to erratic changes, and that while connection is made through the positive pole and without any known alteration of the conditions, the needle has returned to zero, then deflected in the reverse direction, returned to zero, and deflected again to the right without any observed cause, acting very much, however, as though relieved of a static charge and again charged. Edison says that some one once had a theory that a high vacuum was as good a conductor of electricity as copper wire, but that he never succeeded in proving it. This apparatus might help him but for the strange want of apparent conductivity through the negative pole. For the present these curiosities (of no practical use so far as known) attract more attention from the electricians than anything in the Exhibition.

Another curiosity is the Sprague motor, which is remarkable in its performances, and attracts special attention, because the inventor, not having yet secured his patents, declines to explain its action. One of the machines is used for running a loom, which requires to be kept at perfectly constant speed, and to be subject to instant stoppage at the will of the workman. A speed indicator attached to the motor shows that the purpose is attained. It was running when I saw it at 360 revolutions a minute. The indicator hand remained fixed at this point while the loom was running, and when it was stopped or started did not vary more than from five to ten revolutions before settling down to the standard fixed for it. The machine is also under very perfect control by hand, a device which fits it for locomotive service. It can be started slowly, the speed gradually increased, or slowed down, and the action reversed at will. This is undoubtedly done through changes in the strength and in the intensity of the magnet, but exactly how is the inventor's secret. The machine, however, is so plainly effective in doing what is wanted that it has won high commendation. At present the motors are run by the Edison current of about 100 volts, but they can be built for use with currents of any intensity, and the inventor prefers those of high electromotive force.

A strange incandescent lamp is shown by an electrician named Diehl, of Elizabeth, N.J., but he has unfortunately been unable to light it up, his machinery not being ready. The conductors do not extend beyond the glass enclosing bulb, and the current acts by induction. The carbon filament terminates in a coil of fine wire enclosed in a prolongation of the bulb, and is entirely surrounded by glass. In the middle of this coil, separated therefrom by the glass, the terminal of the conducting wire is formed into another coil with iron core. An alternating current is used, which acts by induction on the coil within the lamp, and so produces incandescence of the carbon filament. The lamp presents no apparent advantages in the way of manufacture, and is probably too costly for competition with other and more direct forms of conveying the current through the filament.

The Electrical Conference had long sessions during the two days following the writing of my last letter and then adjourned. In a discussion on the electrical transmission of energy, Professor Nipher said that he was engaged in attempting to represent graphically the energy transmitted by a dynamo generator and converted back to power by a motor. He hoped from his experiments to determine constants of a particular form of machine, which could afterwards be used as a standard of comparison with other machines. Professor E. J. Houston (Thompson-Houston system) thought that a standard for the transmission of energy could best be studied by the light which that energy was capable of producing. Mr. Sprague (the exhibitor of a motor above mentioned) did not agree with this opinion, and said that for effectiveness in transmitting energy it would be found necessary to use currents of much higher potential than any heretofore employed.

The discussion on storage batteries did not develop much that was new, but every speaker seemed to be disappointed with them except as adjuncts to lighting systems where the power was more or less intermittent. It was suggested that carbon be used for the plates of storage batteries, but it was generally believed that they would disintegrate rapidly. Professor Dewar, of Cambridge, thought that experiments ought to be made with a variety of other substances besides suboxide of lead, and suggested such salts as permangates, iodates, and hromates.

In discussing telephones, Mr. Lockwood, electrician for the Bell Telephone Company, expressed the opinion that the disturbing noises in the phones were generally due to atmospheric or terrestrial currents and seldom to induction from other lines. The conclusions he reached were against the use of underground conductors.

It should be explained perhaps that thousands of telephone wires are carried overhead in all our large cities, and that they have become such a nuisance that ordinances have been passed requiring their removal. The telephone companies, objecting to the expense of putting their wires underground, declare that this cannot be done.

Digitized by Google

Mr. Preece combated some of Mr. Lockwood's conclusions, and gave interesting information (to Americans at least) about underground wires in English cities.

The conference during its session adopted resolutions asking the Government to undertake a series of observations of atmospheric electricity and the strength of earth currents. The methods recommended are those of the International Bureau of Telegraphic Administration at Berne, and it is proposed that the telegraph companies and private electricians shall co-operate with the officers of the signal service in making the observations.

Professor George Forbes opened the lecture course last evening by a lecture on the Theory of Dynamo Machines.

PHILADELPHIA ELECTRICAL CONGRESS.

The Conference assembled the fourth day in the Hall of the Franklin Institute, and was called to order by the President, Professor Rowland. The Committee on the Advisability of the Formation of a New Unit of Power reported verbally through Mr. W. H. Preece. The report called attention to the great necessity of some unit of power in accord with the metric system and with electrical engineering. This necessity the watt, in the opinion of the committee, met perfectly. A watt, defined electrically, was the rate at which work is done when a current of one ampere is maintained in a resistance of one ohm.

It has therefore been called the volt-ampere, but this name was awkward, and the name of Watt, himself the first careful measurer of power, was fitly appropriated to it by Professor Siemens. The unit of power which Watt adopted was the horse-power. By a series of experiments he determined the work of one horse to be about equivalent to that of raising 22,000 pounds one foot every minute. This number seeming too small to him, he added 50 per cent., and arbitrarily fixed the horse-power at 33,000 foot-pounds. As the watt is too small a measure to be suitable for large measurement, he proposed that the arbitrary horse-power be raised 34 per cent., so that, instead of representing 33,000, it would be about 44,000 foot-pounds. It would then be equivalent to exactly 1,000 watts. Mr. Preece moved that it is the opinion of the Conference that the unit of power should hereafter be the watt, and that the value of the horse-power should be raised so that it should equal 1,000 watts. After a little discussion the motion was adopted.

The Committee on the Standard Unit for Light reported informally through its chairman, Professor Trowbridge, that in the opinion of the committee the standard unit of light proposed by the Paris Conference was impracticable, and that they did not believe its adoption advisable in this country. He called upon one of his colleagues, Mr. Preece, who had prepared some statements.

[The standard unit of light here referred to is that amount of light of the same character as the light to be examined which is emitted from the surface of one square centimetre of melted platinum at the temperature of solidification.]

Mr. Preece said that he had devoted much time to the study of the measurement of light as a member of a committee of the British Association. Two points are necessary to be considered. First, the formation of a practical standard for all lights; and second, the accurate definition of the standard of white light. The first of these is practically all that is necessary to examine. After referring to the personal equation of the individual observer, he went on to consider the systems which are legal in the various countries. In England they have a standard sperm candle of certain quality and burning 120 grams per hour. In Germany they have a different standard candle. In France they use a lamp known as the Carcel, which represents about 9·7 of the British standard candle-power. Mr. Preece believed that all of these were defective, because they did not relate to the illuminating power, the important point of the light. He had proposed as a standard the light given off from a perfectly white surface when the light from a British standard candle fell upon it from a distance of 12·7 inches. This would correspond to the amount of light given off when the same surface was illuminated by a Carcel lamp at the distance of one metre. He thought the practical method of comparing and studying the three points, the standard of light, the standard of illumination, and the means of photometric measurements were best found in the incandescent electric lamp. It was convenient and accurate, and could always be reproduced. He promised further aid to the committee until their report to the commission should be rendered.

Professor Koyle asked if the surface of incandescent platinum of a certain size would not be better than that of the carbon filament. Mr. Preece replied that in the air the surface of platinum had not been successful, and that sufficient experiments had not been conducted with platinum in vacuo.

Professor Henry A. Rowland, of the Johns Hopkins University, then opened the discussion on the theory of the dynamo-electric machine. He stated that neither time nor opportunity offered for more than a general inquiry into some of the theoretical considerations affecting dynamos. One of the first and most important considerations was that of the causes of loss of power. These he divided into five—mechanical friction, Foucault currents, the current used in sustaining the magnet, the heating effects on the revolving coil, and the production of self-induction in the coil.

The first two of these needed no discussion. Their remedies were obvious and had already been applied. Under the third head the speaker suggested several possible causes of loss of power, such as the use of wrought iron instead of steel in the magnets, the elongated shape of the cross section of the magnets in some of the forms, and especially on the duplication and multiplication of magnets. The form of the poles of the magnets was also a possible cause of loss of energy. He showed how in several forms of the machine leakage of magnetic force would occur. His deductions were that the magnets of a perfect dynamo must be circular in section, of one pair of poles and perhaps of steel; that the poles should be of large size approaching closely to the armature, and that opportunities of leakage should be avoided as much as possible. He believed, with reference to the fourth cause of loss of power, that more was lost than was generally understood.

In the Gramme ring he thought that as much as one half the electric energy was wasted in what was called "dead" wire. In the Siemens armature the loss, while not so great, was yet probably very considerable. In the same way the distance which separated the poles of the magnet from the armature was "dead." The fifth cause he would leave to be discussed by Professor Fitzgerald.

The speaker then proceeded to elucidate by formulæ the strength of the magnetic field, the force necessary to expend in magnetisation, the weight, and, finally, the efficiency and speed of a theoretically perfect dynamo machine of any given size.

His results show that leaving out of the question various minor mechanical considerations, size had nothing to do with efficacy. The increase of efficiency he showed must be due to the greater proportional speed of the armature, and to other considerations.

Professor Francis J. Fitzgerald, of Dublin, Ireland, considered the loss in the dynamo machine from the induction of local currents in the coils. He showed how the sudden reversal of the direction of the current occurred under the brushes of the machine, and how in faulty construction of these brush contacts short circuiting and loss occurred. He agreed with what Professor Rowland put forward, but criticised the statement that the efficiency did not depend on the increase of size, pointing out that several causes of internal resistance, notably in the loss from separation of the armature from the poles of the magnet, did not increase with the increase in the size of the machine.

Professor Elihu Thomson criticised the paper of Professor Rowland in many points. He did not believe that extension of the poles of the magnet would be followed by a gain, since loss by radiation into the air would be inevitable. Neither did he see the objection to having a double magnet with the

Digitized by Google

poles joined and the armature in the centre. He thought that the loss would be far less than where the poles were placed upon and within a few inches of an iron base plate, and with the armature revolving on the internal lateral surface of the poles.

As to the use of steel he had made extensive practical experiments, and had found nothing which was so suitable as was soft malleable iron. In the matter of the "dead" wire of the Gramme ring, as represented by Professor Fitzgerald, he thought that the "loss" was based on a mistaken theory, and that there was no "dead" wire, save possibly at the moment of changing the direction of currents; certainly the statement that fully half the wire was dead was incorrect. He also criticised Professor Fitzgerald's statements as to the internal self-induced currents of the armature.

At this point the discussion was interrupted and a recess ordered until 3 p.m. On reassembling Professor Rowland took the floor to reply to Mr. Thomson's remarks. He claimed that he was correct in stating that steel could be as easily magnetised as iron, and that his experiments in previous years had proved the fact. He reiterated his views with regard to the proper form of magnets and poles.

Mr. N. S. Keith, with the aid of a diagram, drew out the theoretical evolution of a dynamo. He did not agree with Professor Rowland in regard to single magnets, but preferred the form in which the poles were joined and the armature revolved in their mutual axis. He believed that in such machines there was a concentration of the lines of force along the axis of the conjoined magnets. In a single magnet the concentration occurred at the end and not on the lateral surface of the pole, where the armature was placed.

Professor Silvanus P. Thompson, of Bristol, England, gave a comprehensive account of the mathematical laws governing the construction of dynamo machines. His remarks were illustrated by formulæ, which cannot be reproduced here, but some of his conclusions from these formulæ were important.

He believed that future progress in dynamo electricity would not be gained by increasing either the speed or the amount of wire on the armatures, but by increasing the force of the field magnets. He did not agree with Professor Rowland as to the cylindrical magnets being invariably the best form, and pointed out the defects where several cylindrical magnets were joined to a single pole. He was sure that the effects of magnetism were much better where the lines of magnetic force corresponded with the grain of the iron, and hence that the magnets were always best when made of wrought rather than cast iron. He did not agree with the president either in thinking that the double magnet machine was necessarily a bad form. In connection with the form of magnets he stated that he had proved that the entire mass of the iron does not magnetise equally, and that it is possible to have currents of magnetic force inside the core of the magnet itself.

Professor Rowland attacked this statement, which, he said, was evidently a mistake, and that, if true, it would strike at the foundations of all the acknowledged laws of magnetism.

Mr. Thompson replied that he had performed experiments which proved the fact.

Professor Forbes made an explanation reconciling the discordant results. The discussion became general on the methods and time required to saturate masses of iron, and the advantages and disadvantages of a slow or quick magnetisation of the field magnet.

Professor Newcomb introduced the report of the Committee to Consider the Advisability of Establishing a Bureau of Physical Standards.

The resolutions as agreed upon were as follow:—

Whereas, the rapid increase in the applications of electricity requires the adoption and legalisation of common standards of electrical measures to form the basis of contracts for the supply of electricity; and

Whereas, the realisation of such standards requires that all instruments for electrical measurements shall be tested and verified by one central authority; therefore, be it

Resolved, that this Conference deem it of importance that Congress, in pursuance of its constitutional authority to fix a standard of weights and measures, should fix a standard of electrical measures, and in order to secure the use of such standards should establish a bureau charged with the duty of examining and verifying instruments for electrical and other physical measurements.

Resolved, that the President of this Conference be requested to communicate the above resolution to Congress through the proper official channels.

Resolved, that the United States Electrical Commission conducting this Conference shall appoint a suitable committee to represent this Conference before Congress, and to move for such legislation as will secure the object of these resolutions.

After discussion by Captain Michaelis, Professor Newcomb, and Mr. Preece, the resolution was finally carried.

A motion to adjourn finally on Saturday, at noon, subject to a call of the Electrical Commission, was carried, and the Conference adjourned. The subjects to be discussed, should time permit, in the order of their naming are:—"The Electrical Transmission of Energy," "Storage Batteries," "Underground Conductors," and "The Measurements of Currents of Large Volume."*

ON A STANDARD TANGENT GALVANOMETER.†

BY PROFESSOR SILVANUS P. THOMPSON.

It is known that in those tangent galvanometers wherein the coil consists of numerous turns of wire, the simple formula used for the case where the coil consists of a single turn of given radius is no longer applicable, but requires the introduction of certain corrections, depending on the breadth of the coil, and on its radial depth. A coil of great radial depth in proportion to its breadth acts as if its effective mean radius were less than the arithmetical mean radius of the various turns, because of the greater effect of the inner turns which are nearest to the needle. A coil of great breadth in proportion to its radial depth acts as if its mean radius were greater than the arithmetical mean radius of the several turns, because those turns which lie on the ends of the annular cylindrical surface are at a greater distance from the needle.

Now, since the effects of breadth and depth are opposite, one making the effective mean radius greater, the other making it less than the actual mean radius, it is evident that there ought to be a certain possible proportion between depth and breadth, which, if observed in the construction of the coil, will have the effect of causing these two influences to cancel one another. The object of this paper is to make known that proportion which fulfils this condition.

Maxwell has in his treatise made a similar calculation for the case of the Helmholtz two-coil galvanometer, for which he finds that the proportion between breadth and depth ought to be 31:36. Maxwell's equations (see Art. 711 "Electricity and Magnetism") also furnish a basis for the calculation which it is desired to apply to the one-coil tangent galvanometer.

We will adopt Maxwell's nomenclature, and write:—

A = arithmetical mean radius.
ξ = depth of coil in radial direction.
η = breadth of coil in axial direction.

Then, we may write as the value of the current i (in absolute measure) the following expression, involving a series of spherical harmonics as functions of the angle θ between the axis of the needle and the axis of the coil

$$i = \frac{H \cot \theta}{G_1 g_1 + G_2 g_2 Q'_1(\theta) + G_3 g_3 Q'_2(\theta^2) + \&c.};$$

where the coefficients G_1 G_2, &c., refer to the coil, and g_1 g_2, &c., to the needle, and H is the horizontal magnetic field at the centre of the coil. For a symmetrically hung uniformly

* Reference to the further meetings of the Congress will be found at the end of our correspondent's letter, given in another column.

† A paper read before the American Association for the Advancement of Science (Section of Physics). September, 1884.

Digitized by Google

magnetised needle of length $\frac{1}{2} l$, and for a coil of rectangular section, the following are the values of the coefficients :—

$$g_1 = 2\,l.$$
$$g_2 = 0.$$
$$g_3 = 2\,l^3.$$
$$g_4 = 0.$$
$$G_1 = \frac{2\,\pi\,n}{A}\left\{1 + \frac{1}{12}\frac{\xi^2}{A^2} - \frac{1}{8}\frac{\eta^2}{A^2}\right\}.$$
$$G_2 = 0.$$
$$G_3 = -\frac{\pi\,n}{A^3}\cdot\left\{1 + \frac{1}{2}\frac{\xi^2}{A^2} - \frac{5}{8}\frac{\eta^2}{A^2}\right\}.$$
$$G_4 = 0.$$

The higher terms may be neglected. The principal term to take into account is, of course, G_1. Looking at the numerical coefficients of the terms containing ξ and η in this expression, we see that these terms will vanish, provided

$$\frac{\xi^2}{12} = \frac{\eta^2}{8},$$

which is therefore the equation of condition, and may also be written :—

$$\xi : \eta :: \sqrt{3} : \sqrt{2}.$$

The nearest convenient whole numbers that suit this relation are 11 : 9, and this is very nearly accurate, as the exact proportion is 11·016 : 9.

Accordingly the author has constructed a galvanometer on the following plan :—A mahogany ring was built up, and turned so as to have a rectangular channel 2 centimetres broad and 2·5 centimetres deep, the mean radius of the channel being slightly over 25 centimetres. Some silk-covered copper wire was chosen, of such calibre that nine turns would exactly lie side by side in the channel; and eleven layers were wound, making 99 turns in all. Each layer when wound was separately paraffined, the paraffin being smoothed off so that the turns of wire lay in square order above one another. The advantage presented by a coil of this aperture is that when it is set up the magnetometer for determining H can be set up *in situ* at the centre of the coil; and in fact the same magnet arrangement used for the deflection experiment is used as the magnet of the galvanometer. It consists of 4 pieces of watchspring each 1 centimetre long, mounted behind a vane of mica.

Here, then, $g_1 = 1$, $g_3 = \cdot 25$. If the $\eta\ \xi$ were *exactly* as $\sqrt{2} : \sqrt{3}$, then G_1 would have the value $\frac{198\pi}{25}$. As a matter of fact it differs from that value by less than one one-millionth part, the term in brackets in the full expression for G_1 being equal to $1 - 0{\cdot}000005$. The term G_3 also becomes very small, for though the dimensions 9 : 11 in the cross-section of the coil do not in this case entirely eliminate corrections, owing to the different coefficients, the fact that these corrections have to be divided by the third power of the arithmetical mean radius makes them negligibly small. The error thereby introduced, even for large deflections of the needle, is far less than the errors inevitable in the determination of H, which cannot be relied upon, except by taking the mean of a very large number of observations, to a greater accuracy than one part in one thousand.

VARIATIONS IN THE PHYSICAL PROPERTIES OF BISMUTH IN A MAGNETIC FIELD.

BY M. HURION.

Recent experiments by M. Leduc, which it is easy to repeat, show that, if a plate of bismuth be placed in a magnetic field at right angles to the lines of force, the equipotential surfaces of a current traversing the plate become deviated from their original direction, whence it follows that the physical constitution of the metal becomes altered. This change may be illustrated by other effects, especially by the action on polarised light.

The experiments of Dr. Kerr have shown that a steel mirror placed between the poles of an electro-magnet brings about a certain change of angle in the polarisation plane of a ray striking perpendicularly when the current is sent through the electro-magnet, the rotation taking place in a reverse direction to that of the current which causes the magnetisation. Bismuth has similar properties, as shown by the following experiments :—

A mirror is procured, the reflecting surface of which is composed of bismuth, made by running this metal in a molten state on to a glass plate, heated in accordance with M. Righi's practice.

The glass plate with a thin coating of metal is placed between the poles of an electro-magnet, the armatures of which are pierced with a central hole. One of them is flat and the other conical; and the light arrives by the hole of the latter.

The ray reflected normally returns to its original direction, and meets, at an angle of 45°, an unsilvered glass which allows the direct light to pass and throws back the reflected ray laterally. The incident light traverses the polarising system of a Laurent saccharimeter; and the reflected light is received in the analyser of the same apparatus. The electro-magnet may be traversed, sometimes in one direction and sometimes in another, by the current of a Gramme machine.

It is observed that the plane of polarisation of the reflected ray diverges about 30′ when the direction of the current is reversed, the rotation being in the same direction as the current which causes the magnetisation. It is clear that the effect observed is partly due to the action of the glass plate.

In order to account for this last action, the bismuth may be removed from a small portion of the glass plate, and, placing the analyser at the other end of the apparatus, the ray transmitted may be observed. It will be found that the polarisation plane of the light which has traversed the glass turns through an angle of 24′ when the direction of the current is changed, the rotation taking place in the direction of the current. Now, in the first experiment, the glass plate, being traversed by the light twice, should have produced a rotation of 48′, but the observation has given 30′. It must be concluded from this that the bismuth has caused the polarisation plane to make an angle of 18′, in a direction contrary to that of the coil current.

This result may be compared with the effect produced by a steel mirror under the same conditions, experiment showing a rotation of 22′ in a direction contrary to that of the electro-magnet. If the steel mirror be covered by the plate carrying the bismuth mirror, a rotation of 28′ in the direction of the current will be observed, whence it may be concluded that the effect due to the glass plate will be found by adding to this rotation that produced directly by the steel, which gives for the effect of the plate 50′ instead of 48′, the number found above. The verification is therefore satisfactory. Experiments now being carried out have shown that the electric resistance of bismuth increases when placed in the magnetic field.—*Journal de Physique.*

ELECTRIC LIGHT INSTALLATION IN THE LEIPZIGER-STRASSE AND POTSDAMER PLATZE, BERLIN.

Fr. von Henfner-Alteneck describes in a previous paper in the "Electrotechnische Zeitschrift" the engineering details of this installation. The present deals particularly with the commercial results, which are especially interesting, as the circumstances were such as to allow a fair comparison with gas. The installation consisted of thirty-six arc lamps, and the average length of time each arc was in use during the year was 1,900 hours, giving a total of 68,400 lamp hours. Gas engines were used entirely for motive-power, the gas supplied being of the same quality as that used simultaneously for lighting the neighbouring streets. The price of the gas was taken as 13.3 pfennige per cubic metre (approximately 3s. 9d. per 1,000 cubic feet), which is the estimated cost of the gas used for street lighting by the municipality of Berlin, and somewhat less than the retail price. The following is an

Digitized by Google

analysis of the cost of maintenance from the 20th September, 1882, to the 20th September, 1883 :—

	Marks.
Gas consumed (including the lighting of the machine house)	10,156
Water	1,654
Oil and waste	2,096
Carbons for the arc-lamps	5,472
Repairs	540
Labour and attendance	3,836
Rent of ground for the machine house	300
Fire insurance	91
Sundry disbursements	390
	24,535

The author points out that as each arc light required about 1 horse-power the cost of the motive power per horse-power hour is about 20 pfennige, or 2·4d. With a steam engine in place of the gas engines this might be reduced to 0·6d. The actual cost to the municipality of lighting an equal length of the neighbouring streets by gas, though not with the same illumination, was 26,000 marks.

The author proceeds to discuss the question of the depreciation of the plant, and makes, in passing, the interesting observation that the cable employed, which consisted of a copper wire served with steeped hemp and sheathed with lead, showed no signs of deterioration, although subjected to an electromotive force of 650 volts.—*Abstract, Inst. Civil Engineers.*

FATAL ACCIDENT FROM A DYNAMO AT THE HEALTH EXHIBITION.

On Saturday evening, shortly after seven o'clock, Henry Pink, about twenty-one years of age, an attendant in the electric light shed of the Health Exhibition, employed by the Commissioners under Mr. Gooch, the general superintendent of the electrical department, met his death by incautious contact with one of the dynamos used for supplying the electric light. As there has been a great deal of misrepresentation in connection with this sad event, we have been at considerable pains to ascertain the true facts of the case ; and we have been greatly aided in our endeavours by the engineer to the makers of the dynamo, who court the fullest investigation.

It was Pink's duty merely to go round and oil the dynamos, and to ascertain that they ran smoothly and without heating ; and he had been repeatedly cautioned never to touch them with both hands at once. It appears that the deceased had accomplished this duty, and, according to the evidence of a visitor who saw the whole of the sad occurrence, was standing near the larger of the two Hochhausen dynamos, of American manufacture, supplied by Messrs. Edmunds and Goolden, of 2, Victoria Mansions, Westminster, S.W. This machine supplies 25 arc lamps in a single circuit, generating 11 amperes at 1,200 volts. But lately, by desire of the Commissioners, it has been forced beyond its normal duty, so as to maintain 29 lamps, and has consequently been the object of special attention. It may here be mentioned that, since the sad event occurred, this machine has been carefully tested by the electrical staff of the Exhibition, and has been found in perfect working order.

The above-named visitor, Mr. William H. Tilley, whose detailed evidence is reproduced below, saw Pink aimlessly playing with the large Hochhausen dynamo, having his left hand on the upper brushes, and turning half round so as to face the dynamo, having his back to the barrier which prevents the public from approaching the machines. He then mechanically brought his right hand on to the bearing at the top of the standard, as though to feel if it were warm, without removing his left hand from the upper brushes, and then, it is supposed, placed his right hand on the lower brushes, when the fatal event followed. Death, however, was not instantaneous, and, indeed, did not ensue until fully ten minutes after the contact must have been made. It is not conclusively established that the unfortunate man actually touched both brushes at once, though it is proved that he touched the upper brush with the left hand and the spindle bearing with his right. There are therefore two theories as to the immediate cause of death. One that he died from the effects of the shock caused by the full current of the machine, which appears to be the one generally received ; and the other, that he only received the shunt circuit between the upper brush and the bearing, and that death ensued mainly from fright at having received this shock of minor intensity.

The inquest was held on Wednesday, at St. George's Hospital, by the Coroner for West Middlesex, Mr. A. Braxton Hicks, when the case was watched by Mr. A. P. Bower, for Messrs. Edmunds and Goolden, and by Mr. Arthur C. Moore, for the Executive Council of the Health Exhibition.

Charles Pink, tobacconist, of 435, Edgware-road, identified the body of the deceased as his son, who had been an attendant in the electric light shed since the opening of the Exhibition. He had never before been employed in connection with electricity ; but had been in the habit of reading books on the subject, and knew perfectly well the risk he was running, and had even spoken of the painlessness of a possible fatal accident.

William H. Tilley, plumber, of Normanton, Rutland, who gave his evidence in a remarkably clear manner, stated that on Saturday last he was a visitor at the Health Exhibition. About half-past six in the evening he went into the electric light machine room, and witnessed the working of the dynamos. He saw the deceased put his left hand on the brush of the 25-light dynamo, and rub his finger up and down close to where the witness saw some sparks issuing. He had until then been almost facing witness, at right angles with the dynamo shaft ; but he now turned round, so as to directly face the dynamo, and put his right hand on the bearing at the top of the standard, as though to feel if the bearing were warm, and without removing his left hand from the brush. He then slowly brought his right hand towards the lower brush. Witness could not swear that he actually saw deceased touch the lower brush ; but he observed him give a convulsive clutch, and then appear unable to take his hands away. At that time he had both hands on the machine. His head went gradually back ; and then he let go with his left hand, and fell backwards against the barrier, where witness was standing. All this took place in the time one might count three. Deceased then fell back on his right side, when another attendant came up and caught him. Some water was fetched, and his hands were chafed. Brandy also was brought, but was not administered. [The poor fellow was too far gone.]

On a plan of this part of the dynamo shed and a drawing of the machine being produced, witness pointed out the brushes and other parts of the machine alluded to. Respecting the report that the deceased had an oil can in his hand at the time of the accident, witness distinctly stated that this is incorrect.

Eli Bates, electrician, an old servant of Messrs. Edmunds and Goolden, but who had been temporarily handed over to the Exhibition Commissioners, said he was in charge of the machines and the lamps, and the deceased was his assistant. There were two machines. His business at night was to go round and look after lubricators and feel the bearings. When Pink first came to work witness told him not to touch the framework and the brushes at the same time. He was told not to touch the brushes at all. The lubricators were of glass and filled with oil. [A lubricator was produced, showing it to be a glass vessel encased both top and bottom with brass, which was removed from the bearing to be filled.] In answer to questions, witness said it was perfectly safe to touch the machine with one hand. He had scores of times warned Pink against touching it with both hands at one time.

T. Clark, an electrician in the employ of the Brush Company, and in charge of a neighbouring machine, said he saw the deceased stagger against the barrier, with his hands stretched out towards the dynamo. He called Bates' attention to the fact, saying, "Your mate has fainted." He and Bates went to his assistance, and he vomited a white substance like milk, and was then carried away. In answer to the jury, he stated that he considered the machine to be perfectly safe.

Mr. George E. Bloxham, house physician at the above hospital, stated that the man was quite dead when admitted. There were no external marks excepting a mark, as though of a slight burn, between the fore finger and thumb of the left hand. A *post-mortem* examination was made. All the appearances pointed to death from shock by electricity, the condition of the heart and veins, together with the state of the blood, being consistent with death from that cause.

Alexander P. Trotter, civil engineer, engaged on the staff of Messrs. Edmunds and Goolden, produced a diagram of the machine, and briefly described its working. He stated that it was a matter of common knowledge to the workmen and attendants that it was highly dangerous to touch such a machine with two hands. He added that he was in the habit of regularly examining the machine, and feeling it with one hand. There were two classes of machines, one of which was not dangerous [the incandescent], but this one worked twenty-five or more arc lights upon one wire, thus producing twenty-five times the force required for one lamp. If the two brushes were touched, one with either hand, a current would pass through the body of the deceased, which would undoubtedly prove fatal. In reply to Mr. Arthur C. Moore, solicitor to the Executive Council of the Health Exhibition, who asked if every

Digitized by Google

reasonable precaution had been taken against accidents, witness replied distinctly in the affirmative, and took the opportunity of stating that there had been a distinct but unfounded charge of cruelty brought against the owners of the machine for not providing india rubber boots and glass oil cans for the attendants. [This charge was made by a correspondent to a morning paper, who said he had been an eye witness of the accident, and who further took upon himself to say that there was sufficient earth leakage from most machines to cause a fatal shock, if any part were merely touched by a metal oil can. This gentleman had been summoned as a witness; but, as it turned out that he only saw the deceased carried out, and that his other statements were mere assumptions, his evidence was not taken.] Mr. Trotter further stated that there was no necessity for taking an oil can to the lubricators, as they could be removed and then filled.

The Coroner, in summing-up, remarked that it was evident the deceased had been fully warned, or otherwise the accident would have occurred during the first week of his engagement.

After a brief deliberation the jury, in returning a verdict of accidental death, expressed their opinion that, though there was no danger to the public, a notice that the machines should not be touched with both hands at the same time should be posted at the spot.

"Electricians who are anxious to promote the popularity of the new light would do well to pay special attention to whatever means there may be of obviating such accidents as that which befel one of the men engaged in the dynamo shed at the Health Exhibition on Saturday night." So says the *Daily News*, in commenting on this unfortunate accident; and we are entirely of the same opinion. Further, we see no reason why such accidents should not be rendered impossible. The use of an india rubber glove, worn on the left hand, so as to leave the right free for work, in the case of an ordinary right-handed man, should be made compulsory on all who have the conduct of high-tension dynamo machines, and a few short and plain rules should also be printed in large type, and posted up prominently in the neighbourhood of the machines. Apart from humanitarian considerations, the effect which this sad accident is likely to exert on the cause of electric lighting is most serious, in the direction of destroying confidence, especially among those who look only at the sad effect, without going thoroughly into its cause—simple negligence.

PROFESSOR ROWLAND'S PRESIDENTIAL ADDRESS AT THE PHILADELPHIA CONGRESS.

To the student of science who has a disposition to look into the pages of history, no life has greater interest than that of Archimedes, and yet there are few men about whom so little is known. Living more than 2,000 years ago, the accounts of him which have come to us are little short of fabulous, and yet they are of such a nature that we can say without any doubt that he was a genius such as the world has seldom seen. To him we owe some of the fundamental facts of mechanics, such as the principle of the lever and the pulley, and the fact that a body immersed in a liquid loses in weight as much as an equal volume of liquid weighs. And in military engineering his success was so great that he prolonged the siege of Syracuse by the Romans from what would probably have been a few days to three years. His engines shot against the enemy immense numbers of darts and huge stones, which mowed them down in columns, and falling on their ships destroyed them. He thrust out huge beams from the walls over the ships, and drew them into the air, where they swung to and fro to the amazement and terror of the Romans, and were finally dropped and sunk to the bottom of the sea. He is even said to have set them on fire by means of the reflected light of the sun. But his principal work was in geometry, and of this I only need to quote the words of Professor De Morgan referring to those geometrical works of Archimedes which have come down to us. "Here," says Professor De Morgan, "he finds all that relates to the surface and solidity of the sphere, cone, and cylinder and their segment. A modern work on the differential calculus would not give more results than are found here." As to the quality of the individual, the impression which his writings give us is that of a power which has never been surpassed. No one has a right to say that Newton himself, in the place of Archimedes, could have done more.

Thus before the birth of modern science, in the dim ages of the past, when the light of history begins to fade and the mist of legend to cover our view, there lived a man of almost superhuman intellect, whose mind seemed equally adapted to either pure or applied science. And yet Plutarch says of him, "Archimedes possessed so high a spirit, so profound a soul, and such treasures of scientific knowledge, that, though the inventions (referring to his military engines) had now obtained for him the renown of more than human sagacity, he yet would not deign to leave behind him any commentary or writing on such subjects; but, repudiating as sordid and ignoble the whole trade of engineering, and every sort of art that lends itself to mere use and profit, he placed his whole affection and ambition in those purer speculations where there can be no reference to the vulgar needs of life—studies, the superiority of which to all others is unquestioned, and in which the only doubt can be whether the beauty and grandeur of the subjects examined, or the precision and cogency of the methods and the means of proof, most deserve our admiration."

Here, then, at the dawn of science, the question of the relative value of pure and applied science had been brought up. To the people of Syracuse, who had to defend themselves against an overwhelming enemy, the military engines of Archimedes were of far more interest than the whole of geometry, for the knowledge of the ratio of the solid contents of a sphere and its circumscribed cylinder cannot bring a dead man to life or restore wealth to a plundered city. And yet, from a point of view distant more than 2,000 years, we are forced to admit that Archimedes was right. Archimedes' engines of destruction have passed away, but the geometrical and mechanical truths which he discovered are to-day almost the axioms of the mathematician and the worker in physical science, and the ratio of the circumference of a circle to its radius is to-day the most important of our physical constants.

But this is only a meagre part of the influence of this man. The truths which he discovered have formed a part of the education of every student of mathematics to the present time, and have given pure intellectual enjoyment to all. They have helped to form the minds of all those whom we consider great in our science, and they have done their share in that march of progress which is gradually transforming the world.

Great should be the honour in which we hold the intellect of Archimedes, but greater should be our reverence when we approach that noble spirit which could ignore all worldly considerations, and prefer the truths of geometry to the vast physical power given him by his other inventions, which were his amusements for a moment. We now see that he was right, but we cannot for a moment suppose that he foresaw, except dimly, any so-called practical advantages from his discoveries. A thousand times no! He preferred his geometrical labours because of a subtle quality of his mind, an instinct toward that which was highest and noblest, and a faith that the pursuit of what is noble is the surest road to the final happiness of the individual and of the world. Our highest moral qualities are of this nature, and we despise as the lowest of the low one who is honest because "honesty is the best policy," but esteem him whose instincts lead him to honesty whatever the consequences.

So we reverence the noble and lofty spirit of Archimedes, and yet we do not at the present day quite agree with his estimate of the relative value of his works. His military inventions were far from worthy of being despised, even though the only reason were that they gave the world three more years of Archimedes' life. The world is not formed of disembodied spirits, but of men, in whom there is a wonderful combination of mind and matter, and a sound mind in a sound body is the highest type of manhood. But we also know that the mind is hampered by many considerations connected with the body. Archimedes recognised this, and his noble spirit revolted at it. But to-day we see that no progress can come from this method of treatment; the body still remains, however much we may despise it, and the buzzing of a fly can disturb the most profound thought of the philosopher.

We now study the laws of nature and seek thus to assist our bodies in obeying the thoughts of our minds. Our railroads carry us thither and thither on the earth with somewhat the facility of spirits, and our thoughts pass with almost the speed of light to the uttermost portion of the earth. The steam engine does our work, and labour-saving machinery takes the place of our hands. With a minimum amount of labour we can to-day possess luxuries unknown even to kings in ancient times, and our minds are free to study the order of nature or engage in any intellectual pursuit we may desire. Instead of being the slaves of nature and grovelling in the dust before her to find the food which we crave, we have now assumed the command, and find her a willing servant to those who know her language.

But here we reach the keystone of the problem. To command her we must know her language. Knowledge, then, is the price of her service, and she obeys not the ignorant or degraded, but grinds them into dust beneath her heel.

Knowledge, then, is power, and it is more than power; it is that which the intellect most craves, and is the object of many of our highest aspirations. What is the truth is the goal of intellectual mankind in all ages, and its pursuit leads not only to intellectual, but also to physical satisfaction.

The pursuit of the one leads to the other, and we shall see as we proceed that the only way for the world to progress in practical science is by the cultivation of the theoretical science.

Pure science must exist before its applications, and the truths of pure science are far more reaching in their effects than any of its applications; and yet the applications of science often have a much more immediate interest for the world at large than many discoveries in pure science, which will finally revolutionise it, both physically and mentally. They both have their importance and both are at work in causing that intellectual progress in which the world is now pushing forward with giant steps. But there is this difference—the names of the great inventors are seen in every paper and their deeds are recounted to the rising youth of the country as examples to be followed. And yet the discoverers of the principles on which their inventions are based may have died in comparative obscurity, with poverty knocking at the door. We are in no danger of forgetting those who have been successful in those applications of science which are in daily use, and it is useless to repeat the story of the telegraph or telephone, but it will be of more interest for me to recall to your minds a few of the landmarks in our science, and then to consider the present state of our science, with a possible glance into the future.

Thus we shall obtain a clearer view of how our science has been built

Digitized by Google

up, and of the means which are necessary for its further progress. We shall also see the relation between pure and applied science, and the relative importance of the two in the progress of the world.

It is impossible for one here to discuss the reasons why the ancients followed their science to so short a distance, and the world had to wait more than two thousand years before the light of modern science commenced to shine. It must be left to the psychologists and historians. But this I may say, modern progress is cumulative. By the study of the science of the past, the minds of men are trained for its further advance in the future, and so when there was no science to study there could be but little training of the mind in the true methods of thought.

The average intellect of mankind has improved, and what could only have been comprehended in past times by a few is to-day understood by the majority of educated persons. And this increase has been most apparent in the reason and moral sense of mankind, the two qualities of the mind which come most into play in the study of science. To the mind of the ancients, where the imagination ran riot without the guide of reason or a warning from their moral sense to speak the truth, it was easier to attribute the attraction of rubbed amber to an inherent soul or essence, which, awakened by friction, went forth and brought back the small particles floating around, than to examine and find out the truth.

The simple experiment of the amber remained without investigation for 2,200 years. Had the reasoning of many modern persons been followed, we should never have had a science of electricity. Why should anybody investigate this phenomenon, this feeble force, which could only attract a few particles of dust? The world could eat, drink and take its ease without doing anything in the matter, and it did so for more than 2,000 years of intellectual, moral, and physical degradation. Then the awakening came, and men began to feel that they were reasoning beings. They began to see that there were other pleasures in the world besides animal pleasures, and that they had been placed in this wonderful universe that they might exalt their intelligence by its proper study. No question of gain entered into the minds of these early investigators, but they were led by that instinct towards truth which indicates the highest type of man. And yet their researches have transformed the world, not only intellectually, but physically. Some would say that science had been degraded by its applications, but who that looks over the world at the present time can think so? There is no danger of this view becoming general; the danger is in the other direction, and that science shall be degraded in the estimate of the world by the idea that its principal use is to be applied to the common purposes of life. A thousand times no! Its use is in the intellectual training of mankind and the high and noble pleasure it gives to those who are born to understand it; to lift mankind above the level of the brute, and to make him appreciate the beauties and wonders of nature; to cause him to stand in humiliation and awe before that universe which the intellect of ages has attempted to understand, and yet has failed; to make even Newton say: "I know not what the world may think of my labours, but to myself it seems to me that I have been but as a child playing on the sea shore; now finding some pebble rather more polished, and now some shell rather more agreeably variegated than another, while the immense ocean of truth extended itself unexplored before me."

But the great moral law of the universe here enters. If the world would only pursue those things which are high and right and noble its reward would not be confined to the minds of men. Physical rewards await it as well, and disease, that principal cause of human misery, would almost pass away when the effect of inheritance from the present generation had passed. So the pursuit of pure science brings not only the rewards I have mentioned but the physical rewards of applied science, and the pursuit of applied science gives wealth which may be again employed to further pure science. So the two react on each other to produce that perfect whole, modern science, pure and applied.

This moral law of the universe is well illustrated by the well-known story of Solomon.

"The Lord appeared to Solomon in a dream by night; and God said, ask what I shall give thee.

"And Solomon said: Thou hast made thy servant king instead of David my father; and I am but a little child; I know not how to go out or come in.

"Give, therefore, thy servant an understanding heart to judge thy people, that I may discern between good and bad; for who is able to judge this so great people?

"And God said unto him, because thou hast asked this thing, and hast not asked for thyself long life; neither hast asked riches for thyself, nor hast asked the life of thy enemies; but hast asked for thyself understanding to discern judgment. Behold, I have done according to the word; lo, I have given thee a wise and an understanding heart; so that there was none like thee, neither after thee shall any arise like unto thee.

"And I have also given thee that which thou hast not asked, both riches and honour; so that there shall not be any among the kings like unto thee all thy days."

So the world, when it chose knowledge and truth above all things, acquired not only the treasures of pure theoretical science, but also the wealth and riches and honour which come from applied science such as the world has never seen before and could see in no other way.

It is to William Gilbert, an English physician, that we owe the commencement of the modern science of electricity. His book on the magnet was published in 1600 and contained his electrical experiments. Thus, at this early date the similarity of electrical to magnetic attraction was recognised. But how slowly did the subject advance! The difference between conductors and non-conductors was discovered by Grey. But not until 1746, 150 years after Gilbert, was the Leyden jar invented. Then the remarkable nature of the phenomenon became apparent, and the world was startled by it. The subtle spirit which went forth from the amber, which was so feeble as only to attract dust, now flashed forth with light and sound and heat, and could cause the strength of the giant to vanish. To the world at large there was now something worth looking into. But do we think that the spark from the Leyden jar is more wonderful than the gentle attraction of the amber? By no means, for, to the scientist, they are both equally remarkable and beyond our powers of explanation. It is only to the vulgar and uneducated taste that the tinsel and gew-gaws of an electric spark appeal more strongly than the subtle spirit of the amber. Nevertheless, despicable as the means, the spark of the Leyden jar acted as a trumpet call to Europe and even America to come to the study of the wonderful science of electricity. At no other time has there been such excitement over any electrical discovery, and electrical experiments became general.

It was only after the discovery of the Leyden jar that the idea of an electric current occurred to mankind, and this current was even transmitted to a distance by a wire and a shock given to a person across the Thames, the water forming the return circuit. And the English experimenters even went so far as to form a circuit with the two observers two miles apart, using the earth as the return circuit. Thus the fundamental fact which forms the basis of the telegraph was early observed.

But isolated facts are of little value unless connected together by something which we call a theory, and in this line we owe much to Franklin, whose letters on this subject appeared between 1747 and 1754. To him we owe the theory of positive and negative electricity, and the fact that they are always generated in equal amounts, a law whose importance can scarcely be estimated. He investigated the Leyden jar, and showed that the coatings had equal positive and negative charges, and explained the fact that the jar cannot be charged when the outside coating is insulated. He invented the charge and discharge by cascade, and showed that it was the glass of the jar and not the coatings which contained the charge. He discovered the property of points in discharging an electrified body and the identity of lightning with electricity. He also made the first experiments upon atmospheric electricity.

To Canton is due the honour of giving the first experiments of induction, but Franklin is the first who gave the general law of this species of action. Truly our country and this city should honour the memory of this man.

But it is not my purpose to repeat to you in detail the familiar history of our science. Thus far, no important applications of electricity had been discovered; there was nothing but pure science to attract investigators, and thus the science remained for many years after.

But no science is complete unless it is quantitative as well as qualitative. It is now very nearly 100 years since Coulomb laid the foundation of electro-statics and Alpinus and Cavendish commenced to lay the foundation of mathematical electricity, and they were followed by Laplace, Biot, Poison, and Murphy.

The discoveries by Galvani and Volta in 1790 and 1800, and by Œrsted in 1820, gave us the galvanic battery and electro-magnetism, and it was not until the latter date that any useful practical application was possible. Then, so complete was the science that no factor of other than minor importance was necessary to transmit intelligence from one extremity of the earth to the other.

By the labours of the immortal Faraday, electro-magnetic induction was discovered and the modern dynamo-electric machine became a certainty.

To his other labours, both experimental and theoretical, the modern science of electricity owes much, but it is familiar to all. The name of Faraday needs no eulogy from me, for it stands where it can never be hidden, and the spark which Faraday first kindled now dazzles us at every street corner. No wealth came to him, although he had only to hold out his hand for it. But the holding out of one's hand takes time, which Faraday could not spare from his labours, and so the wealth which was rightly his went to others. Who will follow in his footsteps and live such a life, that the thought of it almost fills one with reverence? It is not only his intellect which we admire, it is his moral qualities which fill us with awe, his noble and unselfish spirit.

The name of Faraday brings us down to modern times, whose history it is unnecessary to repeat in detail, especially as there are some now present who have contributed largely to bring the science to its present perfection.

One of the principal features which we remark in our modern science of electricity is the perfection of our means of measuring both electrical and magnetic quantities. In this connection the great names of Gauss and Weber appear, the fathers of the modern absolute system of electrical and magnetic measurement, and that of Sir William Thomson, in no degree less distinguished. On the laws of electric attraction we base our electrostatic system of measurement, and on the magnetic action of the current, the great discovery of Œrsted, we base our electro-magnetic system and we connect these two systems by that great physical constant, the ratio of electro-magnetic to the electro-static system of units.

What can be simpler in theory than the electro-static system, based as it is on the law that electric attraction varies inversely as the square of the distance? We only have to know how the electricity is distributed and its attraction is known. Hence we must select the simplest possible case, such as two parallel discs, and to render the problem calculable, we add a guard ring to the movable disc. We then have the absolute electrometer of Thomson. This gives us a measure of the electric potential. Knowing the capacity and difference of potential of the surface of a condenser, we know its charge. But all these quantities, the calculation of the electrometer and the capacity of the condenser, depend upon the mathematical theory of electric distribution. Are we able to calculate the capacity of condensers of all forms? I am sorry to say we are not. The modern method of treatment is due to James Green, an English investigator, whose name should be held in honour by all electricians. But this method is what is called an inverse one. It is not a method by which we can calculate the distribution on any body at random, but the shape of the body and the electrical distribution on it are both found at once by a

Digitized by Google

species, as it were, of exploration and discovery. So that we cannot make our electrometers and condensers of any shape and then calculate them, but we are forced to make them of some simple geometrical form whose solution is known. We fit our apparatus to the mathematics rather than the mathematics to the apparatus.

But when we have satisfied all the conditions we measure out our static charges as easily as a quantity of matter. The manufacturer sells the oxygen and hydrogen in iron cylinders, and determines the amount by the product of the capacity of the cylinders by the pressure. Were there any buyers of electricity we might sell them a Leyden jar full, and determine the amount by the product of the capacity of the jar by the electric potential. According to this analogy, then, the electricity is similar to matter and the potential to fluid pressure, while the word capacity has a similar meaning in both.

In the electro-magnetic method of electrical measurement we make use of the magnetic action of the current, either on a neighbouring magnet or another current or portion of the same current. The laws of the action of a current on a magnet were discovered by Biol and Savart, and of two currents on each other by Ampère, and the results applied to practical measurement to-day give us galvanometers of all kinds and the electro-dynamometer of Weber. By the galvanometer we can measure the quantity of electricity passing at any moment, but by the electro-dynamometer we measure the integral square of the current, a quantity on which the heating of the circuit and the energy expended depends.

Thus the electro-dynamometer measures the energy from an alternating current dynamo-electric machine as easily as from one giving a continuous current, but to know this energy we must know something else besides the integral square of the current, and this is either the resistance of the circuit or the electromotive force. But the measurement of electromotive force depends on a resistance. The question then comes up as to what unit of resistance is the proper one. Here we have to refer to the mathematical theory of the subject, and the great law of the conservation of energy tells us that what is known as the absolute unit of electrical resistance is the proper one for use in this case. Hence the great practical use of determining this unit. The experiments of Kirchoff, Weber, Kohlrausch and the British Association found a value from one to three per cent. too large.

(TO BE CONTINUED.)

COMPANIES' MEETINGS & REPORTS.

Direct Spanish Telegraph Company (Limited).

The twenty-second ordinary general meeting of this Company was held at the offices, Leadenhall-buildings, Leadenhall-street, E.C., on the 29th September, under the presidency of Mr. Neil Bannatyne.

The MANAGER (Mr. Ch. Gerhardi) read the notice convening the meeting, and the report of the Directors was taken as read.

The CHAIRMAN: From the report and accounts you will be able to form your own opinion as to the present position of the Company, with the aid perhaps of one or two remarks which I shall now make. Although the receipts are, as stated in the report, £243 in excess of those for last half year, the working expenses are only £12 more, and they are £56 less than for the corresponding half of 1883. I need not say to the shareholders that the Board will continue to give their best attention not only to promote the traffic of the Company, but also to keep down the working expenses as much as possible, consistently with the efficiency of the line. It will, perhaps, be in the recollection of the shareholders that—I think it was at the last meeting or the meeting before—I mentioned that the amount of debentures we thought we should have to issue for the payment of the new cable, &c., would be about £65,000. I am glad to state, however, that from our having a quantity of new cable in stock, we now expect that the sum of £62,000 will be sufficient to pay for the new cable and connections. The Board have been able to make arrangements for the more rapid settlement of the quarterly accounts, and in consequence they expect they will be able to pay the dividend on the preference shares in the course of about a week after the meeting, instead of six weeks or two months, as has been the case on the last two or three occasions. As regards the prospects of traffic for the half year which commenced on the 1st July last, I may state that the July receipts were £1,496, those for August £1,173, and those for September—estimating the amount upon the returns for the first twenty-six days—will probably be £1,650. This is the best month since the half year commenced, but the total shows a decrease of £313 on the corresponding period of last half year. This decrease is fully accounted for by the great falling off of trade in Spain, in consequence of the quarantine regulations established by the Spanish Government on account of the cholera epidemic. This quarantine has greatly affected the shipping trade with Spain, upon which the greater part of the traffic of the Bilbao cable depends. On another side, the traffic of the Barcelona-Marseilles cable has been much affected by the cholera, business in both these towns being at a complete standstill. Although no actual outbreak took place at Barcelona, 50,000 people of the better classes, including merchants, stockbrockers, &c., who give us our business, left that town. As an instance of the effect of the epidemic upon trade in Spain, the well-informed correspondent of the *Standard* at Madrid states that "there has been a decline of about one million sterling in the revenue since the middle of June, and a decline of several millions sterling in the values of the exports and imports." In the presence of these facts, we can almost congratulate ourselves that our traffic, which is solely dependent on the Spanish and French business, has not suffered more. Of course, you are all aware that the stagnation of business is not confined to Spain, but is general everywhere and in almost every department of commerce. During the severe outbreak of cholera at Marseilles, our staff in that town behaved very creditably, and stuck to their posts. The Board took steps to make them as comfortable as possible during this trying period. I think I have nothing else to add, but if there is anything in the report or the accounts on which any shareholder would like to put any questions, we will do our best to answer them to their satisfaction. I think, considering the adverse circumstances of the past half year—although we should, of course, like to be in a better position—we may congratulate ourselves that we are no worse off. He concluded by moving the adoption of the report and accounts.

Mr. HUNTER presumed that there was no intention of restoring the original cable for some time, and so spending more capital on the old cable.

The CHAIRMAN: No, I believe it is the intention of the Board at present to take no steps with regard to that matter. It may be our interest by and by to put that cable into working order again, but we shall be quite ready, when circumstances make it our interest to do so, to proceed in that matter then.

Mr. BEARD: What is your opinion of that old cable? Is it worth going on repairing?

The CHAIRMAN: I could not give an opinion, but here is Sir James Anderson, who is very competent to do so.

Sir JAMES ANDERSON: I should not like to give it up. I think the chances are in favour of putting that cable in order some day, when we get richer, and restoring it. It would take a good deal of money to put it thoroughly in order, and it is a pity to spend money in patching.

Mr. ATTRELL inquired when it was proposed to raise the debentures?

The CHAIRMAN replied that they were all raised and issued. In further reply to Mr. Attrell, the Chairman stated that the proportion of interest due on the debentures—to the 30th of June—was paid. The ordinary shareholders must remain in abeyance until the Company was in a position to pay them a dividend. They could not be more anxious to receive a dividend than the Directors were to pay them one. It was difficult to say when that would be, as a cable company was liable to so many contingencies. They saw how the cholera had affected the receipts of the Company in the last half year. As to the directors continuing to receive, notwithstanding, their remuneration of £400 a year, they earned it by their attendance on the Board, the trouble they took about the concerns of the Company, and the attention they gave to its business generally. The directors were considerable shareholders in the Company, and they were obliged to rest content without any dividend on their investment, just as the ordinary shareholders. If any ordinary shareholders were on the register now who were on the register when the preference shares were issued, they would remember that he was chairman at the time, and strongly urged the ordinary shareholders to take up their proportion of the preference shares. He pointed out that, even if the ordinary shares received no return, the dividend on the preference shares was perfectly secure, and that by taking their allotment of the preference shares in proportion to the number of ordinary shares they held they would get a very fair return on their money, even if the ordinary shares paid no dividend. He wished to add to what Sir James Anderson had said that in consequence of their friendly and intimate relations with the Eastern Company they would be in a position to take whatever steps they might consider advisable, with greater advantage, when the time came to deal with the old cable. Of course their relations with the Eastern Company added considerably to the strength of their position, and they had always found those relations work most satisfactorily.

A SHAREHOLDER inquired if there was any limit to the present working with the Eastern Company.

The CHAIRMAN: Twenty years.

The SHAREHOLDER thought that this put them in a satisfactory position.

Sir JAMES ANDERSON: We have a joint-purse arrangement.

The CHAIRMAN: Although the old cable is doing nothing, our new cable is carrying the traffic, and could carry a great deal more.

Mr. ATTRELL: I think the best way would be to sell the whole concern to the Eastern Company. They might make something of it.

The CHAIRMAN: Well, there are two parties to a bargain. Whenever the Eastern Company say they will give us a satisfactory price, I have no doubt that, even though there are two members of the Eastern Company on our Board, we shall be able to deal with them. He then again submitted the motion for the adoption of the report and accounts.

Sir JAMES ANDERSON seconded the resolution, which was carried unanimously.

The CHAIRMAN next proposed the declaration of the preference dividend, at the rate of 10 per cent. per annum, less income-tax, for the half year ended the 30th June last. He added that they hoped to pay it in the course of ten days or so.

Mr. EDMUND ETLINGER seconded the motion, which was carried unanimously.

Mr. COCHRANE then proposed a vote of thanks to the Chairman and Directors for their conduct of the Company's business. He was, he said, one of those who felt some time ago that a change was desirable in the constitution of the Board, but he thought that the present was not the time to raise such a question. They had recently had an accession of strength on the directorate, and he had no doubt that the Board had done their best in past times to carry out what was in some respects—he did not know from what cause—an unfortunate transaction. He had some considerable amount in the ordinary shares, and would be very glad to see a dividend on them. He thought the present time was hardly that at which to blame the Directors, who seemed to have adopted the only course open to them. They had previously gone on spending a lot of money in patching the old cable, which was constantly breaking and constantly entailing fresh expenditure. He thought

Digitized by Google

the shareholders should at least withhold commenting on the very moderate remuneration of the Board, with which he thought they could not reasonably find any fault. He very heartily proposed a vote of thanks to the Directors, and hoped that their united services might bring the Company out of what was at present a rather dull position, and that by and by they might be able to meet them with heartier feelings than at present.

Mr. KIDMAN seconded the motion, which was carried unanimously.

The CHAIRMAN: On behalf of my colleagues and myself I return you our best thanks for your vote of approval and confidence. We have done all we could to promote the prosperity of the Company under somewhat adverse circumstances, which were entirely beyond our control. We could not control the state of trade in Spain and France, or the outbreak of cholera. For myself I will only say that I have not at all lost confidence in the ultimate success of the Company. When we have a revival of trade generally, and more especially in Spain and France, I have no doubt, with our new cable and our connection with our friends of the Eastern Company, that we shall, after a moderate period of time has elapsed from the commencement of that prosperity, be in a position to give a fair return on our ordinary shares.

Mr. HUNTER inquired whether the new cable was of a different type from the old.

Mr. ETLINGER replied in the affirmative, and observed that the new cable was much stronger.

Mr. ATTRELL proposed a vote of thanks to the officers for their services in the past half year, coupled with the name of the manager.

Mr. KIDMAN seconded the motion.

The CHAIRMAN in putting the resolution observed that it had the cordial approval and support of every member of the Board.

At the suggestion of Sir JAMES ANDERSON the auditors were included in the vote, and the motion was then carried unanimously.

The MANAGER, in reply, expressed his acknowledgements, and said he would do his utmost to promote the the welfare of the Company.

The proceedings then terminated.

Great Western Electric Light and Power Company.

The Directors beg to submit to the shareholders their second annual report upon the operations of the Company, for the year ending June 30, 1884, together with the statement of accounts, duly certified by the auditors. The Directors beg to report that the necessary steps for the reduction of the Company's capital have been completed, and the assent of the Court given on August 6, 1884. The shareholders are thereby freed from any further liability in respect of their shares, and the Directors' promise on taking office is thus fulfilled. That after considerable negotiation the claim made by the liquidator of the Devon and Cornwall Electric Light Company has been settled upon the following terms:—The surrender to the liquidator of the shares held by your Company in the Devon and Cornwall Electric Light Company, and the issue to him of 3,000 fully paid shares of £2 10s. each in your Company. These terms your Directors consider fair and equitable. That the action referred to in last year's report as pending against your Company by certain shareholders in the Devon and Cornwall Company has been dismissed. Your Company is now clear of litigation, and free to carry out the objects for which it was formed. That considerable reductions have been made in the expenses of management, which, including Directors' fees, last year stood at £4,297 4s. 9d., this year £1,676 15s. 8d. This amount would have been still smaller had all the economies introduced been in force during the entire year, but it was only in March last that the Directors succeeded in placing the expenditure upon what they consider a satisfactory basis. The amount of business offering has been considerable, but only a small portion could be secured at such rates as the Directors could entertain, as they are determined to undertake no work except at a fair profit. The lighting stations at Bristol and Cardiff have been maintained during the year, and the most anxious attention has been given to reducing the working expenses and increasing the income. The following figures show the receipts as compared with last year:—1882-3, £520 8s. 6d.; 1883-4, £1,433 14s. 5d.; increase, £913 5s. 11d. The Fine Art Exhibition held at Cardiff, from February to May this year, was lighted from your Cardiff station. The light was much appreciated, and the installation was in every way a success. As fast as possible the old yearly contracts are being terminated, and all lights charged for by the hour instead. The number of lamps in use is as under:—Bristol, arc 28; Cardiff, arc 34; total, 62. Bristol, incandescent 334; Cardiff, incandescent 64; total 398. These numbers will probably be increased during the coming winter. The plant is in good working order, and fully capable of the work required of it. That a portable plant, consisting of engine, boiler and dynamo, and five 2,000 candle-power arc lamps has recently been purchased. This plant is especially adapted for the lighting of fancy fairs, bazaars, *fêtes*, flower shows, public meetings, &c., and is often the means of introducing the light into a district, and thus making it known. Shareholders hearing of local bazaars, *fêtes*, &c., would materially assist the Company by sending early particulars to the office, so that the Company may have an opportunity of tendering for the lighting. Steps have been taken to canvass one or two likely towns, with a view of testing their suitability for erecting lighting stations, but so far no town has held out a sufficient promise of support to warrant the erection of plant. That in the early part of the present year negotiations were opened with the Anglo-American Brush Electric Light Corporation, which resulted in the sale to them by your Company of the right to light by electricity railway trains in your district, together with the right to erect in your district any plant that may be necessary to carry out such lighting. In exchange for this concession the corporation surrendered £5,750 in fully paid shares in your Company, thus reducing your capital account by that amount. That in looking forward to another year's working, whilst a large business must not be expected, your Directors trust by exercising prudence and economy to be able to carry on the Company for a small outlay, in the belief that for those electric lighting companies which can live through the present period of depression there remains a good prospect of success in the future. One of the chief difficulties in the way of profitable business—the fact that so many companies were ready to undertake work at a loss—is now rapidly disappearing, several such companies having gone into liquidation during the year. This reduces the competition and increases the chances of obtaining profitable work. The result of this year's trading shows a loss of £537 19s. 11d.; to this must be added £529 5s. 3d. written off for depreciation of plant, making a total loss of £1,067 5s. 2d. for the year. Deducting this and the law charges incurred during the year from the £5,750 received from the Anglo-American Brush Electric Light Corporation, there remains a profit of £4,073 16s. 11d., which it is proposed to write off the shares to be issued to the Devon and Cornwall liquidator. The balance sheet has been drawn accordingly. Under the Articles of Association one of your Directors, Mr. J. B. Braithwaite, jun., retires by rotation, and, being eligible, offers himself for re-election. The auditors, Messrs. Turquand, Young, and Co., also retire under the Articles of Association, and, being eligible, offer themselves for re-election. The new certificates will be ready in exchange for the old certificates on the re-opening of the transfer books on 11th October, and shareholders will oblige by sending in their old certificates for exchange as early as possible after this date.

UNIVERSITY COLLEGE, BRISTOL.

In the Department of Experimental Physics at this College LECTURES and CLASSES arranged progressively are given throughout the Session, and Instruction is given in the Physical and Electrical Laboratory. In the Engineering Department Special Courses have been arranged for Students studying for the profession of Engineering who wish to include in their professional training some knowledge of Electricity and its technical applications, especially with regard to Electric Lighting and Transmission of Power, Telephones and Telephonic Systems, Telegraphy, Electro Plating, &c.

UNIVERSITY LECTURES at POPULAR PRICES.—Courses of WEEKLY LECTURES, accompanied by CLASS TEACHING, will be held during the Coming Session (October-December, 1884), in connection with the London Society for the Extension of University Teaching, as under:—ELECTRICITY, at Highbury; SOME PHYSICAL PROPERTIES OF AIR AND WATER, at Whitechapel. Lecturer, J. W. WAGHORN, D.Sc., R.N., Instructor in Physics at the Royal Naval College, Greenwich. For prospectuses and all information apply to the Secretary, University Extension, 22, Albemarle-street, W.

NOTES.

TELEGRAMS FOR TASMANIA.—The cable between Australia and Tasmania is now repaired.

THE TELEGRAPH IN BOKHARA.—From Vienna it is reported that telegraphic communication has been completed to Bokhara.

TELEGRAMS FOR CHINA AND JAPAN.—The cables between Hong Kong and Saigon and between Haiphong and Hong Kong are interrupted.

UNIFORM MERIDIAN.—The International Prime Meridian Conference, which has been sitting at Washington for about a week, has adjourned without coming to a decision on the question at issue.

THE MACKAY-BENNETT CABLE. — On Wednesday the "Faraday" completed the work of laying the second Mackay-Bennett cable, when the shore end was made fast at Dover, New Hampshire.

THE MILITARY TELEGRAPH CORPS.—The transport ss. "Deccan," carrying the final detachment of telegraphists belonging to the Postal Telegraph Service and Royal Engineers, arrived at Alexandria on Tuesday, 7th inst.

EASTERN EXTENSION TELEGRAPH COMPANY.—The traffic receipts of this company, including all subsidies, for the month of September amounted to £41,590, and to £39,576 in the corresponding period of 1883, being an increase of £2,014.

THE TELEPHONE IN THE DOCKYARDS.—The Admiralty have directed telephonic communication to be established at Sheerness Dockyard between the offices of the captain-superintendent and the chief constructor and the various workshops.

WESTERN AND BRAZILIAN TELEGRAPH COMPANY.—The traffic receipts of this company for the week ending 3rd October, were £2,779, after deducting the "fifth" of the gross receipts payable to the London Platino-Brazilian Telegraph Company.

ELECTRICAL COMPANIES IN BRUSSELS.—It is rumoured that a project is on foot for an amalgamation of two leading electrical companies under the style of "Syndicat d'Electricité," with the material support of one of the Belgian banking companies.

FIRE TELEGRAPH.—At the usual weekly meeting of the Oldham Board of Guardians the seal was affixed to a contract between the Postmaster-General and the Board for the maintenance of telegraphic communication between the workhouse and the fire brigade station.

ANTWERP EXHIBITION.—On account of the numerous applications for space, the last date for receiving exhibits has been deferred to the 20th inst. A much larger covered area than that originally contemplated will be required, and the works are being pushed forward with spirit.

FROM AMERICA.—A new telephone instrument has been invented by which the crying of a baby may be heard at the distance of a hundred miles, and bachelors are beginning to consider whether it is better to marry or move out of the country.—*Cincinnati Merchant Traveller.*

ELECTRIC LIGHT IN BRUSSELS.—The temporary lighting of the Grand' Place, Brussels, by two 10,000 candle Jaspar lamps, mounted on masts 62ft. high, is most successful. The fine old Hôtel de Ville and the façades of the ancient houses of the various guilds appear to great advantage in the artificial moonlight.

APPOINTMENT.—With a view to the better administration of the telegraph arrangements in Egypt Her Majesty's Government have, at the nomination of the Postmaster-General, appointed Mr. A. Otway, one of the assistant-superintendents at the London Central Telegraph Office, to be Superintendent of the Telegraphs at Cairo.

ELECTRIC LIGHT ON THE CALEDONIAN RAILWAY WORKS.—A party of Royal Engineer officers lately visited the Airdrie branches in construction of the Caledonian Company's new Lanarkshire Extension. The excavation is being effected by steam navvies, which work, with the aid of the electric light, by night as well as by day.

THE TELEPHONE AT MONTE VIDEO.—The Uruguayan Telephonica Compagnia, founded 1st February of the present year, numbered 632 subscribers on 1st July, notwithstanding the competition of the River Plate Telephone Company, with 450 subscribers, which had been in existence a long time previously. The former company use Blake-Bell, and the latter Gower-Bell instruments.

GLOBE TELEPHONE SHARES.—In consequence of an advertisement, headed as above, issued in the newspapers by Messrs. W. Gutteridge and Co., the secretary of the United Telephone Company (Limited) writes as follows to the *Daily Telegraph*:—"I am instructed to inform you that the statements therein contained concerning this company's arrangements with the Globe Company are erroneous, and calculated to mislead the public."

LA LUMIERE ELECTRIQUE.—Dr. Cornelius Herz, who was at one time connected with the Mount Sinai Hospital, New York, is very prominently connected with electrical enterprise in Europe. He is editor and proprietor of *La Lumière Electrique*, Paris. He is French by birth, but emigrated to America at a very early age. He returned to France in 1870, to organise the telegraphic department under Gambetta.—*Jewish World.*

THE ELECTRIC LIGHT IN DUBLIN.—A *fête* has been held in Dublin at which a number of Weston arc lamps have been used. These gave so much satisfaction that another *fête* was given, at which a still larger number of the lamps were employed. The lights were very brilliant, and were much admired by a numerous and critical assemblage. The arrangements were under the management of the Maxim-Weston Company, who supplied the whole of the plant.

ELECTRIC LIGHT AT ANTWERP.—Unlike the telephone, the electric light has not been taken up to any extent at Antwerp. The large goods station is thus illuminated, and the proprietor of a café adopts it as an attraction, taking his power from a neighbouring manufacturer's engine. There is here a fine field for a company who would generate current at a central station and supply it to subscribers for electric lighting, as the Hammond Company does at Middlesbrough.

EASTERN TELEGRAPH COMPANY.—This company announces the payment of a dividend of 3s. per share on the preference shares for the quarter ending 30th September, 1884, and an interim dividend of 2s. 6d. per share on the ordinary shares, in respect of profits for the quarter ended 30th June, 1884. The register of transfers will be closed from the 8th to the 15th instant, both days inclusive. The traffic receipts of this company for the month of September amounted to £50,913, and to £42,778 in the corresponding period of 1883.

THE ELECTRIC LIGHT AT HEBBURN.—At the last monthly meeting of the Hebburn Local Board, Mr. C. F. Forster presiding, a discussion took place on the price paid for gas by the ratepayers of Hebburn. It was resolved that the chairman and Messrs. Tennant and Richardson be appointed a deputation to wait upon the Gas Company with a view to have the scale of charges reduced, and that Swan and Company be communicated with for the purpose of obtaining information as to the probable cost of lighting Hebburn by electricity.

ELECTRIC TRAMCARS IN BRUSSELS.—We assisted at some remarkably successful trials of electro-locomotive tramcars on the Brussels boulevards, and duly recorded the results. We also saw a contract that had been made between the electric company and the tramway company for working the Rue de la Loi line by accumulators for six months at the price of horse traction. A start was to have been made on 1st July. This was altered to 1st August, then to 15th September. In fact, the electric working was, like shows at a fair, always "going to begin." Now, however, the trials are suspended, and we do not even hear of a prospective date being named.

THE TELEPHONE IN FRANCE.—We learn from an article bearing this title in the *Bulletin de la Compagnie Internationale des Téléphones* that there is a question of the Société Générale des Téléphones granting a discount of 5 per cent. off subscriptions when paid for three years in advance. Further, that four persons occupying the same block of buildings may unite in a subscription of 300f. (£12) per annum. Increased facilities in provincial centres are contemplated. On the 2nd inst. the company had 5,417 subscribers, or 655 more than at the same time last year. Contrary to its original intention, the council of management has decided to take part in the Antwerp Exhibition of next year.

THE ELECTRIC LIGHTING ACT.—The electric lighting interest have, says the *Pall Mall Gazette*, commenced proceedings against the Electric Lighting-Act, which is now so generally regarded as a failure. At a recent meeting of the Dynamicable Society it was resolved to form a committee, including the names of most of the prominent electricians of the day, to draw up a report setting forth the errors in the evidence given by the "expert" witnesses before the Parliamentary Committee of 1882; and to organise a movement for the repeal of the impossible clauses in the Act of that year. More freedom to develop our industry according to the light of our own practical experience is the demand of the electricians.

PERSONAL.—We understand that Mr. J. Kenneth D. Mackenzie, lately engineer to the National Company for the Distribution of Electricity by Secondary Generators (Limited), and for some time practising on his own account at 25, Queen Anne's-gate, Westminster, has just entered into partnership with the Honorable Reginald Brougham, late engineer to the British Electric Light Company (Limited), and that they will commence business as engineers and electricians. We believe that Messrs. Mackenzie and Brougham do not intend to confine themselves to electricity alone, Mr. Brougham having practised for some years as a civil engineer, but will undertake any work connected with the principal branches of engineering. Their offices are at 15, Great George street, Westminster, S.W.

HEALTH AND ELECTRIC LIGHTING.—Mr. J. Angelo Fahie, C.E., member of the Society of Telegraph Engineers and Electricians, read a paper, on 3rd inst., before the Engineers and Architecture Section of the Sanitary Congress, Dublin (Mr. C. P. Cotton, M.I.C.E., in the chair), on "Electric Lighting considered from a Sanitary Point of View." The light afforded by electricity, he said, was far superior to all other illuminants in the fulfilment of health conditions. An ordinary gas burner deprived 17 cubic feet of air of its oxygen in an hour, and furthermore contaminated it with poisonous compounds. Electric lighting by incandescence consumed no oxygen, gave off no carbonic acid, or other compounds, and consequently did not at all vitiate the atmosphere. A full report of this paper, and the discussion that ensued, will appear in our next issue.

TELEGRAPH CLERKS' GRIEVANCES.—A large meeting of telegraph clerks was held at the Edinburgh Ship Hotel on Saturday last, to consider the reply of the Postmaster-General with reference to their Sunday duty petition. Several letters were read, reporting the progress of the agitation throughout the country. The following resolution was unanimously adopted :—"That this meeting of Edinburgh telegraph clerks records its feeling of regret and disappointment at the unsatisfactory reply received from the Postmaster-General with reference to their Sunday duty petition, and resolves to use every effort to obtain redress of the glaring anomaly in the treatment of provincial telegraph clerks, in so far as they are exceptionally treated by not being paid uniformly with the London clerks for Sunday work." Similar meetings are being organised throughout the country.—*Scotsman*, Oct. 7.

THE TELEPHONE IN BELGIUM.—During the month of September just past no less than 15,064 messages were exchanged by telephone between the subscribers to the telephone companies holding concessions and the telegraph offices which form the points of junction. Of this number 3,342 originated in Brussels, 2,904 in Liége, 2,841 at Antwerp, 2,345 at Ghent, 1,691 at Charleroi, 985 at Louvain, and 956 at Verviers. The whole population of Belgium does not much exceed that of London and its suburbs. It is stated that a definite understanding has been come to between the Belgian Government and the Bell Telephone Company for the working by this company of telephonic communications between towns on the Van Rysselberghe system ; and that a few privileged individuals who have exchanged telephonic messages between Brussels and Antwerp find no greater difficulty than in speaking to any part of the capital.

ELECTRICAL BALLOON PROPULSION.—MM. Tissandier, who were the first to apply electricity to the propulsion of balloons, have, since their ascent of 8th October, 1883, introduced some improvements into their balloon, and especially the rudder. On 26th September last they made a fresh ascent, with a result quite commensurate with their anticipations. Starting from Auteuil, a suburb of Paris, at twenty minutes past four in the afternoon, they made several evolutions in different directions over the city, progressing at one time for more than a quarter of an hour against the wind, in the presence of thousands of spectators. The speed of the wind was about 3 metres a second, and that of the balloon rather higher. With a screw speed of 190 revolutions per minute, an actual power of 1½ horse was obtained, the battery being provided with larger zinc plates than before, and a hotter, more acid, and more concentrated solution of bichromate of potash.

BLACKBURN'S PORTABLE TESTING APPARATUS.—This instrument, of which Messrs. Clark, Muirhead, and Co. are the manufacturers, contains a Wheatstone bridge, resistance coils, galvanometer, and battery, with the necessary keys and connections joined up, for instant use. The dimensions permit of its being carried in the pocket, and it may be used for measuring resistances ranging between ·005 and 2,000 ohms. The arrange-

Digitized by Google

ment of the branch coils is the same in principle as in Thomson and Varley's slide resistance box. Eleven coils, with contact pieces, are arranged in series in the base beneath the turntable, the latter carrying two contacts which serve to embrace two of these coils. A wire, having double the resistance of a single coil, is stretched round the edge of the table and joins the two contacts, being, for final adjustment, capable of division at any point by the index arm which carries the battery current. The galvanometer has a resistance of 4 ohms; the needle is astatic, and is suspended by a silk fibre.

THE TELEPHONE AND GUNNERY.—The telephone was used, for the first time in connection with volunteer artillery practice, by the Risca detachment of 1st Worcestershire A.V., at the Nash ranges, Newport, Mon., on Monday week. A 64-pounder was brought up to 2,500 yards from the marking point, and 6,000 yards from the target, but so placed that the detachment working the gun could not see the target. The firing was rather wild at first, but owing to the directions given through a Gower-Bell telephone, with portable lead, consisting of a double cable, as to the effect of each shot, the gun was eventually trained to cover the target. The whole apparatus consists of a cart and limber carrying the 4,000 yards of wire in 500-yard sections for convenience of carriage, the lengths being coupled up by an ingenious joint devised by Mr. G. Wilson, electrical engineer of the Risca Collieries, by whom the whole apparatus has been arranged and supplied. The result was considered by the volunteers, under the command of Col. Cumings, a complete success.

ELECTRIC LIGHT ON THE INNER CIRCLE RAILWAY.—The Inner Circle of the Underground Railway was opened for public traffic on Monday last. The Edison and Swan United Electric Light Company received the order to illuminate the new Cannon-street Station on Saturday week, and the work was commenced last Tuesday. The whole station was completely lighted by the following Monday, including all the booking and other offices. The installation consists of an Edison "L" dynamo, driven by a Marshall portable engine, placed on Dowgate-hill. The number of lamps is 80, about 30 of which will be of 30 to 40 candle-power, according to requirements. The whole of this very rapidly-executed work has been completed in a thorough and substantial manner, all joints being soldered, and all the necessary switches and cut-outs being inserted. The railway company have been willing to pay the cost of lighting this station, which is in a measure experimental, so as to enable them to ascertain the working cost, and what effects can be satisfactorily produced with incandescent lamps, as we understand that they intend, if the results are satisfactory, to light up the remainder of their new stations in a similar manner."

THE BRIGHTON ELECTRIC RAILWAY.—The extension of this line having now been in operation for six months, a few particulars may be interesting as showing the capabilities of a light line of this description. The details of construction have been already described in our columns, and need not therefore be repeated. The car mileage amounts to 15,600 miles, or 100 miles per diem; and the number of passengers in round numbers, to 200,000. These figures would have been increased but for the fact that at certain hours the would-be passengers exceeded the capabilities of the car, which seat 30 persons only. No accident has occurred to either the general public or to passengers by the car. The consumption of gas in the gas engine has been 300,000 cubic feet, or 1½ cubic foot per passenger per mile. The total cost of traction, including interest and depreciation on engine, dynamo, and motor, cost of gas, oil, and attendance, has amounted during that period to 15s. 6d. per day (100 miles run), say 2d. per mile. The car service has only been stopped for one day, through the tyres of the wheels giving out, owing to the heavy pressure of the holiday traffic, when there was no second car available.

UNDERGROUND TELEPHONE WIRES IN EDINBURGH.—We learn that the Streets and Buildings Committee of the Edinburgh Town Council have had under consideration an application by the National Telephone Company for permission to lay underground telephone wires in the city. After deliberation, the committee agreed to recommend that the council sanction the laying of two main lines by way of experiment. The wires are to be enclosed in metal pipes and laid two feet from the surface of the streets, with branch lines at various points on the route, where inspection boxes will be placed. As it is necessary to provide occasional means of communication between the underground pipes and the roofs of adjoining buildings for affording electrical communication with the company's subscribers, it is proposed to convey a cable or bundle of wires from the most conveniently situated box under the footpath to the wall of the building with which it is required to establish communication, and to carry the cable enclosed in a small pipe up the wall of the building to the roof. On the roof will be erected a standard similar to those now used by the company in Edinburgh, to which the cable or bundle of wires will be attached. From the standard, ordinary naked wires will be led to the offices of the subscribers.

CARDEW'S SYSTEM OF DYNAMO WINDING.—This invention consists in an arrangement to enable the same dynamo to be used for working arc, incandescent, or search lights at pleasure. By means of a switch-board placed on the machine, it is possible to so connect up the coils of the magnet fields as to allow of four powerful arc lights being worked simultaneously; or, if four be not required, three, two, or one may be worked in parallel. The arrangement also permits of any of the arc lamps being worked independently of the others. Moreover, by a simple alteration on the switch-board, the machine can be used for working a single powerful hand-regulated search light of 25,000 candles, suitable for naval or military purposes. The same machine will maintain 100 twenty candle-power, sixty-volt Victoria lamps, and, being self-regulating, these lamps may be turned on and off at will in any required number, the speed remaining practically constant. It is also possible to work arc and incandescent lamps in parallel simultaneously. The system is peculiarly applicable to differentially wound lamps; and it is stated that no artificial resistance is required in the circuit of the arc lamps to ensure perfectly steady burning and complete independence of action in the lamps. The machine is the invention of Captain Cardew, R.E., and is supplied by Messrs. Clark, Muirhead, and Co., who are prepared to grant licenses for its use.

ELECTRIC LIGHT ON STEAMERS.—The Great Eastern Company's last new steamer but one, the "Norwich," was fitted with sixty-two Swan incandescent lamps, in opal globes, by Siemens Brothers' northern agent, just sixteen months ago, and they have been maintained ever since by a Gramme 60-light dynamo, driven with rope gear by a Shanks' horizontal engine, without a single hitch due to the electrical portion. There are twelve lamps in the saloon and one in each cabin, besides staircases, &c. When the steamer is running, the special engine takes its steam from the main boilers, but while in port, from the steam-winch boilers, the change being now made without extinguishing the light. The lamps, which

Digitized by Google

cost 4s. 6d., are warranted for 1,000 hours, but many of them last three times as long. There is no electrician on board, but the engineer looks after the dynamo and the chief steward superintends the lamps and connections. He testifies to the great cleanliness and convenience as well as saving effected by the electric light, breakage of glasses being no small item with the petroleum lamps formerly used. The "Ipswich" is similarly fitted, but the switches for turning each lamp on or off are placed outside the cabin door instead of inside, a more convenient arrangement. We may add that all the arrangements on board for passengers' comfort are quite on a par with this great progress of adopting the electric light.

The Telephone at Antwerp.—The telephone has entered so thoroughly into commercial life at Antwerp that its suppression would now lead to something like a cessation of business. A local Bell Company started the lines about three years ago, the original subscribers paying only 200f. (£8) per annum, but new subscribers are charged half as much again. For this the company lays the wires, supplies the instruments, and maintains the whole in working order. The police stations and also the leading medical men are put in communication, and the current is on day and night. It may be said that at least one in five of the principal business houses is connected, together with all the leading hotels and cafés. What astonished us was to see the words "teléphone publique" put up at some quite minor *estaminets*, or public houses, and we learnt that the instruments were at the disposal of all and sundry who might call for a glass of beer, as the telephone brings custom to the tap. There are also three telephone offices on the boulevards, whence the public can hold converse with subscribers for the small charge of 50c. (5d.). These offices also serve as tramway stations and ladies' retiring rooms. All the fire brigade stations are of course connected, as also the office of the new water works, owned by an English company. This company has also a private single wire telegraph between its office and the works at Walhaem, twelve miles off, that only cost £300, and seven minutes after the outbreak of a fire the pressure is increased all over the town.

The Atlantic Cables.—It having been reported that both cables of the Western Union Cable Company had met with serious accidents, the *Standard's* correspondent at Penzance telegraphed as follows on Tuesday:—"It has been ascertained so far as actual tests have gone that only one of the cables has been really severed. It was on Friday evening last, at 9 p.m., that communication ceased with one cable, and at four on Saturday morning the second and only remaining cable of this company became inactive. The test which has been applied in respect to the second cable leads those who have made it to imagine that it is not broken, but that the gutta percha is pressing on the wire itself. It is believed that the cables have been thus interrupted eighteen hundred miles from the Land's End, the one that has broken having gone somewhat nearer the English coast than the spot at which the second has been interfered with. It is not credited, however, that icebergs have had anything to do with the matter. It is feared that the Western Union Company will not be in a position to renew operations for several months. An electrician from Messrs. Siemens is expected in Penzance this evening to test the cables, with the view of definitely ascertaining where the accidents have occurred." One of the Mackay cables just laid was also *hors de combat* on Monday. It is thought the Western Union cables will take some time to repair, but the Mackay-Bennett cable can be spliced in a short time, as the "Faraday" is on the spot, and can effect the necessary repairs after laying the section of cable she has now on board.

Electric Light at Deal.—The secretary of the Deal and Walmer Electric Light Company recently addressed a letter to the Deal Town Council, making a second application for permission to lay a cable for electric lighting between Alfred-square, along High-street, to Deal Castle, and adding that one of the principal clerks to the Board of Trade states that the Electric Lighting Act does not render necessary a licence or a provisional order, provided the sanction of the Local Authority be obtained to laying the wires. He enclosed letters from the secretaries of the Brighton, the Hastings, and the Eastbourne Electric Lighting Companies, all of whom stated that they had laid wires without a licence or provisional order. After a long discussion, during which Councillor Ramell stated that if the Council granted permission to lay the wires, M. Jarman, inventor of the Jarman arc lamp, would carry out the work, the following resolution, drawn up by the town clerk, was carried unanimously:—"That provided the directors of the company or some other responsible persons will enter into personal guarantee to be responsible for all the expenses of laying down the cable, making good the pavement to the satisfaction of the surveyor, and the making good of all other damage that may be done either in pavement or to the pipes of the Gas and Water Company, that the Council would permit the application without prejudice to any rights which the Council may think fit to exercise hereafter in regard to a licence, provisional order, or otherwise in connection with such electric lighting, and subject to a proper agreement to be entered into with the town clerk."

Mercurial Electro-Dynamometer.—An abstract in the *Chem. Soc. Jour.* describes M. G. Lippmann's electro-dynamometer as follows:—"A small parallelopipedal chamber filled with mercury and communicating laterally with the two branches of a manometer is supported in the centre of a bobbin of copper wire. The current passes through the wire and thus through the mercury, and the manometer shows a permanent deviation due to the electro-dynamic action exerted on the mercury by the remainder of the circuit. The deviation is strictly proportional to the square of the intensity of the current, and the apparatus can be used to measure alternating currents. All the parts of the apparatus are rigid and immovable with the exception of the mercury, and even in this latter case the points at which the current enters and leaves the mercury have an invariable position with respect to the rest of the apparatus. In consequence of this rigidity the form and sensibility of the apparatus remain perfectly constant. This instrument can be constructed to measure currents in absolute measure, for the pressure, p, indicated by the manometer, is connected with the intensity I, by the formula $p = \frac{C}{E} I_2$, where E is the thickness of the layer of mercury and C is the intensity of the magnetic field produced at the centre of the bobbin by a current of unit intensity. The former is measured directly; the latter is deduced from the dimensions of the bobbin, and increases indefinitely with the number of turns of the copper wire. In the mercurial galvanometer both the numerator and denominator in the expression $\frac{H}{E}$ have a maximum limit."

The Approaching Telegraph Conference.—The following letter has been forwarded to *The Times* by Mr. H. R. Meyer in reference to this subject:—"I beg you will allow me space to remind the commercial community of the fact that early next year a telegraph conference will be held in St. Petersburg, which will possibly pass such new rules as will very seriously affect every firm using submarine cables. For instance, I am given to understand that a strong effort

Digitized by Google

is to be made by the cable companies to reduce the limit for code words from ten letters to eight. In effect, I estimate this alteration, if passed, to be equivalent to an increase of 25 per cent. in rates, because the number of words of that length suitable for code ciphers is too limited to allow of a code anything like sufficient to meet business requirements being constructed therewith; consequently, in many cases where one word would now suffice two will then have to be used. I hear also of other proposals, all in the direction of limiting the use of telegraphic codes, and consequently increasing the cost of telegraphing. On the last occasion of a similar conference, although you were good enough to admit my letter in reference to the matter, neither did the various Chambers of Commerce, whose province the subject distinctly belongs to, nor did commercial men do anything until the new rules were passed, and they then found their loud complaints in consequence of the inconvenience they were put to calmly ignored. I would suggest that those interested should move in the matter at once in order to prevent any needless changes in existing regulations affecting the codes now used. Either the commercial interest should be specially represented at the conference, as from its importance it certainly deserves to be, or the Government should be strongly and influentially memorialised to secure instructions being given to the British representative to protect commercial firms from any further annoying changes. What is everybody's business becomes nobody's, to prevent which in this case I am willing to place my services at the disposal of the mercantile community, being well known in connection with the subject, and shall be glad to receive communications and support from all whom it may interest, with a view to combined action before it is too late."

Application of Electricity to Chemical Industry.—The Chemical Society's *Journal* gives the following abstract of a paper by Mr. F. Fischer:—"Lermann recommends the electrolytical deposition of zinc from dilute solutions of the sulphate, by the aid of potassium, sodium, ammonium, strontium, magnesium, or aluminium sulphates, used singly or mixed together. Kiliani states that during the electrolysis of a solution of zinc sulphate of 1·38 sp. gr. (the anodes and cathodes consisted of zinc plates), the evolution of gas is greatest with a weak current, diminishing with an increasing current, and ceasing when 3 mgrms. of zinc are deposited on 1 square centimetre pole surface per minute. The deposits obtained with strong currents were firm. From a 10 per cent. solution the precipitate was obtained in the best form with a current of from 0·4 to 0·2 mgrm. zinc. From weak solutions the zinc was always deposited in a spongy condition, with evolution of much hydrogen. Kiliani concludes that the size of the pole surfaces depends on the intensity of the current and the concentration of the solution. For the extraction of metals from ores Blas and Miest employed a process which depends on the fact that the natural sulphides conduct electricity when they are rolled into plates whilst hot. These plates are then suspended as anodes in a suitable bath. For the separation of zinc from blende the bath consists of zinc sulphate, and the following reaction takes place:—$ZnSO_4 + ZnS = Zn + S + ZnSO_4$. The advantages of this process are—(1) the ores do not require to be roasted; (2) the sulphur is obtained as such; (3) less current energy is required for the decomposition of zinc sulphide. In the case of galena, a bath of lead nitrate is used. Marchese has patented a similar process, the essential difference being the suspension in the depositing tanks of the ores in lumps or small pieces filled into iron baskets. Referring to the electrolytic extraction of copper, the author states that the firm of Siemens and Halske, of Berlin, have five machines C_1, each with 12 baths in action, at the Oker Works; each machine is worked with a water-power of 4e. to 5e. and deposits 1 kilo. copper per cell per hour, *i.e.*, about 300 kilos. per diem. At the North German Refining Works in Hamburg, six Gramme machines (No. 1), and one Wohlwill machine are in operation precipitating 2,500 kilos. of copper daily. Oescher and Mesdach have constructed a Gramme machine according to Wohlwill's instructions, which yields 800 kilos. of copper daily. Hilarion Roux, in Marseilles, works with a No. 1 Gramme machine (5e) connected with 40 baths, having 900 square meters anode surface; the cathodes are only 0·5 mm. thick, and are 5 cm. from the anodes. The machine makes 850 revolutions a minute, consumes 240 kilos. coal per day, and deposits, with 8 volts and 300 amperes, 250 kilos. of refined copper. Keith's process for refining lead is worked by the Electro-Metal Refining Company in New York. The bath consists of lead sulphate dissolved in sodium acetate. Gold, silver, and antimony are retained by the anode. The deposition of aluminum by electrolytic means is discussed by the author. According to Weldon, the cost of preparing alumina from bauxite at Pechiney's Works at Salindres amounts to 9·7 per cent., that of the preparation of double chloride of aluminium and sodium 33·4 per cent., and for the decomposition of the double chloride with metallic sodium 56·9 per cent. of the total expenditure. The manufacture of one kilo. sodium costs about 7s., the largest item being for the costs of the vessels in which the sodium carbonate is heated with powdered charcoal, and which are so rapidly destroyed that their cost stands for one-half the total cost of sodium, and a third of the total cost of aluminium. It is further considered an impossibility to reduce alumina by carbon, for the reactions which occur correspond with the following numbers:—

$$2Al_2O_3 + 3C = 2Al_2 + 3CO_2$$
$$-783,200 + 291,000 = -492,200 \text{ cal.}$$
$$Al_2O_3 + 3C = Al_2 + 3CO.$$
$$-391,600 + 85,770 = -305,830 \text{ cal.}$$
$$Al_2Cl_6 + 3H_2 = Al_2 + 6HCl$$
$$-321,870 + 132,000 = -189,870 \text{ cal.}$$

That in spite of these unfavourable thermo-chemical relations sodium can be formed from sodium carbonate and carbon is explained by Weldon as follows:—When a mixture of sodium carbonate and carbon is heated intensely, some of the sodium oxide becomes dissociated, and the carbon then combines with the oxygen, sodium being liberated. The temperature required for the dissociation of Al_2O_3 is, however, considered to be unattainable on a large scale. The author is of opinion that if this explanation is correct there should be no difficulty in obtaining this dissociation temperature by the aid of the electric furnace. Moreover, the reaction $C + 2H_2O = CO_2 + 2H_2$ corresponds with $= 136,800 + 97,000 = -39,890$ cal., and yet it takes place when steam is passed over lignite coke heated to 300 to 350°, a temperature at which steam could not undergo dissociation; the reaction $ZnO + C = Zn + CO$ yields $-85,430 + 28,590 = -56,840$ cal. If, therefore, heat be supplied by external means, reactions accompanied by the absorption of heat would be possible. For the separation of iron from the solutions of aluminium sulphate, sodium sulphate, &c., Löwig and Co. in Goldschmieden deposit the iron electrolytically. When treating solutions of sulphates the anode is to be of lead. The separation of the iron does not take place unless the production of oxygen at the anode can be almost entirely prevented. This is effected either by using an anode with a large surface, or by causing as much resistance as possible to be offered to the passage of the current at the anode."

ELECTRIC LIGHT AT THE CRITERION THEATRE.

Visitors to the Criterion Theatre during the hot weather must have experienced to the full one of the many advantages the electric light possesses over gas. Mr. Wyndham paid a deserved tribute to its excellence when, in a recent communication to the Press, he stated that the temperature of his theatre was lower than that of the outside air. And when it is remembered that the ceiling of the theatre is some feet below the level of the street, it will be understood how difficult a problem the architect, Mr. Verity, has solved in securing proper ventilation. This difficulty was one of the main reasons for the recent alterations to the building; and it was only by the substitution of the electric light for gas that it could practically be overcome. The result is that this theatre, which was almost unbearable during the hot weather, is now one of the coolest and most charming in London, and is worthy, in respect of the purity and coolness of its atmosphere, of being placed in the same rank as the Savoy.

It has been found at both these theatres that the electric light lends itself to stage effects with much greater facility than gas, and can be used for novel and artistic arrangements in the body of the theatre in situations which are impossible with any other illuminant.

As a case in point we may cite the position of the ring of lights placed round the dome, but one perhaps more noticeable is found in the position of the ceiling lights used in the pit and dress circle. These lights are so recessed into the ceiling itself that it is not necessary to turn them down even when the auditorium is supposed to be in complete darkness; the audience are thus enabled to read their programmes at any part of the performance.

On the stage itself, among other advantages which the electric light brings with it, may be mentioned the substitution of light over-head battens, in place of the cumbersome battens (each weighing several hundredweight) necessary where gas is used. As a consequence of this alteration, the elaborate system of iron extract flues is now dispensed with, and a valuable addition to the height of the stage secured.

The lighting plant, of which we publish a plan, is situated under the new grill room, about 30ft. from the Jermyn-street side of the stage, and adjoining it on the south side is the boiler room, in which three of Messrs. Galloway's boilers are erected. These boilers, two of which will at any time do all the work, are used for various purposes; in fact the electric light is only one of several purposes for which they are employed, some of the others being ventilation, heating, pumping, cooking, &c.

The electric plant proper, as put down by the Edison-Swan Company, consists of two Armington and Sims engines of the high-speed type, the cylinders being 13in. diameter, with 13in. stroke. At present each engine is giving about 83 horse-power, at 250 revolutions, and 75lb. pressure, and as these engines are not yet nearly loaded up to their work, the automatic expansion gear is effecting an extremely early cut off. It is calculated that with the aid of two additional dynamos, for which there is still just enough available space in the present engine room, each of these engines will be able to drive nearly all the lights intended to be used.

The engines drive on to a 4in. steel countershaft, the driving and transmitting pulleys on which are fitted with coned friction clutches, one engine at a time only being used and the other kept slowly revolving as a reserve. These pulleys have been fitted with the Stauffer patent lubricator and grease, which has been found to work very satisfactorily. The friction gear and the runners for tightening the belts are worked by hand wheels on a platform running down the centre of the engine room. A thrust block with hardened centre is fixed at the end of the shaft to contract the end thrust of the main clutch gear. In putting down the shafting provision has been made for the addition of two dynamos at a future time, it being the intention of Messrs. Spiers and Pond to extend the light to their new grill room and other parts when the building is completed.

The dynamos are four Edison 150-light machines, making about 800 revolutions per minute, and running 640 Edison 16 candle-power lamps. All four machines are coupled in multiple arc to one set of mains, and the positive shunt wire of each machine is connected with a general field wire, which insures an equal proportion of current circulating through all the fields and admits of their being simultaneously regulated by the introduction of external resistance. Switches are inserted in the main and field circuits to cut off each machine without intercepting the current from the others, and by a comparatively slight increase of speed any three of the machines could maintain the full load in the event of failure of the fourth.

The mains pass under a corridor to the switch-board at the prompt side of the stage, on which are arranged all the switches, cut-outs, and the regulating apparatus, and from this point each circuit can be separately tested. The switches are all fitted with loose T handles, and can therefore only be manipulated by the attendant in charge. The regulating apparatus consists of ten dials, each subdivided into thirteen segments and controlling the various circuits by means of German silver wire resistances as follows:—

Footlights and proscenium	82 lamps	2·9 ohms	by gradations of	·24	ohm.
Six overhead battens, each	34 „	5· „	„	·41	„
Vertical battens	54 „	3·7 „	„	·3	„
Dome lights ...	59 „	3·3 „	„	·27	„
Auditorium ...	70 „	2·9 „	„	·24	„

The six overhead battens can be regulated separately, or, by a simple mechanical contrivance, can be worked simultaneously, as was shown during the recent performance of *Featherbrain*, in which a daybreak effect had to be produced by gradually increasing all the stage lights from a dull red to full incandescence. The resistance coils are compactly arranged under the stage, in slate boxes, provided with apertures permitting of a free circulation of air.

The whole of the lights on the stage, including the footlights and proscenium lights, numbering 360, are portable, the various connections being made by means of stout flexible cord encased in india rubber tubing. The ends of these cords terminate in copper contact pieces, which can be readily attached to the main wires at a number of specially arranged points both under the stage and in the flies.

The dressing rooms are fitted with double swing brackets, and the corridors, refreshment rooms, crush room and vestibules with handsome brass chandeliers and brackets.

Since the completion of the above work by the Edison and Swan Company, a second contract has been made and completed by them for Messrs. Spiers and Pond for the extension of the light to the east room in the restaurant, consisting entirely of portable table lamps. These lamps are connected in a simple manner with either side of the table at will, and the tables themselves may be detached and moved to almost any part of the room, and reconnected by pins with spring contacts let in flush with the carpet, the only visible connection being a short length of silk covered flexible cord passing over the table cloths to the lamp. Each lamp circuit has a fusible cut-out inserted. This adaptation has been found to add much to the comfort and beauty of the room.

The total number of lamps, as already stated, is about 640, but we are informed that by the beginning of December next twenty-four lights will be added in the west room and about forty in the new grill room, making over 700 lights, and that as the building is completed more will be added, until probably a total of about 1,000 will be employed. Even with this large number it will be necessary to light many places by gas. These facts will give our readers some idea of the elaborate nature and extent of the additions, now fast reaching completion, to the Criterion.

We hear that by special permission of the Edison Swan Company's directors, at the request of Messrs. Spiers and Pond, Mr. J. F. Albright has been retained as their consulting engineer to supervise the working of this recent and important addition to electrical work. We need hardly say he continues to hold his position with the Edison-Swan Company.

THE BRITISH ASSOCIATION MEETING AT MONTREAL.

On a Gyrostatic Working Model of the Magnetic Compass.*

BY PROFESSOR SIR WILLIAM THOMSON, F.R.S.

In my communication to the British Association at Southport† I explained several methods for overcoming the difficulties which had rendered nugatory, I believe, all previous attempts to realise Foucault's beautiful idea of discovering with perfect definiteness the earth's rotational motion by means of the gyroscope. One of these, which I had actually myself put in practice with partially satisfactory results, was a

Gyrostatic Balance for Measuring the Vertical Component of the Earth's Rotation.—It consisted of one of my gyrostats supported on knife-edges attached to its containing case, with their line perpendicular to the axis of the interior fly-wheel and above the centre of gravity of the fly-wheel and framework by an exceedingly small height, when the framework is held with the axis of the fly-wheel and the line of knife-edges both horizontal, and the knife-edges downwards in proper position for performing their function. The apparatus, when supported on its knife-edges with the fly-wheel not spinning, may be dealt with as the beam of an ordinary balance. Let now the framework bear two small knife-edges, or knife-edged holes, like those of the beam of an ordinary balance, giving bearing-points for weights in a line, cutting the line of the knife-edges as nearly as possible, and of course (unless there is reason to the contrary in the shape of the framework) approximately perpendicular to this line, and, for convenience of putting on and off weights, hang, as in an ordinary balance, two very light pans by hooks on these edges in the usnal way. Now, with the fly-wheel not running, adjust by weights in the pans if necessary, so that the framework rests in equilibrium in a certain marked position with the axis of rotation inclined slightly to the horizontal, in order that the axis of the fly-wheel, whether spinning or at rest, may always slip down so as to press on one and not on the other of the two end plates belonging to its two ends. Now, unhook the pans and take away the gyrostat and spin it; replace it on its knife-edges, hang on the two pans, and find the weight required to balance it in the marked position with the fly-wheel now rotating rapidly. This weight, by an obvious formula which was placed before the Section at Southport, gives an accurate measure of the vertical component of the earth's rotation.‡

Gyrostatic Model of the Dipping Needle.—I also showed at Southport that the gyrostatic balance described above, if modified by fixing the knife-edges, with their line passing as accurately as possible through the centre of gravity of the fly-wheel and framework, and with the faces of the knives so placed that they shall perform their function properly when the axis of the fly-wheel is parallel to the earth's axis of rotation, and the rotation of the fly-wheel in the same direction as the earth's, will act just as does an ordinary magnetic dipping needle; but showing latitude instead of dip, and dipping the south end of the axis downwards instead of the end that is towards the north, as does the magnetic dipping needle. Thus, if the bearing of the knife-edges be placed east and west, the gyrostat will balance with its axis parallel to the earth's axis, and therefore dipping with its south end downwards in northern latitudes and its north end downwards in southern latitudes. If displaced from this position and left to itself, it will oscillate according to precisely the same law as that by which the magnetic needle oscillates. If the bearings be turned round in azimuth, the position of equilibrium will follow the same law as does that of a magnetic dipping needle similarly dealt with. Thus, if the line of knife-edges be north and south, the gyrostat will balance with the axis of the fly-wheel vertical, and if displaced from this position will oscillate still according to the same law; but with directive couple equal to the sine of the latitude into the directive couple experienced when the line of knife-edges is east and west. Thus this piece of apparatus gives us the means of definitely measuring the direction of the earth's rotation, and the angular velocity of the rotation. These experiments will, I believe, be very easily performed, although I have not myself hitherto found time to try them.

Gyrostatic Model of a Magnetic Compass.—At Southport I showed that a gyrostat supported frictionlessly on a fixed vertical axis, with the axis of the fly-wheel horizontal or nearly so, will act just as does the magnetic compass, but with reference to "astronomical north" (that is to say, rotational north) instead of "magnetic north." I also showed a method of mounting a gyrostat so as to leave it free to turn round a truly vertical axis, impeded by so little of frictional influence as not to prevent the realisation of the idea. The method, however, promised to be somewhat troublesome, and I have since found that the object of producing a gyrostatic model of the magnetic compass may, with a very remarkable dynamical modification, be much more simply attained by merely suspending the gyrostat by a very long, fine wire, or even by floating it with sufficient stability on a properly planned floater. To investigate theory of this arrangement let us first suppose a gyrostat, with the axis of its fly-wheel horizontal, to be hung by a very fine wire attached to its framework at a point, as far as can conveniently be arranged for, above the centre of gravity of fly-wheel and framework, and let the upper end of the wire be attached to a torsion head, capable of being turned round a fixed vertical axis, as in a Coulomb's torsion balance. First, for simplicity, let us suppose the earth to be not rotating. The fly-wheel being set into rapid rotation, let the gryostat be hung by the wire, and after being steadied as carefully as possible by hand, let it be left to itself. If it be observed to commence turning azimuthally in either direction, check this motion by the torsion head; that is to say, turn the torsion head gently in a direction opposite to the observed azimuthal motion until this motion ceases. Then do nothing to the torsion head, and observe if a reverse azimuthal motion supervenes. If it does, check this motion also by opposing it by torsion, but more gently than before. Go on until when the torsion head is left untouched the gyrostat remains at rest. The process gone through will have been undistinguishable from what would have had to be performed if, instead of the gyrostat with its rotating fly-wheel, a rigid body of the same weight, but with much greater moment of inertia about the vertical axis, had been in its place. The formula for the augmented moment of inertia is as follows. Denote by—

- W, the whole suspended weight of fly-wheel and framework;
- K, the radius of gyration round the vertical through the centre of gravity of the whole mass regarded for a moment as one rigid body;
- w, the mass of the fly-wheel;
- k, the radius of gyration of the fly-wheel;
- a, the distance of the point of attachment of the wire above the centre of gravity of fly-wheel and framework;
- g, the force of gravity on unit mass;
- ω, the angular velocity of the fly-wheel; the virtual moment of inertia round a vertical axis is

$$W K^2 \left(1 + \frac{w^2 k^4 \omega^2}{W^2 K^2 a g}\right) \quad . \quad . \quad . \quad . \quad (1)$$

The proof is very easy. Here it is. Denote by—

- ϕ, the angle between a fixed vertical plane and the vertical plane containing the axle of the fly-wheel at any time t;
- θ, the angle (supposed to be infinitely small and in the plane of ϕ) at which the line a is inclined to the vertical at time t;
- H, the moment of the torque round the vertical axis exerted by the bearing wire on the suspended fly-wheel and framework.

---

* A paper read at the British Association meeting, Montreal.

† No report of this communication has, so far as I know, hitherto appeared in print.

‡ The formula is $g w = \frac{1}{a} W k^2 \omega \gamma \sin l$,

where w denotes the balancing weight, gw the force of gravity upon it, a the arm on which this force acts, W the weight of the fly-wheel, k its radius of gyration, ω its angular velocity, γ the earth's angular velocity, and l the latitude of the place.

Digitized by Google

By the law of generation of moment of momentum round an axis perpendicular to the axis of rotation requisite to turn the axis of rotation with an angular velocity $d\phi/dt$, we have

$$w k^2 \omega \frac{d\phi}{dt} = g W a \theta \quad . \quad . \quad . \quad . \quad . \quad (2)$$

because $gWa\theta$ is the moment of the couple in the vertical plane through the axis by which the angular motion $d\phi/dt$ in the horizontal plane is produced. Again, by the same principle of generation of moment of momentum taken in connection with the elementary principle of acceleration of angular velocity, we have

$$w k^2 \omega \frac{d\theta}{dt} + W K^2 \frac{d^2\phi}{dt^2} = H \quad . \quad . \quad . \quad . \quad . \quad (3)$$

Eliminating θ between these equations we find

$$\left(\frac{w^2 k^4 \omega^2}{g W a} + W K^2\right)\frac{d^2\phi}{dt^2} = H \quad . \quad . \quad . \quad . \quad (4)$$

which proves that the action of H in generating azimuthal motion is the same as it would be if a single rigid body of moment of inertia given by the formula (1), as said above, were substituted for the gyrostat. Now, to realise the gyrostatic model compass, arrange a gyrostat according to the preceding description with a very fine steel bearing wire, not less than 5 or 10 metres long (the longer the better; the loftiest sufficiently sheltered enclosure conveniently available should be chosen for the experiment). Proceed precisely as above to bring the gyrostat to rest by aid of the torsion head, attached to a beam of the roof or other convenient support sharing the earth's actual rotation. Suppose for a moment the locality of the experiment to be either the North or South Pole, the operation to be performed to bring the gyrostat to rest will not be discoverably different from what it was, as we first imagined it when the earth was supposed to be not rotating. The only difference will be that, when the gyrostat hangs at rest, relatively to the earth, θ will have a very small constant value; so small that the inclination of a to the vertical will be quite imperceptible, unless a were made so exceedingly small that the arrangement should give the result, to discover which was the object of the gyrostatic model balance described above; that is to say, to discover the vertical component of the earth's rotation. In reality we have made a as large as we conveniently can; and its inclination to the vertical will therefore be very small, when the moment of the tension of the wire round a horizontal axis perpendicular to the axis of rotation of the fly-wheel is just sufficient to cause the axis of the fly-wheel to turn round with the earth. Let now the locality be anywhere except at the North or South Pole; and now, instead of bringing the gyrostat to rest at random in any position, bring it to rest by successive trials in a position in which, judging by the torsion head and the position of the gyrostat, we see that there is no torsion of the wire. In this position the axis of the gyrostat will be in the north and south line, and, the equilibrium being stable, the direction of rotation of the fly-wheel must be the same as that of the component rotation of the earth round the north and south horizontal line, unless (which is a case to be avoided in practice) the torsional rigidity of the wire is so great as to convert into stability the instability which, with zero torsional rigidity, the rotational influence would produce in respect to the equilibrium of the gyrostat with its axis reversed from the position of gyrostatic stability. It may be remarked, however, that even though the torsional rigidity were so great that there were two stable positions with no twist, the position of gyrostatic unstable equilbrium made stable by torsion would not be that arrived at; the position of stable gyrostatic equilibrium, rendered more stable by torsion, would be the position arrived at, by the natural process of turning the torsion head always in the direction of finding by trial a position of stable equilibrium with the wire untwisted by manipulation of the torsion head. Now, by manipulating the torsion head bring the gyrostat into equilibrium with its axis inclined at any angle, ϕ, to that position in which the bearing wire is untwisted; it will be found that the torque required to balance it in any oblique position will be proportional to the sin ϕ. The chief difficulty in realising this description results from the great augmentation of virtual moment of inertia, represented by the formula (1) above. The paper at present communicated to the Section contains calculations on this subject, which throw light on many of the practical difficulties hitherto felt in any method of carrying out gyrostatic investigation of the earth's rotation, and which have led the author to fall back upon the method described by him at Southport, of which the essential characteristic is to constrain the frame of the gyrostat in such a manner as to leave it just one degree of freedom to move. The paper concludes with the description of a simplified manner of realising this condition for a gyrostatic compass—that is to say, a gyrostat free to rotate about an axis either rigorously or very approximately vertical.

THE ACCIDENT AT THE HEALTH EXHIBITION.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: We have had several letters in the dailies this week on the subject of the accident at the Healtheries, each recommending, or in other words advertising, some particular system of electric lighting which is said to be "free from danger."

As long as the multiplication of machines and leads means extra expense there is no doubt but that "high tension" machines will be made and used for arc lighting. Why should not "high tension" machines be made "free from danger?" This may surely be done provided that all parts which require handling, such as brush rockers and binding screw heads, be made of vulcanised fibre, or some other non-conductor. India rubber gloves are all very well, so are rules printed and put up in the vicinity of the machines; but as men get used to the machines they get to look on the danger with contempt, the rules are forgotten, the gloves laid aside, and however careful at first, the men, for convenience sake, handle the machine bare handed. With regard to the use of one glove, in the use of low tension systems high insulation is an absolute necessity, but where high E.M.F. is used it is apt to be neglected. Given a damp day, and bad, or even slightly defective insulation, don't you think it is dangerous to handle a high tension or alternating current machine, even with *one* bare hand? Again, could not some kind of thermal alarm be added to the bearings, so that any rise of temperature would at once indicate itself, and then with no necessity for handling anything but insulated portions of the machine there would be (excepting carelessness and foolhardiness) *absolute safety* to the *employés*? The confidence of the public would be increased, and the progress of electric lighting doubtless accelerated.—Yours, &c., A. GRUNDY.

Law Courts, Oct. 8th, 1884.

DUNDEE TELEPHONY.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: You have printed "Curiosity's" inquiry in last week's *Electrician*, and I have pleasure in giving a few facts in regard to the Dundee Telephone Company to satisfy that curiosity.

The company was started in the latter part of 1880. At present it has 330 subscribers on its exchange, besides a few private wires. The length of wire erected is about 280 miles. The instruments in use are chiefly the Gower-Bell, with a few of the Bell-Johnson. In the switch room the boards are of my own design, and are ample and effective. We employ five men, who construct new lines, make replacements, and repair all faults, and I find that number ample.

Financially the company has been a success. The first 16 months' working, at a rental of £10, showed a dividend of nearly 30 per cent., which was paid.

Since then, with a rental of £5 10s., including Government royalty, 5 per cent. per annum has been paid, and a considerable sum has also been set aside for contingencies.

If "Curiosity" wishes any further information he may apply direct to, yours, &c., E. J. B. LOWDON,
Engineer and Electrician to the Dundee and District Telephonic Company.

104, Commercial-street, Dundee, Oct. 6, 1844.

DANGEROUS DYNAMOS.

It is generally feared that the fatal accident at South Kensington, reported in our last week's issue, may seriously affect the interests of Electric Lighting at this crisis in its history. These apprehensions will of course disappear in due course, as all such apprehensions do; but our first impressions naturally are that the killing of a presumably skilled workman at an exhibition devoted to the preservation of health and life is a most unfortunate business, discreditable to those responsible for the disaster, and a discouragement to the employment of powerful dynamos for any purposes whatsoever. Further reflection will, to be sure, restore confidence both to the public and the profession; but meanwhile we express our firm conviction that the steps taken till now to reassure the non-professional world are far from calculated to attain that object. On the contrary, the letters addressed to the newspapers on the subject, so far from bringing any comfort to the thoughtful reader, will only rouse his suspicions and increase his misgivings. Some of these letters, although quite true as far as they go, are so manifestly designed to "improve the occasion" that the public will attach no weight to them; of the rest we shall speak presently.

In the note appended to our report of the coroner's inquest on the unfortunate man who lost his life by placing his hands on a dynamo at the Healtheries we stated that the one precaution necessary to guard against such accidents was the wearing of india-rubber gloves, and this precaution, we urged, was not merely effectual, but indispensable. When we have said this we have practically exhausted the subject, except to add that the suggestion is not new, but has been adopted in a good many places already, with, of course, the most satisfactory results. The mere fact of protective gloves being provided for the attendants is a better security for their being used, and certainly for more general care in handling than would be insured by any number of verbal warnings. Why this precaution was not taken at the Health Exhibition we are not in a position to say; but we do say this, that if the jury had been composed of professional men the verdict might have been somewhat different. The man had been warned scores of times. Standing by itself this warning does more harm to electric lighting than the death of several workmen would have done. It shows that the fatal risks were well known, and the inference is—a wrong inference, but a quite natural one—that no protection was possible beyond repeating a warning. If a man keeps a vicious dog within reach of the public, it is not sufficient that he stick up a warning notice. In some unguarded moment a passenger unwittingly rouses the animal, and is badly bitten. He naturally protests that the brute ought to have been muzzled or the public fenced off its beat. This is just what the world is saying about dynamos, and this is precisely what the owners of dynamos do not seem at all to realise.

For what do they say in extenuation or deprecation of this mishap? One writer, a high authority on the subject, tells *The Times* that he has never been able to trace any accident to life or health from contact with electric wires provided the electromotive force has not exceeded 600 volts. A doctor might just as well urge in mitigation of hydrophobic panic that he had never traced any ill effects from the bite of a dog whose pulse did not exceed 80. The same writer, with equal forgetfulness of the audience he is addressing, explains that high pressure currents are sometimes used from reasons of economy, but adds that this motive was absent at the Health Exhibition. Thus, then, it seems that the risk of employing dangerous currents is run both by promoters who are obliged to study economy and by those who are not—information which readers of *The Times* may be excused for regarding with much dissatisfaction. These facts, says the unconscious alarmist, are well known to the scientific world; but to the untrained public there is only "one kind of electricity, and they cannot readily understand why it should be dangerous to life in one form and not in another." We think, on the contrary, that the public are not troubling themselves about any such question. They certainly do know without any further training than the electric telegraph and the galvanic machine have afforded that some forms of electricity are harmless; and recent recurring accidents of a fatal kind have demonstrated that some new form of electricity—that, to wit, employed by certain providers of electric light—is highly dangerous. What they really would like to know is why, when dangerous currents are not necessary, they are needlessly employed; and why when they are necessary proper precautions against accident are neglected.

These pertinent questions have not yet been answered, and our object in putting them thus plainly before our professional readers is to get the right answers made public. It would have been better, for example, to have seized this present opportunity for frankly admitting that dangerous currents are commonly used, that such currents (except in special circumstances) need not be used; and where unavoidable the simple and well-known precaution already referred to should be made compulsory. By co-operating with the public in this manner the "scientific world," instead of bewildering them, would win their confidence and sympathy. It is childish and even mischievous to go on repeating the statement that certain currents may be handled with impunity. This irrelevant boast

Digitized by Google

has been made a little too often. Probably men like Pink have not infrequently heard it, and have grown less and less cautious in consequence. So long as some currents, by no means the exception, are dangerous, none should be proclaimed harmless, unless we are prepared to proclaim also that none but the harmless should ever be employed. As nobody is inclined to go this length, there should be a general agreement to acknowledge risks and to adopt precautions all round, so that neither through carelessness, ignorance, nor momentary inadvertence may the public again be shocked by a preventable fatality like the one we are now deploring. The employment of electricity will of course never be wholly free from danger; and, as in the case of steam, the more it is used the more accidents will perhaps ensue. But this is no reason for minimising the risks; and in the early stages of electric lighting there are the strongest reasons for multiplying precautions, so as to add nothing to those prejudices which have already retarded its progress very seriously.

THE AMERICAN ASSOCIATION.

The American meeting was held this year in Philadelphia, its birthplace thirty-six years' ago, and it was so timed that those who visited Canada to attend the British Association could go to Philadelphia to attend the American Association; but it was too hurried. Our American friends ought to have made it a week later, for we had to rush away in an apparent hurry, treating with scant courtesy our Canadian hosts. The British Association meeting finished on Wednesday, and on Thursday morning a special train carried away about two hundred to Philadelphia, another hundred journied there leisurely later, but many were prevented from seeing more of Canada, and especially from visiting Toronto and the great North West. An electrical conference under the auspices of the United States Government was also to be held under the presidency of Professor Rowland, and notwithstanding the pressing and warm invitations of those interested, many interesting parties formed to visit the Rocky Mountains and the Yellowstone Park had to be given up. The Britishers were unfortunate enough to bring with them a hot wave. They encountered a temperature that was excessive. Ninety-eight degrees in the shade is something to be experienced, it cannot be described. The air in Philadelphia is so charged with moisture that the perspiration remains on the skin without evaporating away, and the difference between night and day is so small that night is even worse than day. No one who was in Philadelphia in September, 1884, will ever forget it. It is impossible to pursue science with pleasure when you are in the "nineties." Discussion in a furnace is trying. Besides, the accommodation provided for the Sections was not equal to that at Montreal. Some Sections were very close and confined. The American Association is founded on the British Association, but their arrangement of Sections differs. For instance, Section A deals with astronomy and mathematics and Section B with physics, while Section D is the mechanical section. The American Association have no council but a general committee, which does the work of our council. Their general committee does much of the work that is done in the British Association by the sectional committees. The Americans adopt the capital plan of indicating on the programme the probable time that each paper will take to read, and the limitation of the discussion is in the hands of the Section—a power which is very freely exercised. They do not form committees as we do to carry on the work inaugurated at the meeting, and though the meeting at Philadelphia was a highly representative affair, there is reason to believe that the Association has not taken the position in the States that the British Association has in Great Britain. Our visit will probably do them good in this respect.

There is a very peculiar feature of the American Association meeting. The address is given by the outgoing president, and not by the incoming one. The present president is Professor Lesley —a noted geologist—but the address was given by Professor C. A. Young, a noted astronomer, and the retiring president. It was not a general address, but a special one on some pending problems of astronomy—a kind of dip into the future. He dealt with the dimensions and rotations of the earth; he raised the question whether the earth's rotation was uniform, and whether we could rely on the accuracy of the second as the unit of time? Is the position of the earth's axis fixed? He dealt with the moon, her radiant energy and her atmosphere; he does not believe in the existence of Leverrier's Vulcan; he reviewed our knowledge of the features of the different members of the solar system; and dwelt at length on our knowledge of the sun, its constitution and its influences.

The sun is a great ball of intensely heated vapour and gases, clothed outwardly with a coat of dazzling clouds formed by the condensation of the less volatile substances into drops and crystals like rain and snow. Sun spots are dark floating chips or scales thrown up from beneath, like scum in a cauldron. He pronounced himself to be no "sunspotist," except as regards their influence on terrestrial magnetism. He suggested that the prominence of iron in the sun had something to do with this. Solar theories, the hypothesis of the ether comets and meteors, and the stars were finally reviewed, and an exceedingly interesting address was wound up with a few platitudes as to the *cui bono* of all this trouble.

As an electrical meeting the American Association did not shine brightly. The sole paper of interest that was read was by Mr. Hall, who attempted to refute Mr. Shelford Bidwell's criticisms upon his previous paper. He did not accept Mr. Bidwell's thermo-electric theory, and adhered to his original views. The paper led to an extremely interesting discussion, in which Sir William Thomson, Professor Rowland, Silvanus Thompson, G. Forbes, Mr. Preece, and several others took part. It led to Sir William Thomson reading a second paper on the subject, and in fact the "Hall effect" became the feature of the meeting. No fresh facts were brought out, but the theory was discussed, though not elaborated. Bidwell's views were not accepted, though they were not refuted.

Prof. Bell described a proposal to communicate between ship and ship at sea by means of telephones, the circuit being formed partly by wire extending along each ship and trailing out behind by a long insulated wire ending in an earth connection, and partly by the sea between them. He had demonstrated practically the possibility of this by experimenting from boats. In the discussion that followed, Professor Trowbridge described how it was possible to speak across the Atlantic without a wire by having earth plates in Greenland and Patagonia connected by wire, and Mr. Preece explained how communication had actually been made across the Solent through a sea space of six miles and one mile. Professor Silvanus Thompson read two papers, "On a Standard Tangent Galvanometer," and "On the Government of Electric Motors," and General Hazen gave a paper on thunderstorms and their relation to low pressure. Professor Canhart read an interesting paper on the variation of the electromotive force of a Daniell cell, due to the presence of sulphate of zinc, but there was scarcely any other paper of value or novelty.

The meeting would probably have been a very enjoyable one if the weather had been bearable, but as it reminded one

Digitized by Google

of Pluto's regions and Dante's Inferno, rather than of our fair earth, it left a search after coolness instead of after knowledge the only possible occupation of the mind. There is some talk of the Association visiting London in 1886. If they come, we can promise them a welcome.

THE PHILADELPHIA EXHIBITION.—III.

(FROM OUR SPECIAL CORRESPONDENT.)

PHILADELPHIA, SEPT. 26.

Notwithstanding the great variety of dynamo machines at the International Electrical Exhibition, there are very few that present points of construction with which the readers of *The Electrician* are not familiar. At the risk of repeating some known facts, I shall describe a few that strike me as novel. The usual form of the Edison dynamo has two or three pillars forming the cores of magnet coils. At the Electrical Conference it was declared that the inductive action of these adjacent coils weakened the magnet, the current reacting upon itself. A suggested improvement was the construction of electro-magnets of equal weight of metal, but with the cores in one piece of elliptical instead of round section. Noticing that some of Edison's new machines (and especially the smaller sizes) were made in this way, I asked him whether the change had been made to prevent this inductive action. He said that there was no such action; that as a matter of fact the more pillars or sections in the field magnet the better, and that the only reason for the change was that the single form was easier and cheaper to construct. In proof of his belief in this theory he pointed out that the very latest machines of the larger size (from 400 to 1,200 lights capacity) were made in the old form.

"Jumbo," his great dynamo of 1,200 light capacity, has a new feature in the armature. Instead of being wound with wire in the usual fashion, longitudinal bars of copper are used, connected together as coils would be by copper discs insulated from each other by mica. Air spaces between the bars (which are ¾in. by ½in. in section) help to keep the armature cool.

He has another form of dynamo which may be used for electro-plating, but it is, I think, merely an experimental machine. It is called the "disc dynamo," and is based upon a machine described by Arago. Instead of revolving a solid disc of copper before the poles of a magnet Edison has cut up the disc into insulated sections, the electromotive force being increased in proportion to the number of sections used. In construction four electro-magnets are laid horizontally, so that the disc revolving between them shall pass between the four pairs of poles. The disc is built up of radial sections insulated from each other, and carried out to the commutator, which is of the ordinary construction. Opposite pairs of the radial sections are connected by insulated bands of copper passing around the circumference of the disc. The faces of this disc or wheel, with its tyre of insulated copper bands, are closely hugged by the poles of the electro-magnet. The disc is about one inch thick, and the tyre probably half an inch wider. The machine is said by Edison to be very efficient, and he says that he can modify the principle to make it effective for electric lighting. He is, however, an exceedingly sanguine man, and sometimes, I think, invents things to show his ability to overcome difficulties rather than follow other inventors in easier ways.

Another strange dynamo reviving an old principle has just been entered at the Exhibition. It is called the pipe dynamo, is used for electro-plating, and has no commutator. It is a commercial application of one of Faraday's earliest experiments, and nothing is yet known of its efficiency. It is a difficult matter to make its method of construction plain without diagrams, but I will try to do so. Two copper cylinders, each about four feet long, four inches in diameter, and half an inch thick, are mounted so as to revolve horizontally parallel to each other, and at a distance apart of, say, eighteen inches. Through each of these cylinders passes an iron bar fixed in position, and these two bars are connected at each end by yokes wrapped with many turns of copper ribbon, the equivalent of coils. The revolving copper cylinders are also enclosed by fixed iron cylinders connected by yokes, wound, like the yokes of the bar, with copper ribbon. These coils are in a shunt circuit. The bars and the enclosing iron cylinders or "pipes" are poles of the magnets between which, in an extended magnetic field, the copper conductor revolves. The current is taken from these cylinders by brushes as from a commutator, but there is, of course, no sparking. I cannot explain the connections, as they are hidden from view, and there is no explanatory diagram—in fact, the exhibit has come in so late that it is not even mentioned in the catalogue.

A dynamo machine with which readers of *The Electrician* are probably familiar is doing remarkable work at the Exhibition. It is Ball's "unipolar dynamo," and came in for a good share of ridicule at the Conference of Electricians. Two Gramme rings are mounted upon a single shaft. Each revolves before *one* pole of a magnet. As the two armatures are on the same shaft, the poles are not opposite each other, but one is above and the other below the armatures, and they are a foot or more apart horizontally. Although some electricians undertook to show that theoretically this was a bad arrangement, the inventor seems to be content with the proof that comes of eating his pudding. I believe electric light companies ordinarily promise one arc light per horse-power. But the Ball unipolar machine is actually engaged in furnishing 17 arc lights from five horse-power transmitted through a 1in. belt.

Nearly all the arc light companies are now introducing incandescent lights, and Edison, in self defence, though he does not believe in arc lighting, is about to introduce this form for the accommodation of his customers who want both systems. The Brush Company have just made a very efficient low tension machine for incandescent lighting with the Swan light. Its secondary batteries used with the same lights are apparently a failure—at least, they have very little to say about them, and have made this new machine, which would seemingly be unnecessary if the storage batteries were to be used.

The Thompson-Houston Company has also begun to introduce incandescent light plants of its own manufacture. It formerly supplied the Edison plant to customers who wanted both kinds. There are besides a number of new incandescent light companies, which make their first appearance at the Exhibition.

The Weston Company has a new and very beautiful carbon filament for their lamps, which is said to be of exceptional long life. As prepared, it is cut into a wave-like loop, and when made incandescent presents a crimped appearance. It is called tamidull, and is prepared from pyroxilline (gun cotton). By treatment with a reducing agent a base is left of homogeneous cellulose, which is carbonised in the usual way. The Weston Company adds to the interest taken in the lamps by showing the whole process of manufacture with samples of the parts in all the various stages of preparation.

The attendance at the Exhibition is increasing daily, and there is talk of extending the time of the Exhibition. There is one exhibit not yet shown, if you can understand such a paradox. All that one can see is a large case covered with muslin, and a placard which states that underneath there is a full display of Daniel Drawbaugh's telephones, not to be shown until after the close of arguments in the great telephone suit now before one of the United States Courts in New York. The Bell Telephone Company sued the People's Telephone Company for infringement of patent rights. The defence is that General Drawbaugh invented the telephone years before Bell began his experiments, and that the latter's patents are therefore void. The case engages some of the greatest lawyers in the country. There are 10,000 printed pages of testimony, and it is as conflicting and curious as that brought forth in the Tichborne trial. Another exhibitor of telephones claims priority of invention over Drawbaugh himself. This is Antonio Meucci, who certainly has a patent twenty years old for a "speaking telegraph." But this and other telephone matters I must leave for a future letter, when, perhaps, I may be able to give more particulars of the great telephone suit.

THE BRITISH ASSOCIATION MEETING AT MONTREAL.

The Seat of the Electromotive Forces in the Voltaic Cell.*

I. ORTHODOX STATEMENTS BELIEVED BY PROFESSOR O. J. LODGE TO BE TRUE IN THE FORM HERE SET DOWN.

A.—Volta.

1. Two metals in contact ordinarily acquire opposite charges; for instance, clean zinc receives a positive charge by contact with copper, of such a magnitude as would be otherwise produced under the same circumstances by an E.M.F. of about ·8 volt.

2. This apparent contact E.M.F. or "Volta force" is independent of all other *metallic* contacts wheresoever arranged, hence the metals can be arranged in a numerical series such that the "contact force" of any two is equal to the difference of the numbers attached to them, whether the contact be direct or through intermediate metals. But whether this series changes when the atmosphere, or medium surrounding the metal, changes is an open question; on the one side are experiments of De la Rive, Brown, Schultze-Berge; on the other side of Pfaff, Pellat, Von Zahn. It certainly changes when the free metallic surfaces are oxidised or otherwise dirty. And in general this "Volta force" is very dependent on all non-metallic contacts.

3. In a closed chain of any substances whatever, the resultant E.M.F. is the algebraic sum of the Volta forces measured electro-statically in air for every junction in the chain, neglecting magnetic or impressed E.M.F. [Verified most completely by Ayrton and Perry.]

B.—Thomson.

4. The E.M.F. in any closed circuit is equal to the energy conferred on unit electricity as it flows round it.

[Neglect magnetic or impressed E.M.F. in what follows.]

5. At the junction of two metals any energy conferred on, or withdrawn from, the current, must be in the form of heat. At the junction of any substance with an electrolyte, energy may be conveyed to or from the current at the expense of chemical action as well as of heat.

6. In a circuit of uniform temperature; if metallic, the sum of the E.M.F. is zero by the second law of thermo-dynamics; if partly electrolytic, the sum of the E.M.F. is equal to the sum of the energies of chemical action going on per unit current per second.

7. In any closed conducting circuit the total intrinsic E.M.F. is equal to the sum of the chemical actions going on per unit electricity conveyed ($\Sigma . J \theta \epsilon$), diminished by the energy expended in algebraically generating reversible heat.

8. The locality of any E.M.F. may be detected, and its amount measured, by observing the reversible heat or other form of energy there produced or absorbed per unit current per second. [This is held by Maxwell but possibly not by Thomson, though its establishment is due to him.]

II. STATEMENTS BELIEVED BY PROFESSOR O. J. LODGE TO BE FALSE, THOUGH ORTHODOX.

9. Two metals in air or water or dilute acid, but not in contact, are practically at the same potential. [Sir Wm. Thomson, Clifton, Pellat.]

10. Two metals in contact are at seriously different potentials (*i.e.*, differences of potential greater than such milli-volts as are concerned in thermo-electricity). [This is held by nearly everybody.]

11. The contact force between a metal and a dielectric, or between a metal and an electrolyte, is small. [Ayrton and Perry, Clifton, Pellat, and probably Sir Wm. Thomson.]

III. STATEMENTS BELIEVED BY PROFESSOR O. J. LODGE TO BE TRUE, THOUGH NOT ORTHODOX.

12. A substance immersed in any medium tending to act upon it chemically will (unless it is actually attacked) be at a different potential to the medium in contact with it, positive if the active element in the medium is electro-positive, negative if the active element is electro-negative.

13. The above difference of potential can be calculated approximately from the potential energy of combination between the substance and the medium, the energy being measured by compelling the combination to occur and observing the heat produced per amount of substance corresponding to one unity of electricity.

14. In addition to this contact force, due to potential chemical action or chemical strain, there is another which is independent of chemical properties, but which seems to be greatest for badly conducting solids, and which is in every case superposed upon the former contact force, the two being observed together and called the Volta effect. Very little is known about this latter force except in the case of metals; and in these it varies with temperature, and is small. In the case of non-metals it is often much larger than the chemical contact force.

15. The total contact force at any junction can be experimentally determined by measuring the reversible energy developed or absorbed there per unit quantity of electricity conveyed across the junction. [Practical difficulties, caused by irreversible disturbances, being supposed overcome.]

16. In a chain of any substances whatever, the resultant E.M.F. between any two points is equal to the sum of the true contact forces acting across every section of the chain between the given points (neglecting magnetic or impressed forces).

17. In a closed chain the sum of the Volta forces, measured electro-statically in any (the same) medium, is equal to the sum of the true contact forces, whether each individual Volta force be equal to each individual true force or not.

18. Wherever a current flows across a seat of E.M.F. there it must gain or lose energy at a rate numerically equal to the E.M.F. multiplied by the strength of the current.

Development of the above and special application to metals.

19. A metal is not at the potential of the air touching it, but is always slightly below that potential by an amount roughly proportional to its heat of combustion, and calculable, at any rate approximately, from it. For instance, clean zinc is probably about 1·8 volt below the air, copper about ·8 volt below, and so on. If an ordinary oxidising medium be substituted for air in the above statement it makes but little difference.

20. Two metals put into contact reduce each other instantly to practically the same potential; and consequently the most oxidisable one receives from the other a positive charge, the effect of which can be observed electro-statically.

21. There is a slight true contact force at the junction of two metals which prevents their reduction to *exactly* the same potential, but the outstanding difference is small and varies with temperature. It can be measured thermo-electrically by the Peltier effect, but in no other known way. It is probably entirely independent of surrounding media, metallic or otherwise.

22. If two metals are in contact, the potential of the medium surrounding them is no longer uniform; if a dielectric it is in a state of strain, if an electrolyte it conveys a current.

23. In the former case the major part of the total difference of potential is related closely to the difference of the potential energies of combination, and is approximately calculable therefrom. In the latter case the total E.M.F. is calculable accurately from the energy of the chemical process going on, minus or plus the energies concerned in reversible heat effects.

24. There are two distinct and independent kinds of series in which the metals (and possibly all solids) can be placed; one kind depends on the dielectric or electrolytic medium in which the bodies are immersed, the other kind depends on temperature. The one is something like the Volta series, but it is really the Volta series minus the Peltier; the other is the Peltier. To reckon up the total E.M.F. of a circuit we may take differences of numbers from each series and add them together.

IV.—Brief Summary of the Argument.

25. Wherever a current gains or loses energy, *there* must be a seat of E.M.F.; and conversely, wherever there is a seat of E.M.F. a current must lose or gain energy in passing it.

26. A current gains no energy in crossing from copper to zinc, hence there is no appreciable E.M.F. there.

27. When a current flows from zinc to acid, the energy of the combination which occurs is by no means accounted for by the heat there generated, and the balance is gained by the current; hence at a zinc-acid junction there must be a considerable E.M.F. (say at a maximum 2·3 volts).

28. A piece of zinc immersed in acid is therefore at a lower potential than the acid, though how much lower it is impossible to say, because no actual chemical action occurs. [If chemical action does occur it is due to impurities, or at any rate to local currents, and is of the nature of a disturbance.]

29. A piece of zinc, half in air and half in water or acid, causes no great difference of potential between the air and the water (Thomson, Clifton, Ayrton and Perry, &c.), consequently air must behave much like water.

30. If the air were not slightly positive to the water, as it is (Hankel), it might mean that the potential energy of combination of air with zinc is slightly greater than that of water, or it might represent a difference in the thermo-electric contact forces between zinc and air, and zinc and water, or it might depend on a contact force between air and water. [If such a contact force between air and water exists, it is obviously of great importance in the theory of atmospheric electricity, for the slow sinking of mist globules through the air would render them electrical.]

31. Condenser methods of investigating contact force no more avoid the necessity for unknown contacts than do straightforward electrometer or galvanometer methods; the circuit is completed by air in the one case and by metal in the other, and the E.M.F. of an air contact is more hopelessly unknown than that of a metal contact.

32. All electrostatic determinations of contact force are really determinations of the sum of at least three such forces, none of which are knowable separately by this means.

33. The only direct way of investigating contact force is by the Peltier effect or its analogues. [Maxwell.]

34. Zinc and copper in contact are oppositely charged, but are not at very different potentials; they were at different potentials before contact, but the contact has nearly equalised them.

Certain portions of these statements which may appear wildly hypothetical, such as 13, are to be justified by figures. The justification is not complete, for lead and iron are untractable, but it does not affect the main position.

The Use of Secondary Batteries in Telegraphy.*

BY W. H. PREECE, F.R.S.

About the middle of last year a series of experiments with secondary batteries was commenced on some of the telegraphic circuits, terminating at the General Post Office, London, and their satisfactory behaviour during twelve months' trial leads me to bring this subject before this section.

Dynamo-electric machines are regularly employed for signalling purposes in the United States. I think, therefore, before detailing the results of the experiments with secondary batteries in England it would be advisable to mention the experiments made with such machines there also. So long ago as the year 1865 the late Mr. Cromwell Varley tried a Wildes machine on several circuits at the Electric and International Telegraph Company's station in Telegraph-street, London. About 1870 the Lancashire and Yorkshire Railway Company used one at Manchester. In 1872 Mr. Culley experimented with a Gramme magneto machine on several Post Office lines of moderate length. It was found, however, that the trouble arose from the great variations in the strength of the current due to variations in speed, from the rapid corrosion of the contact points in the instruments, and from the intermittent disconnections at the machine. These disconnection were apt to cause serious errors in a message by changing the character under transmission, or at least to produce loss of time by creating repetition.

The improvements made in dynamo machines since 1872 would doubtless overcome these difficulties, but no advantage would be gained by using them for the English system of telegraphy, for it would be difficult to obtain suitable changes of potential, or to adjust the dynamic effects of the very numerous classes of lines radiating from the machine. England, unlike America, is subject to frequent meteorological variations, and the majority of its telegraphic circuits are always liable to a transformation from simplex to complex systems of signalling, or *vice versa*; moreover, the double current open circuit system being in use throughout Great Britain, uniformity of current is absolutely essential, especially where automatic working is in use. Rapid reversals of equal strength cannot be insured from dynamo machine.

In 1879 Mr. Louis Schwendler, the late electrician of the Indian Government, communicated to the *Philosophical Magazine* an interesting account of some experiments he had made with a dynamo-electric machine for signalling purposes, while the dynamo was simultaneously working a powerful electric light. The telegraphic circuits were applied as a leak to the main lamp circuit, and it was apparently found that the small signalling currents tapped off did not produce any perceptible variation of the electric light. He therefore suggested that if the main current from the dynamo could be employed for electric lighting, or other useful work, which would repay the expense of the erection and working of the dynamo electric machine, the signalling currents would cost nothing. This, of course, assumed that the electric light machine was always running.

In telegraphy exceedingly weak currents produce the desired signals. These currents are expressed in milliamperes, (the thousandths of an ampere), and can conveniently be obtained from a battery at pleasure. Furthermore, the number of independent units into which a battery of even a moderate size can be subdivided is a very weighty advantage of which a dynamo-electric machine is wholly void. Now, if dynamo-electric machines were substituted for batteries at convenient English offices, there would still be a very large percentage of batteries required. The Postal Telegraph depot had in use last year 129,789 cells of the bichromate, Daniell and Leclanché type. And if at the seven principal centres where steam engines are working for the pneumatic system all the cells (amounting, approximately, to 38,773) were replaced by dynamos, we should still have 70 per cent. more batteries than those replaced, for which dynamo-electric machines could not be substituted.

I will consider the London central station alone, as it contains about six times more cells than either of the other six offices. In March of the current year there was a total of 687 circuits, radiating from the chief offices through England, Ireland, Scotland, and Wales; and the various classes of circuits require different strength of current ranging from 14 to 80 milliamperes. The full current for all the circuits, viz., 20 amperes, has been approximately determined by adding together the currents necessary for each kind of instrument. The total battery-power for these circuits was about 20,000 cells, which implies an approximate electromotive force of 28,000 volts, or an average of 40·75 volts per circuit. From this data we find that the total electric energy for all the circuits would be $\left(\frac{28{,}000}{687} \times 20\right) = 815$ watts, or 1·09 horse-power, which would equal 0·0016 of a horse-power nearly for each circuit.

The total number of circuits include 290 distinct sets of special apparatus like those aforementioned, and employ 7,956 cells, or an average electromotive force of 11,112 volts. The output of current for these circuits is estimated at 6 amperes, therefore the energy expended equals $\left(\frac{11{,}112}{290} \times 6\right) = 230$ watts, which are equal to 0·3081 horse-power. After deducting this from the total horse-power, 1·09, we have left 0·782 as that which might be developed by

* A paper read at the British Association meeting, Montreal.

Digitized by Google

aid of a dynamo-electric machine in place of batteries. But this small amount of energy represents 397 circuits, which must be divided into groups of, say, 40 circuits, to facilitate expeditious removal of faults, as well as to reduce the number of lines subject to stoppage by a fault occurring on either branch within reasonable limits. We should then have to provide eleven dynamo-electric machines, ten for the actual work and one for reserve, for we must endeavour to avoid a long cessation of telegraphic transmission. Suppose the 40 circuits grouped on one dynamo demanded an electromotive force of 40 volts, and a flow of one ampere current from the generator, when all were working simultaneously the maximum horse-power would be 0·053, as compared with the minimum, 0·0013, horse-power required for a single circuit, showing a variation between ·0013 and ·053 of a horse-power. We clearly have an exceedingly small expenditure of electrical energy for a dynamo to develop in compensation for the constant consumption of coal, wear and tear of engine, &c., and incessant attention required. Calculation, however, brings out the annual cost of maintenance of dynamos considerably below the annual cost of maintenance for voltaic cells. We find the mean cost per cell per annum to be 2s., which, for 12,044 cells (the number we assumed to be replaced in the London Post Office by dynamo-electric machines) amounts to £1,204 8s. a year. Now, suppose the dynamos had a commercial efficiency of 80 per cent., the mechanical energy necessary to produce 0·782 of a horse-power, as electrical energy would be 0·977, or say 1 horse-power, and as horse-power requires about 4½lb. of coal for its production, the cost of coal at 20s. a ton for twelve months' running of dynamos averaging 18 hours a day, would be £14 16s., the annual cost may be specified thus :—

Wages of four men at 25s. a week......	£260	0	0
Four per cent. interest on the plant valued at £1,300	52	0	0
Depreciation at 10 per cent..................	130	0	0
Coal at 20s. a ton	14	16	0
Waste and oil	10	0	0
	£466	16	0

which shows a balance of £737 12s. in favour of dynamo-electric machines. Nevertheless there would be a decided disadvantage in using them, not only for the reasons already assigned, but also in the event of fire, when we could not so quickly or so aptly restore communication as with batteries. In the latter, batteries could be easily applied to the respective circuits at the nearest point of safety, whereas engines or dynamos would introduce many difficulties, and cause much loss of time. Finally, it should be remembered that the cost of batteries is so small an item in the general maintenance of the entire system of telegraphy that its consideration may be ignored. It is a question of efficiency and not of economy that will determine their use.

The first experiment with secondary batteries was that of eight so-called half horse-power Faure-Sellon-Volckmar cells, working a universal circuit system consisting of 31 distinct and separate circuits. These worked continuously for seven weeks without the slightest hitch or attention. Then came eight of Mr. Tribe's secondary cells, which were put on a similar universal set of 30 circuits, and worked it successfully for 52 days 2 hours. When exhausted the cells were joined to a dynamo, and a current of three amperes passed through them for 48 consecutive hours, no attendance beyond a casual glance being required. They were again started on the same circuit and lasted 58 days; a third similar charge was given them, and the circuit worked efficiently for another seven weeks. Their behaviour was so good that we had no occasion even to look at them until a day or two before exhaustion. With two of the same kind of cells a local sounder circuit, requiring five of our largest Daniells, was sucessfully worked without any attention for eight weeks. A further and very valuable experiment was also made with twelve Faure-Sellon-Volckmar cells on a universal set consisting of fifteen circuits, which terminated after fifteen weeks, or, excluding Sundays, ninety-two days' work. These were replaced by fifteen double fluid bichromate cells of quart size, and instructions given to carefully note the quantity of material used and time of attention bestowed upon them during the same period of action, viz., fifteen weeks. The particulars of this comparative test were as follow :

The secondary battery worked ninety-two days, averaging twelve hours a day, and the mean current was 0·5 of an ampere per hour, which six ampere-hours = a day, 552 ampere-hours for the whole time.

From what has been stated it will be evident that soon secondary batteries will be made the most economical of the three classes of generators considered. In them there is no waste nor trouble due to diffusion of liquids, as in primary batteries, while they possess all the features necessary for the requirements of the service of large offices. Even while they are being recharged, it would be possible for the circuits to work from the batteries simultaneously.

The only caution we have to exercise is that of preventing the current, in case of a short circuit accidentally occurring from fusing parts of the instruments, or injuring by heat the gutta percha insulation of the leading wires, which run together in large numbers from the battery room to the instrument room. This we can do by constructing the secondary cells with a suitable resistance.

Lastly, it is worthy of notice that a charge of acid does not want renewing. All that is necessary is simply to recharge them electrically.

LITERATURE.

The Electricians' Pocket Book. Being the English edition of Hospitalier's "Formulaire Pratique de l'Electricien." Translated, with Additions, by GORDAN WIGAN, M.A.

This is a work which is much more bulky than is necessary, in that the useful portions of it are too greatly mixed up with what is either unimportant or ill-explained; and its title of *pocket book* is an entirely honorary distinction, for not only has it no pocket itself, but it will not willingly enter any known pocket. In these two particulars it falls decidedly below its German congener by Rohrbeck. Unlike the latter, too, it is printed on disagreeably thick paper, and will not remain open upon a table, an unpardonable sin in books of reference, or indeed in any book.

There is, however, a very great deal of useful matter in the work. Would that it were furnished with an adequate index, in the absence of which much of the usefulness depends upon chance. The mathematical part of the book is far away the weakest, and this is likely to create in the minds of those who find it out an unnecessary doubt about the rest. Thus, at p. 4, in describing the coefficient of induced magnetism, or magnetising function, we have :—"Let H be the intensity of a magnetic field, γ the intensity of magnetisation, the magnetising function k is given by the equation $k = \frac{\gamma}{H}$. It is proportional for very small values of H; beyond such values k is a function of H, which diminishes when H increases, and tends towards a final value, which is called the limit of magnetisation." Possibly this may deceive no one, for nobody who is likely to employ the coefficient of induced magnetism will require to be reminded of the proper connection between k H and γ. The sentence of explanation, if any is required after the formula, should be—"It is constant for small values of H, but afterwards diminishes, and tends to an inverse proportionality to H." There occurs at p. 13 the now commonplace confusion on the subject of energy and power, a confusion which Mr. Preece has been recently exhibiting and reprobating in the same breath in Canada, when charitably endeavouring to show that Professor Adams labours under the same disadvantage. A battery is said to be doing its maximum work when the external resistance is equal to its internal resistance. This is known to be the condition under which most *power* is developed in the external circuit, *i.e.*, when the *rate* of external work is a maximum. If a certain

Digitized by Google

number of coulombs, dependent upon the weight and chemistry of the battery, have to flow away before the battery becomes useless, which, whether exactly true or not, is at least the first approximation to the truth, then obviously most work will be done in the external circuit when the resistance is infinite. W_u in the middle of p. 13 should be taken to mean the maximum *power* possible in the *external* circuit, and the equations should be written $W_u = \frac{E\,C_m}{2 \times 9{\cdot}81} = \frac{E^2}{4\,r \times 9{\cdot}81}$.

After this formula the phrase is altered to *rate of work*, which is right, but the casual alteration of important ideas without change of symbol betrays the prevalent confusion of thought, which is also apparent in the expression, p. 16, $W = \frac{E^2}{R}$ *t watts*, instead of *joules*, or *decamegergs*.

The translator has adhered rather too much to assumptions, which would be natural enough in France. Thus, with the calorie at p. 15, there is no sign whatever that the centigrade scale upon which, with the gramme of water, it is based, must be used.

It is very unnecessary perhaps to indicate the fact, but not more so than to indicate the weight (gramme) without the substance (water), and the degree of scale (d) without the kind of scale (centigrade), which is done. It may be said that values of the terrestrial magnetic elements are of little use, as being variable, but at least the values at Greenwich at two epochs would have been of more use to Englishmen than those at Paris, which alone will be found at p. 183. Here, again, the units have led the writer astray. The earth's magnetic field is said to be of so many *dynes*. Now these *dynes* would only be the *force* (C.-G.-S.) which would act on a unit *pole* (C.-G.-S.), if it were there. The field itself has for a formula $[L^{-\frac{1}{2}}\,T^{-1}\,M^{\frac{1}{2}}]$, the same thing as intensity of magnetisation, and to this idea Sir Wm. Siemens gave the name of gauss, though it is doubtful whether he meant the word to apply to the C.-G.-S. unit or to the quadrant unit, which are to one another as $10^{10} : 1$. Force, the C.-G.-S. unit of which is called a *dyne*, is of the dimensions $[L\,T^{-2}\,M]$. The field when acting on a pole $[L^{\frac{3}{2}}\,T^{-1}\,M^{\frac{1}{2}}]$ produces force. The unit of pole is said (p. 40) to have no name. This is an error, as Sir Wm. Siemens called it a weber, though here again it seems doubtful whether weber was to apply to the C.-G.-S. unit of pole or to the quadrant unit, which are as $1 : 10^8$ to one another. Any writer attempting to give formulæ as guides to others should be most careful to define exactly the meaning of his symbols. At p. 22 we have the action of an elemental conductor carrying a current upon a magnetic pole formulated. The form involves the angle α, which is left quite unexplained. It is the angle which the line joining the pole and the element of a linear conductor, makes with the direction of the conductor.

At p. 23 there is the statement that the intensity of the field of a solenoid is at a maximum at the centre. This is misleading, for it is true only when points along the axis of the solenoid are considered. As far as points in the *transverse plane* through the centre are concerned, the intensity is a a minimum at the centre.

The mathematical formulæ in the mechanical portions of the book show signs of having been copied in straight from another source without the limitations to which they are subject being stated. Thus the square of the radius of gyration of a rod bent into the arc of a circle, the axis of rotation passing through the middle of the arc along a radius, is said to be $\frac{r^2}{2}$ when r is the radius of the arc of the circle. This is only true when the angle which the arc forms is some multiple of two right angles. The true square of this radius of gyration is $\frac{r^2}{2}\left(1 - \frac{\sin\alpha}{\alpha}\right)$. Where α is the angle of the arc, $\sin\alpha$ will vanish when $\alpha = n\pi$, n being any integer. Thus the formula, as given in the book, is true for semi-circles and whole circles, but not for other portions of a circle. It is also true for quarter circles, if the axis is a radius passing through the end of the arc.

Having mentioned most of the errors and oversights which have presented themselves more obviously, it will be only candid to say that these form a very minute portion of the whole work, the practical matter of which seems very well selected, and only to want a thorough index. At the end of the book are a good many pages of diagram paper, ruled to squares whose areas are ·25 C.-G.-S. units. This is an excellent point in itself, and would be still more valuable if the work were a real pocket book. To point out slips will, it is hoped, only render a useful book more useful, and it is in this mood that the book has been dealt with now. It is satisfactory to learn that Mr. Wigan contemplates issuing it periodically, and if it reappears as a real pocket book we hope that the period will be 31·6 mega-seconds.

PROFESSOR ROWLAND'S PRESIDENTIAL ADDRESS AT THE PHILADELPHIA CONGRESS.

(*Concluded from page 483.*)

Many years ago I myself experimented on the subject and obtained a result about 4 per cent. too high. Recently Lord Rayleigh has taken up the matter and made a series of experiments of unparalleled accuracy in this line. The International Commission, determined on by the Electrical Congress in Paris in 1881, met in April of this year at Paris, and has now given us a legal ohm defined as being the resistance of a column of mercury 106cm. long and 1mm. in section at 0° C. The length best satisfying the experiments is about 106·25, but it was considered best to use the round number. The experiments which I have been making under an appropriation from the Government are now barely completed, but they will probably agree very well with the latter figure. Hence, we can say that we now know this unit of resistance to one part in one thousand, at least. And so we are in a position to measure the energy of a current to the same degree of accuracy, as far as this quantity is concerned.

But to measure a current by the tangent galvanometer one requires to know the intensity of the earth's magnetism, a quantity difficult to determine and constantly varying with time and place. The electro-dynamometer, when made with care, is excellent, but a good one is immensely expensive. Our methods, then, of current measurement are bad, unless carried out in a completely equipped physical laboratory. With a practical standard of electromotive force, such as a Clark's standard cell or a thermo-electric battery, this difficulty partially vanishes. Better, perhaps, we might make simple electro-dynamometers with constants determined by comparisons with a more costly instrument.

But where shall these standards be kept? Evidently the Government, which decides on our standards of weights and measures, should take in charge the electrical standards, and possibly also the thermometric standards. The formation of such a bureau of physical standards will be brought to the attention of this conference.

Having given certain standards, then the measurement of currents and current energy becomes easy. The amount of heat generated in a wire of known resistance by a known current is also easily found from the absolute system of electrical measurement.

Besides the two so-called absolute systems of measurement of electricity and electric currents, we have also one based on the chemical action of the current whose laws were discovered by Faraday. Knowing the electro-chemical equivalent of some substance we are able to measure the time integral of the current or the total quantity of the current which has passed.

The absolute measurement of magnetism is equally simple with that of electricity, and it is a common observation to find the earth's magnetic force. But Faraday has put in our hands a very simple method of measuring a magnetic field, and to-day all are familiar with his beautiful laws with respect to magnetic lines of force. We know the laws of electro-magnetism, and just how many lines of force (better induction) can pass through a piece of iron of given cross section, and what is their relative resistance when passing through air or iron. In fact, we have all that is necessary for a complete theory of the dynamo-electric machine, and consequently we find that the latter agrees perfectly with theory, and no fact has been observed with reference to it which could not have been foreseen from theory by a person of proper intelligence.

This part of electrical science, the measurement of electrical and magnetic quantities, is thus in a very forward state, based as it is on the mathematical theory of the subject. But, in reality, this forms but a very small portion of our science. Shall we be contented with a simple measurement of what we know nothing? I think nobody would care to stop at this point, although he might be forced to do so. The mind of man is of a nobler cast, and seeks knowledge for itself alone. We are not so base as to be honest because "Honesty is the best policy," neither are we so ignoble as to seek knowledge because "Knowledge is power," two sayings which are certainly true, but low and sordid in their tone.

We have, then, the beautiful fabric of mathematical electricity given to the world by Poison, Green, Helmholtz, Thomson, Maxwell, and others whose names are immortal. No hypothesis as to the nature of electricity rests at its base. Starting from the most simple laws of electricity and

Digitized by Google

magnetism, it rises from a stable foundation and rears its form high in air, never to be overturned, whatever the fate of the so-called electric fluid or the ultimate theory of magnetism. On the simple fact that there is no electric force inside a closed conductor, it is proved that the electric attraction and repulsion varies inversely as the square of the distance. This fact is sufficient to give us the whole theory of electrostatic distribution on conductors.

From the simple fact that we can break a magnet up into parts which are similar to each other, and that these parts attract and repel each other in a certain manner, we derive many important facts with regard to magnetism.

From the magnetic action of the current we find, by an application of the great law of conservation of energy, all the laws of induced currents, either from magnets or other currents. By an almost superhuman effort of the intellect we detach our electric currents from matter, and suppose them to take place in the ether of space, and we have the grand electro-magnetic theory of light given to us by Maxwell.

But the subject is too vast to be treated in a moment. Suffice it to say that no person at the present day has the right to express an opinion on any theoretical question connected with electricity without a knowledge of its mathematics.

This study has led us to alter our ideas on many questions. What is the mechanism of electric or magnetic attraction? Faraday has given us his idea of lines of force, and has made them play an important part in the theory of magnetic induction. When treated mathematically, Maxwell has shown that all electric and magnetic attractions can be explained by a tension along the lines of force and pressure at right angles to them, an idea due to Faraday.

The mathematical theory of these lines shows that all electro-static forces between either conductors or non-conductors can be explained in this manner. As the laws of magnetic attraction are the same in every way as electro-static attraction, if we should do away with electric conduction, it follows that magnetic attraction is to be explained in exactly the same manner. In obtaining this result Maxwell calculated the forces acting on the medium at every point, and compares these with imaginary stresses in a medium at the given point. Hence, the energy stored up can be represented either as due to the mutual attraction of the electricity at a distance or to the stresses in the medium at every point, and thus, as Thomson has shown, by a volume integral of the square of the force at every point. Hence, we are at liberty to deny the existence of all action at a distance and attribute it to the intervening medium, which, to be logical, we must assume to be continuous and not molecular in constitution.

Thomson has pointed out that magnetism must be of the nature of rotation, such as possibly vortex motion in a fluid, and Maxwell has done something towards making a mechanical model of such a medium. Thomson's wonderful address at Montreal has also given us much to think of in the same direction.

But here we have reached the limit of our science, and even that servant of our reason, imagination, fails us. We are yet unable to picture to ourselves what takes place in a medium subject to electro-static action. We are face to face with the great problem of nature and the questions, what is matter? what is electricity? evoke no answer from the wisest among us. Our mathematics have guided us safely up to a certain point, and will guide us still further; science will advance and we shall know more. But, for the present, this is the limit which we have as yet attained in this direction. However, the idea of a medium is still serviceable in other portions of our science.

We have seen that the medium explains the electrical and magnetic attraction of bodies at rest. The question then comes up as to what happens in the medium when these bodies move. Are the imaginary stresses in the medium transmitted from place to place instantaneously, or do they require time? Mathematics in the hands of the immortal Maxwell have answered this question, and we now know that any magnetic or electric disturbance is propagated through space with a velocity equal to the ratio of the electro-magnetic to the electro-static unit of electricity. This great physical constant has now been found by experiment to be equal, to the velocity of light, and thus has arisen that great modern theory, Maxwell's electro-magnetic theory of light. Indeed, at the present day, so perfectly does this theory agree with experiment that we can almost regard it as a certainty. The velocity of light and the ratio of the units agree far within the limits of experimental error. The fact that bodies having a true (not electrolytic) electric conduction are always more or less opaque, the refraction and dispersion of light, double refraction and diffraction, all are explained on this theory with an ease and simplicity wanting in all other theories; and lastly, an electro-magnetic phenomenon has been discovered, which, when applied to this theory of light, explains the rotation of the plane of polarisation produced by a magnet. There is no fact in nature seriously in disagreement with this theory, and it serves to connect two of our most important branches of physics, light, and electricity.

But some physicists say that it is not a true theory because it is not mechanical, the object of these physicists being to reduce every phenomenon of nature to matter and motion. Whether this is necessary or not I leave to the philosophers. But it is to be noted that the old mechanical theory that light is a vibration in a medium having the properties of an elastic solid is not entirely at variance with the new theory. The medium we call ether. The electro-magnetic theory says that the waves of light are waves of electric displacement, while the old theory says they are waves of ether. Make electricity and the ether equal to each other and the two theories become one. We have arrived at that hazy and unsatisfactory theory of Edlund that ether and electricity are one, except that by this theory electricity is presented to us as an elastic solid!

But the ground trembles beneath us, and we shall soon be plunged in the mire of vague speculation if we do not draw back.

Among the other questions which depend for their solution on the presence of a medium may be mentioned the mutual action of two electrified bodies moving in space. It has been found that electricity carried through space on a charged body has exactly the same magnetic effect on a stationary magnetic needle as if it had been conducted.

But when electrified bodies move uniformly forward in space we can conceive of no mutual effect from such motion unless it is relative to a medium. For we cannot even conceive of absolute motion.

Assuming the medium to exist, we then know that a positively and negatively charged body flying through space with the velocity of light would have their electric attraction just balanced by their magnetic repulsion, and so would exert no force on each other.

But it is a most wonderful fact that we have never been able to discover anything on the earth by which our motion through a medium can be directly proved. Carried as we suppose by the earth with immense velocity through regions of space filled with ether, we have never yet been able to prove any direct influence from this etherial wind.

The assumption of a medium allows us to solve in some cases that problem so long under discussion by electricians—namely, the true velocity of an electric current. We now know that the term velocity hardly applies to this case, and that the current arrives at different points so gradually that we know not when to say it has arrived. But there is certainly a minimum time when even an infinitesimal current can reach a distant point. Suppose two wires stretched in space with their ends near together at one end, and a Leyden jar be discharged from one to the other at the near end. The *minimum* possible time of obtaining a spark at the distant end will evidently be the time required by light to pass from the Leyden jar to the distant point, not around the wire, but in a straight line. In this case the greatest maximum velocity is thus twice that of light reckoned around the wire, and may be any amount greater when we bend the wire. For all ordinary distances this velocity may be considered infinite, and the retardation to depend only on the electro-static capacity and magnetic self-induction of the wire. Treated in this way, we have Thomson's mathematical theory of the propagation of an electric wave along a telegraph wire or cable, a theory of great practical use in telegraphy and telephony. But until the action in the external medium is also taken into account, it can only be considered an approximation. For we can never move a magnet, discharge a Leyden jar, or complete the circuit of a battery, without causing a wave of electro-magnetic disturbance in the ether, and every signal which is sent along a telegraph line is accompanied by a wave in the ether, which travels outward into space with the velocity of light. Truly, the idea of a medium is to-day the keystone of electrical theory, but we can hardly suppose that it has even yet attained a fraction of the importance to which it is destined to rise.

Let me now call your attention to one of the most wonderful facts connected with electrical science. When we are dealing with the electro-static action of electricity, we find that it is the so-called electric fluid which attracts the opposite. Not only do we observe the attraction of bodies oppositely charged, but the electricity itself on the two bodies is displaced by its mutual action. But when we come to investigate the mutual attraction or repulsion of electric currents on each other, we find an entirely different law. In this case the conductors carrying the currents attract or repel each other, but the currents within those conductors have no influence of attraction or repulsion to displace themselves within the body of the conductor. In other words, the current is not displaced by the action of a neighbouring magnet, but flows on calmly as if it were not present.

This to me is one of the most wonderful facts in electrical science, and lies at the foundation of our science. It cannot be ignored in any further progress we may make in electrical theory, but points out a radical difference between electro-static and electro-magnetic action.

I have said there is no action of a magnet in displacing an electric current, and have thus stated the broad general fact, and which is perfectly true in some metals. But in others there is a small action which changes in direction with the material. The elements of the electric current within the material are rotated around the lines of magnetic force; sometimes in one direction and sometimes in the other, according to the material. But the action is, in all cases, very weak. When applied to the electro-magnetic theory of light, this action leads to the magnetic rotation of the plane of polarisation of light. As to the explanation of both these actions, Thomson has remarked in the case of light, from dynamical considerations, the rotation can only come from a true rotation of something in the magnetic field, and leads us to think of all magnetic action as of the nature of vortex motion in a fluid. But here our theory ends for the present. We have obtained a clue, but it is not yet worked up.

I have now taken a rapid glance at some of the modern advances of electrical science, and we have not yet had to give up the old idea that electricity is liquid. To the profound thinker this idea is very vague, and there are some facts at variance with it, but it is still useful. We often hear persons say that this old idea is gone, and that electricity is "force," whatever they may mean by that. But let us see. The work or energy of an electric current between any two points is the quantity of electricity passed multiplied by the potential; this work goes to heating the wire. Let a current of water be passing in a pipe and the quantity of water multiplied by the difference of pressure between two points gives us the work which has been done in the intervening space, and which has produced heat. The analogy is complete. No electricity has been destroyed in the one case, or water in the other, but the work has come from the fall of potential in the one case, and the fall of pressure in the other; the resultant is the same in both—heat. Again, we can obtain work from the mutual attraction and repulsion of electrified bodies, and the work in this case always comes from the change of potential between the bodies while the electric charges remain undisturbed in quantity. Electricity, then, is not energy, but is more of the nature of matter.

So far for electricity in the state of rest or steady flow. But when it changes from rest to motion, all known liquids have a property known as

Digitized by Google

inertia; furthermore, they have weight. But the electric fluid has neither inertia nor weight as far as we have yet experimented, and in this respect differs from all known matter. Furthermore, we have never yet been able to separate electricity from ordinary matter. When we pass electricity through a vacuum, the resistance becomes less and less, and one may have hopes of finally having an electric current through a vacuum. But, as the exhaustion proceeds, we observe that the resistance begins to increase until it reaches such a point that no discharge can take place. Electricity cannot exist, then, without matter, a fact fatal to the idea of a fluid, however useful that may be. We have but one conclusion from this, and that is that *electricity is a property of matter*. Do with it what we may, it can never be separated from matter, and when we have an electrical separation the lines of force must always begin and end in matter.

The theory of matter, then, includes electricity and magnetism, and hence light; it includes gravitation, heat, and chemical action; it forms the great problem of the universe. When we know what matter is, then the theories of light and heat will also be perfect, then and only then shall we know what is electricity and what is magnetism.

It is the problem of the universe which *looms* up before us and before which we stand in awe. The intellect of the greatest among us appears but feeble, and we all, like Newton, appear but as children on the sea-shore. But how few of us find the shells which Newton did, and how few of us try. The problem is vast, and the means for its solution must be of corresponding magnitude. Our progress so far has been but small. When we push our inquiry in any direction we soon reach a limit; the region of the unknown is infinitely greater than the known, and there is no fear of there not being work for the whold world for centuries to come. As to the practical applications which await us, the telegraph, the telephone, and electric lighting are but child's play to what the world will see in the future.

But what is necessary to attain these results? We have seen how the feeble spirit, which was waked up by friction in the amber and went forth to draw in light bodies, has grown until it now dazzles the world by its brilliancy, and carries our thoughts from one extremity of the world to the other. It is the genius of Aladdin's lamp which, when thoroughly roused, goes forth into the world to do us service, and returns bearing us wealth and honour and riches. But it can never be the servant of an ignorant or lazy world. Like the genius of Aladdin's lamp it appeared to the world when the amber was rubbed, but the world knew not the language in which to give it orders, and was too lazy to learn it. The spirit of the amber appeared before them to receive its orders, but was only gazed at in silly wonder, and retired in disgust. They had but to order it and it would have gone to the uttermost part of the earth with almost the velocity of light to do their bidding. But in their ignorance they knew not its language. For two thousand yea s they did not study it, and when they then began to do so, it took them two hundred and fifty years to learn the language sufficiently to make a messenger of it. And even now we are but children studying its A B C. It is knowledge, more knowledge, that we want.

I have briefly recounted the advances which we have now made in one science, and, however beautiful it may appear, we have soon reached the limits of the known, and have stood in wonder before the vast unknown. For very much of our science we see no practical applications, but we value it no less on that account. We study it because we have been gifted with minds whose exercise delights us, and because it seems to us one of the highest and noblest of employments. And we know by the history of the past that the progress of the world depends on our pursuit, and that practical applications, such as the world has never even conceived of, await us. It is necessary that some should go before to clear the way for the world's advance.

This is the work of the pure scientist; to him the problem of the universe is worth devoting his life, and he looks upon wealth as only adding to his means of research. He hopes not to solve the problem himself, but is contented if he may add some small portion to human knowledge; if he may but do his part in the march of human progress. He looks not for practical applications, but he knows full well that his most abstruse discoveries will be made useful to mankind at large, and so troubles himself no further about it.

The science which he creates is studied by others. Their minds are educated by it, and their hearts entranced by its beauties. And some are led to devote their lives to its further advancement. But the whole world benefits by it intellectually. The wayward spirit of the amber has vanished for ever, and prosaic, law-abiding electricity has taken its place even in the estimation of the most ignorant. The world has advanced, and in great part from the study of science.

Then comes the practical man who sees that other benefits can be reaped besides those of pure intellectual enjoyment. While the investigator toils to understand the problem of the universe, the practical man seeks to make a servant of our knowledge. He seeks to increase the power of our bodies and so make the bonds by which the mind is united to it less irksome. It is he that increases the wealth of the world and thus allows those so disposed to cultivate their tastes and to elevate themselves above the savages. The progress of the world depends upon his inventions.

Let not, then, the devotee of pure science despise practical science, nor the inventor look upon the scientific discoverer as a mere visionary person. They are both necessary to the world's progress, and they are necessary to each other.

To-day, our country, by its liberal patent laws, encourages applied science. We point to our inventions with pride, and our machinery in many of the arts is not surpassed. But in the cultivation of the pure sciences we are but children in the eyes of the world. Our country has now attained wealth, and this wealth should partly go in this direction. We have attained an honourable position in applied science, and now let us give back to the world what we have received in the shape of pure science. Thus shall we no longer be dependent, but shall earn our own science as well as inventions.

Let physical laboratories arise; let men of genius be placed at their head, and, best of all, let them be encouraged to pursue their work by the sympathy of those around them. Let the professors be given a liberal salary so that men of talent may be contented. Let technical schools also be founded, and let them train men to carry forward the great work of applied science.

Let them not be machines to grind out graduates by the thousand, irrespective of quality. But let each one be trained in theoretical science, leaving most of his practical science to be learned afterwards, avoiding, however, overtraining. Life is too short for one man to know everything, but it is not too short to know more than is taught in most of our technical schools. It is not telegraph operators but electrical engineers that the future demands.

Such a day has almost come to our country, and we welcome its approach.

Then and not till then should our country be proud, and point with satisfaction to her discoveries in science, pure *and* applied, while she has knowledge enough to stand in humiliation before that great undiscovered ocean of truth, on whose shores Newton thought he had but played.

SELECTED CORRESPONDENCE.

THE RECENT FATAL ACCIDENT AT THE HEALTH EXHIBITION.

The following correspondence has appeared in the London and provincial press in reference to this subject:—

TO THE EDITOR OF THE TIMES.

Sir: The recent accident to an attendant on a dynamo machine at the Health Exhibition, which caused his death, may very seriously prejudice the minds of those about to use the electric light in their houses. Will you allow me, through the medium of *The Times*, to point out that currents of extremely high electromotive force, such as that which caused the accident, have never been, and can never be, used for electric lighting in the form of the incandescent lamp, which is the only form suitable for domestic use?

My intimate connection with electric lighting has rendered it necessary for me to obtain exact data as to the extreme safe electromotive power or electrical pressure which can be safely used in situations accessible to the touch of human beings or animals. I have never been able to trace any accident to life or even injury to health from contact with electric wires, provided that the electromotive force has not exceeded 600 volts. The object of using such high pressures is to economise the weight and cost of conductors when the lamps are scattered over a wide area; but at the Health Exhibition there was no such necessity for economy, and it is much to be regretted that those responsible for the scientific management of the Exhibition should have allowed such dangerous pressures to be used in such a crowded and unprotected situation.

The electric light has had a hard battle to fight, and this bugbear of the supposed danger to life has not been one of the least of its enemies. So long as currents of low electrical pressure (such as are used with incandescent lamps) pass through the wires, they may be safely touched with one or both hands by a young child or delicate person with absolute impunity, and with no disagreeable sensation beyond a slight pricking, if the hands are damp. These facts are, of course, well known to the scientific world; but to the untrained public there is only "one kind of electricity," and they cannot readily understand why it should be dangerous to life in one form and not in another.

Your obedient servant,
R. E. CROMPTON.

Mansion House-buildings, E.C., Oct. 4.

TO THE EDITOR OF THE DAILY CHRONICLE.

Sir: The recent sad fatal accident in connection with a dynamo machine at the International Health Exhibition has naturally caused a good deal of comment, and may probably lead many of the public to believe that danger is inseparable from the use of dynamos. As this would be extremely prejudicial to the business of this company, I trust that you will permit me to say that the Edison dynamos supplied by this company do not generate a current of sufficient electrical tension to be in any way dangerous to life or limb. It is difficult to understand why any one should put a dynamo which may occasion a serious or fatal accident into a factory, or house, or ship, when machines of greater electrical efficiency, and containing no element of danger to the person, can be purchased as cheaply as these undoubtedly dangerous machines.—I am, Sir, your obedient servant,

S. FLOOD PAGE, Secretary.

Edison and Swan United Electric Light Company (Limited),
57, Holborn-viaduct, E.C., Oct. 4.

TO THE EDITOR OF THE MANCHESTER COURIER.

Sir: The recent death of an electrician at the Health Exhibition, while oiling a dynamo machine, has doubtless caused alarm to some who think of adopting the electric light in their houses. The circumstances of the case have not been clearly given in any of the public papers. I think it right, therefore, that it should be stated that, in incandescent lighting, there is not the slightest danger, and little inconvenience, experienced from handling the naked terminals of a machine driving a circuit of

Digitized by Google

Edison lamps; and as the resistance of the Edison lamp is higher than any other form of incandescent lamp, it follows that the inconvenience is still less when lamps of the Swan type are used. What I have said may be put to the test any evening by any one who will visit this company's central station in Mount-street. Here the current for lighting the Theatre Royal is generated; and any one who cares to do so may handle the terminals of the powerful dynamo machines employed without suffering more than a slightly uncomfortable feeling such as is usually experienced when receiving a "shock" from an ordinary electrical machine. The reason of this is that incandescent lamps are generally run in what is called "multiple arc," by which means the tension employed remains the same, whether one lamp be used or a thousand. Arc lamps, on the contrary, are usually lighted "in series;" in other words, the current is forced through each in succession, and must necessarily have an electromotive intensity capable of overcoming the combined resistances of the total number of lamps. As arc lamps usually need somewhat more than 40 volts of electromotive force for each, and as there were in this case 25 arc lamps "in series," it follows that more than 1,000 volts were passing through the circuit. This, you will observe, is 10 times the force employed in incandescent lighting, and it is this difference between the two methods of producing the electric light which it is desirable to make clear to your readers. When large numbers of arc lamps are lighted "in series" there is always danger, and the greater the number, the more the danger. But when incandescent lighting has been properly prepared for, by a careful installation carried out by competent persons, and with conducting wires of sufficient sectional area, there is no mode of producing artificial light at once so pleasant and so free from danger, either to life or from fire. This last mentioned advantage has not yet been sufficiently recognised by the insurance offices; but with the increaseing premiums now being demanded from Manchester warehouses, for covering fire risks, it cannot be long before the incandescent light will be included amongst those "safety appliances," for the adoption of which a liberal discount from fire premiums is allowed. My object, however, is not at present to discuss this question. My purpose will have been served if I shall have removed any needless alarm on the subject of incandescent lighting.—Yours, &c.,

GEO. FREEMANTLE, Secretary.

The Manchester and District Edison Electric Light Company (Limited), 19, Victoria-buildings, Manchester.

COMPANIES' MEETINGS & REPORTS.

Great Western Electric Light and Power Company (Limited).

The second ordinary general meeting of the shareholders of this Company was held at the City Terminus Hotel, Cannon-street, on the 6th inst., under the presidency of Mr. J. B. Braithwaite, jun.

The notice convening the meeting having been read, and the minutes of the last meeting read and confirmed,

The CHAIRMAN moved the adoption of the report. He observed that the efforts of the Board had of course been directed to two main things—first, to reduce the expenses of the Company, and get them on a satisfactory basis; and in the second place, to develop, if possible, a profitable business in electrict lighting in their district. They had reduced the expenses to a considerable extent, and with regard to the receipts, they were also glad to be able to state that, as far as their lighting stations were concerned, the receipts had been almost trebled during the year. The other business they had undertaken during the year had been of a very limited amount, owing to the fact that, though a large amount of business had been offering, only a small portion could be regarded by them as at acceptable rates. There had been a very large number of companies who had been willing to take work at no profit, and sometimes even at a loss, for the purpose of advertisement. They themselves had had a large number of inquiries from people who had business to offer on such terms as these, but he was glad to say that those people who thought that the Company would undertake work for nothing were disappearing, and that they were receiving inquiries from more substantial quarters. Passing to the report, he stated that with regard to the reduction of the capital he ought perhaps to apologise for the fact that the meeting of the Company this year was held somewhat later than before. The reason for this was that the Directors had thought it would be more satisfactory to the shareholders when they met to know that their liability in respect to their shares was wiped out. The assent of the Court to the reduction of the capital was only given on the 6th of August, and there was a further month during which the liability existed. Therefore their liability did not end really until the 6th of September, but it was now wiped out, and that part of the pledge which the Directors gave when they took office had been fulfilled. As to the claim made against them by the liquidator of the Devon and Cornwall Electric Light Company, that gentleman had very properly, and in accordance with his duties, no doubt, made a claim on this Company amounting to a very large sum—for the whole of the purchase money, both in cash and shares, for the money spent in the wrecking of the Company (or the working of it, as it had been called), and for the whole of the money sunk in plant. This matter had given the Board very great anxiety, but they were glad to be able to announce that it had been settled. They had surrendered the fully paid shares allotted to them in the Devon and Cornwall Company, and the 500 shares purchased by the late Board, on which they had paid £1,250. Besides that when the liquidation of the Devon and Cornwall Company was completed they would allot to the shareholders in that Company 3,000 fully paid shares of this Company, at £2 10s. each. The result of these proceedings was that the claim which had been made by the liquidator of the Devon and Cornwall Company had been withdrawn, and the Directors had been enabled to proceed with the reduction of the capital of the Company. As he had said, that liability was now wiped out, and really the practical result was this—that, for the first time, they had control of their property, because, while they had the claim referred to hanging over them, it would have been impossible, had they desired to do so, to wind up the Company. Their property was not their own until they had got rid of this claim. They were now, for the first time, free from all litigation, and free to go forward with the business of the Company. With respect to the lighting stations, they were a bequest of the late Board, and the Directors had done, and were doing, their best to develop them, in order that they might become profitable. They had a considerable amount of money locked up in plant at these stations, and it was necessary for them, if possible, to utilise them. Their efforts during last year had resulted in a large reduction in the working expenses, and an increase of some 200 per cent. in the receipts. This increase was still going forward. Since the report was issued they had received a considerable number of new orders for lights from these stations, and they quite anticipated in the coming year to be able to bring about an equilibrium between receipts and expenditure at them. They had purchased a portable plant, which they had found very useful for developing the lighting throughout their district. There were many places where their light had not been shown, and in those places people did not know what it was. They had, therefore, spent a small sum on this portable plant, which they could send at two or three days' notice to any part of their district for lighting up flower shows, bazaars, &c. The plant paid very well in itself—for they received very good rates for these installations—and, in addition, it tended to make the Company and the light known throughout their district. They had taken steps to canvass two or three likely towns in their district to see what prospect there was from putting down their apparatus, but so far they had not received such indications of support as would warrant them in proceeding further. With respect to the Anglo-American Brush Corporation, they had opened negotiations with them, the result of which had been that in exchange for the right which they had given to the Corporation to light railway trains in their district, and to put up the plant necessary for the purpose, they had surrendered to this Company £5,750 in fully paid shares of the Company. The directors regarded this as an advantageous arrangement, as it reduced the capital of the Company to the extent mentioned. As to the future, he did not think he could add much to what was stated in the report. They trusted, by prudence and economy, to be able to carry on the Company at a small outlay. That was the worst view. They had, however, now got the Company established on a satisfactory and commercial basis, and it was merely a question whether there was enough business to do to give them a sufficient margin of profit. They saw indications on all sides that the electric light was coming to the front. Every new building was now either lighted with the electric light, or arrangements were made for the purpose. This showed that the electric light was regarded as the light of the future. With regard to the result of the year's trading, unfortunately they had made a cash loss on trading account of £538, and they had also made a paper loss of £529, the latter representing the amount written off for depreciation. The total loss for the year had thus been £1,067. In drawing the accounts they had written off that loss against the amount received from the Brush Company in shares, and they had written back the balance which remained to the credit of profit and loss, to meet the shares which they had arranged to give to the liquidator of the Devon and Cornwall Company. He concluded by moving the resolution.

Mr. C. H. STEWART, in seconding the motion, said he could confirm all that the Chairman had stated as to the difficulties which the Directors had had in adjusting matters with the Devon and Cornwall Company and the solicitors connected with the bringing out of that Company. He need not say that all these complications had arisen from the accounts of the late Board, but he was very glad to say that they were now all closed, and that they were now in a position to go on with the business of the Company. It was simply a question whether the public would take to the electric light, but they would do so if they followed in the footsteps of their American cousins. The electric light was now in use in almost every town in the United States, and many of the mines there were similarly lighted. For his own part, he believed that if it had not been for the unjust legislation of the Government, which seemed to him to have been entirely in favour of the gas companies, much more progress would have been made with the electric light in this country. He, however, looked to the justice of Parliament to rectify the mistake which had been made, and to introduce a Bill in the coming session with that view, which might give a fair chance to electric light companies. He would advise the shareholders to continue to have confidence in the Directors. They would do their utmost to carry on the Company with the least possible expense, and they would only take orders where they saw a prospect of obtaining some small profit. He hoped at the end of next year that the Directors would be able to come before the shareholders with a more favourable statement than that which they submitted on the present occasion.

A short discussion followed, in which Messrs. HILYARD, COLE, and BROOKER took part, the latter gentleman suggesting that while the Company had a little money left the Directors should divide it among the shareholders. He was convinced that the thing would not pay, and that therefore it would be wise for them to get back what they could.

The CHAIRMAN said that Mr. Hilyard had asked for an explanation of the difference in the amount on deposit as compared with last year. Well, there was a difference of £1,500 in the amount owing to the Company, as

Digitized by Google

Mr. Hilyard had himself pointed out. Then there had been a loss on the lighting stations of about £800, and they had invested in plant—machinery and materials—roughly, to the extent of about £1,000.

Mr. HILYARD asked the Chairman to show at once how the difference of £4,000 was to be accounted for.

The CHAIRMAN: We show a loss of £81,000 on the year. There has been an increase of £1,700 in the amount of plant in stock, and there is a difference of £1,500 in the amount owing to us; that makes £4,200. In further reply, he stated that the number of shares allotted had been 22,000, and not 20,000 as stated in the balance sheet, owing to a clerical error. Altogether, with the vendor's shares, the number allotted was 24,744. There were 25,000 unissued, 3,000 of which they proposed to issue in due course to the liquidator of the Devon and Cornwall Electric Light Company. He had been rather surprised to hear Mr. Brooker say in one breath that the Directors were honest men, and in the next breath to state that they were aware that the Company could not possibly pay. If that were the view of the Board they would recommend the shareholders to wind up immediately; but they thought that there was a possibility of the Company paying. As to the expenses, they amounted last year to £1,676, and they expected in the course of the current year to reduce that amount to well within £1,000—they anticipated to between £800 and £900. Their receipts, too, at their lighting stations and from their general trading went on increasing. He might point to the last number of *The Electrician* to show that electric lighting was going on at an increasing ratio, and particularly with the Brush system. People were getting rid of the idea that they could obtain the electric light for nothing, or that they could have it for less than gas. They had never had one customer leave them on account of the light, but they had cut off one or two through their not having paid. No one had given up the electric light because he did not like it. On the contrary, many of them had increased the number of lights, and also the price paid to the old Board. On behalf of himself and his co-Directors he would say that the moment they came to the conclusion that there was no prospect of the Company paying, that moment they would recommend and urge the shareholders to wind up. The full amount of the Directors' fees was £1,000, but they were content with £500 for the year. The motion was then carried unanimously.

Mr. OFFOR next moved the re-election of Mr. Braithwaite as a Director of the Company. He stated that he could endorse the remarks of the Chairman as to the future, and he thought the immediate future. Those who studied the journals connected with electric lighting would thoroughly agree with the Chairman when he said that they were now in a very much better position than they were twelve months ago. They had had difficulties to contend with, no doubt, as to the Electric Lighting Act, and they had also other difficulties. They had had their partners in the electric light business proclaim to the world that the business was a failure. He thought that that was a great mistake, and his opinion was that those who were partners in the business should do their utmost to inspire confidence in the public.

Mr. LADD, in seconding the motion, expressed his belief that the Directors were doing all they could for the benefit of the Company. Electric lighting was, he said, steadily increasing—he knew that from the Anglo-American Brush Corporation. They were now doing work in other districts, and he did not see why the Company should not increase in the same way in the district they served. The motion was then carried unanimously.

The CHAIRMAN, in reply, expressed his thanks for the confidence shown in him by his re-election, and stated that the Directors during the current year would do their utmost to make the Company a paying concern.

The auditors, Messrs. Turquand, Youngs, and Co., were next re-elected, and a vote of thanks to the Chairman and Directors brought the meeting to a close.

Eastern Extension, Australasia, and China Telegraph Company.

Report of the Directors for the six months ended 30th June, to be presented at the twenty-second ordinary general meeting of the Company, to be held at the Cannon-street Hotel on Wednesday, the 15th inst., at two o'clock:—

The gross receipts, inclusive of Government subsidies, have amounted during the half year to £237,672 11s. 5d., against £213,729 4s. 5d. for the corresponding period of 1883, showing an increase of £23,943 7s. The working and other expenses (including £22,784 5s. 9d. for cost of repairs and laying of new cables and expenses of ships) absorb £66,658 18s. 9d. against £62,778 11s. 7d. for the corresponding half year of 1883, leaving a balance of £171,013 12s. 8d. From this is deducted £2,002 17s. for income tax, and £41,595 for interest on debentures and contributions to sinking funds, leaving £127,415 15s. 8d. as the net profit for the half year, against £107,356 2s. 1d. for the corresponding period of 1883. Against this the Directors have charged £22,767 17s. 7d. for the partial renewal of the Java-Australian (original) cable, which is referred to below. One quarterly interim dividend of 1¼ per cent., amounting to £31,250, has been paid during the half year, and it is now proposed to distribute another of like amount, together with a bonus of 2s. per share, payable on the 15th inst., making a total payment of 3½ per cent. for the half year, leaving £17,147 18s. 1d. to be carried forward. In accordance with the provisions of the Trust Deed dated 10th May, 1879, 909 Five per Cent. Australian Government Subsidy Debentures were drawn on the 23rd April last for payment at par on the 1st July. Up to date 654 debentures have been presented, and paid off by the trustees. During the half year under review the policy of strengthening the Company's system by judicious extensions, and the renewal of those portions of the cables exposed to damage from the teredo has been continued. The cable between Tonquin and Hong Kong, to which reference was made in the last report, has been successfully laid by the Company's steamship "Sherard Osborn," and opened for traffic. The cost of the same, and of the cable between Cape St. James, Thuan-an, and Tonquin is shown in the capital account. The cable between Hong Kong and Macao has also been completed and opened for traffic. The cost of this will appear in the current half-year's accounts. It will be satisfactory to the shareholders to learn that during a recent short interruption of the direct Hong Kong-Cape St. James cable the whole of the China traffic was transmitted *viâ* Tonquin without any appreciable delay, thus showing that the new cables give the Company a valuable alternative route between Cochin-China and China. The operation of picking up the old cable on the Sahul Bank, which has been renewed by brass-ribboned cable, as stated in the last report, was attended with considerable success, 394 knots being recovered out of a total length of 404 knots. This cable has been taken into the spare cable account at a moderate valuation, and when it has been overhauled and re-served on board the Company's hulk at Singapore will be available for renewals or extensions in other directions as required. By these means the cost of the renewal is reduced to £22,767 17s. 7d., which has been met, as shown in the accounts, without any addition to capital expenditure. The threatened opposition line *viâ* Tavoy, which was likewise referred to in the last report, has been closed for several months past owing to excessive mortality amongst the staff employed, and to difficulties of maintenance during the rainy season. It is, however, expected to be re-opened during next month. Several cable interruptions have occurred at various points of the system, which have given the repairing ships full employment during the half year. The traffic, however, has been transmitted by the duplicate lines. All the Company's cables, with the exception of the Saigon-Hong Kong and Hong Kong-Tonquin sections, which are expected to be repaired in a few days, are in good working order. The Government land line between Port Darwin and Adelaide has been well maintained by the South Australian Government during the half year.

NOTES.

BRAZILIAN SUBMARINE TELEGRAPH COMPANY.—The traffic receipts of this company for the week ended 3rd inst. amounted to £3,409.

BOOKS.—Messrs. Crosby Lockwood and Co.'s new catalogue contains the titles of numerous books (published by that firm) suited to electrical and general engineers.

DIRECT SPANISH TELEGRAPH COMPANY.—The estimated traffic receipts of this company for the month of September are £1,619, against £1,710 in the corresponding period of last year.

ELECTRIC LIGHT AT THE MANSION HOUSE.—We learn that negotiations are going on for entirely lighting the Mansion House by electric light, at the suggestion of the Lord Mayor-elect.

PROFESSOR HUXLEY.—It is announced that Professor Huxley, who is suffering from the effects of overwork, has been ordered to the South of Europe for some months of absolute repose.

PERSONAL.—We hear that the works of the Signal Engineering Company have been bought by Messrs. Gillett and Harry, who intend carrying on the business of electrical engineers at 181, High Holborn, London, W.C.

PRICE LISTS.—Messrs. Paterson and Cooper send us a copy of their new price list, which contains information upon matters relating to electric lighting. The catalogue relates principally to the apparatus constructed by the firm.

WESTERN AND BRAZILIAN TELEGRAPH COMPANY.—The traffic receipts of this company for the week ending 10th October, were £2,592, after deducting the "fifth" of the gross receipts payable to the London Platino-Brazilian Telegraph Company.

CIRCUS, LIVERPOOL.—Messrs. Cooke Brothers' new circus at Liverpool is to be illuminated by the electric light. The order for the necessary work has been placed in the hands of Mr. F. D'A. Goold, electrical engineer and contractor, Arcade-chambers, St. Mary's Gate, Manchester.

POPULAR FALLACIES AS TO LIGHTNING.—That chewing the splinters from a tree struck by lightning will cure the toothache; that such splinters will not burn; that the bodies of those killed by the lightning shock do not become corrupt; and that no one is killed by lightning while asleep.

CHICAGO.—The trunk lines of the Chicago Fire-Alarm Telegraph have been placed underground in La Salle and Washington Streets, and the underground system will be extended as fast as possible. It is thought that the entire cost of putting police and fire-wire plant underground will be about 150,000dols.

A NEW ACCUMULATOR.—M. Parod has invented an accumulator, which differs from Planté's in having a copper plate, covered with lead, so as to be hermetically closed. By means of this copper core the primary current reaches all the secondary plates simultaneously, so that all the parts develop an equal electro-chemical activity.

IMPROVEMENT IN THE MICROPHONE.—M. Vandenberghe has secured a patent from the Belgian Government for improvements in microphones, especially the Ader instrument, which dispenses with the call push and one of the batteries, substituting an arrangement which keeps the call bell ringing until the receiver is taken off its hook.

TRANSMISSION OF CURRENT TO A DISTANCE.—An electric current, capable of maintaining distinct groups of lamps, has been transmitted from Turin to Lanzo, a distance of 40 kilometres, or 25 miles. Gaulard and Gibbs secondary generators, with two 3-millimetre bronze wires (one for return), were used, and the experiment is said to have been perfectly successful.

TROUVÉ'S ELECTRIC LAMP.—The energetic Trouvé, who, having "found," continues to find, and will probably go on doing so for the term of his natural life, has now introduced a regulator of current intensity into his system of safe electric lighting and automatic extinction. He has also devised a new type of lamp specially adapted to domestic lighting.

UNITS OF POWER AND WORK.—In the last number of *L'Electricien*, M. E. Hospitalier demonstrates that it is as incorrect to express work in *watts*, as power in *kilogrammètres* (1 kilogrammetre = 7·23 foot-pounds), and he hopes that Messrs. Rothen and Rousseau will modify their definitions, so as to accord with the exact signification of the new mechanical and electrical units.

PRIME MERIDIAN.—The International Conference has at length come to a decision; and the time of Greenwich was definitely adopted as the First Meridian. The representatives of France, who at first stoutly opposed this choice, finally abstained from voting either way. On Wednesday the Conference carried a resolution proposing the adoption of a "universal day."

ELECTRIC LIGHT IN LIBRARIES. — In reproducing our note on the electric light at the British Museum, the *Annales de l'Electricité* advises the authorities of the Royal Library, Brussels, to satisfy themselves as to the steadiness of the light, with a view, we suppose, of adopting it. Seeing that the library in question closes at the early hour of four, this would be a highly judicious step.

INDUCTION ELECTRIC LAMP.—In Belgium M. Delaurier has patented an electric lamp, in which a hammer, carrying one of the carbons, receives a rapid reciprocating motion from a coil, through which the intermittent current of one or more battery cells is made to pass. The sparks caused by the alternate contact and separation of the carbons produce upon the retina of the eye the effect of a continuous light.

SIXPENNY TELEGRAMS.—With the view of meeting the great addition of business anticipated when the sixpenny rate for telegrams comes into operation, four wires are being added to the west coast system between England and Glasgow, these being in addition to those recently put on. During the last three or four years the means of telegraphic communication by this route have been more than doubled.—*Pall Mall Gazette.*

THE GLOBE TELEGRAPH AND TRUST COMPANY.—The directors, at the board meeting held on Tuesday, declared the payment of an interim dividend on and after the 24th inst. of three shillings per share on the preference shares, less income tax at fivepence in the pound, and of two shillings per share on the ordinary shares, free of income tax, for the quarter ending the 18th inst. The transfer books were ordered to be closed from the 15th to the 24th inst., both days inclusive.

ANGLO-AMERICAN TELEGRAPH COMPANY.—The Board of Directors have resolved, after placing the quarterly sum of £37,500 to the renewal fund, to declare an interim dividend for the quarter ending 30th September, 1884, of 15s. per cent. on the ordinary stock, and 30s. per cent. on the preferred

Digitized by Google

stock, payable on the 1st November to the stockholders registered on the books of the Company on the 30th September, 1884.

Electric Communication in Railway Trains.—Messrs. Collingwood and Mortin have devised an arrangement for establishing all the electrical communications necessary in a train, for signalling, lighting, &c., without its being necessary to establish connections when making up a train. The contacts are attached to the springs, rest on the axle-boxes, and carry rods, which remain in electrical communication without the necessity for any coupling up.

Gas and Electricity.—Mr. F. D'A. Goold, electrical engineer and contractor, Manchester, has been favoured by the Manchester Corporation with instructions for the lighting of their New Victoria Hotel by electricity. The installation will comprise both arc and incandescent lamps. It is not often that we have the pleasure of recording the fact of an order being given for electric lighting upon such a large scale by gas owners to their rival—electricity.

The Late Accident at the Health Exhibition.—Our contemporary, the *Bulletin*, falls into error when it says that the unfortunate man killed by a Hochhaussen dynamo was "*foudroyé*," that is, struck as if by lightning. Such is not the case, for he lived fully ten minutes after the shock. Some of our English contemporaries still persist in saying that the accident happened during the operation of oiling, whereas it was proved that Pink had not even an oil can in his hand.

Extension of the Telephone in Europe.—In London, of the 3,350 telephone subscribers, 785, or 25 per cent., were enrolled during the last year; and in Manchester and Liverpool 475, or 17 per cent., out of 2,734. In France the increase is 15 per cent., or 796 out of 5,535; and in Belgium, 9 per cent. in 6½ months, or 194 out of 2,284. In Italy, from a total of 5,301 subscribers (not including Turin and Genoa), 1,591, or 30 per cent., have been added during the last 13 months.

Electric Light at the Healtheries and Fisheries.—The *Bulletin des Téléphones* says that the Health Exhibition has been a veritable success for the electric light, which almost exclusively supplies the illumination of the buildings; that the installation was better organised than at the Fisheries last year; and that the various systems of this the most extensive application of the electric light ever made in England were arranged so as to set forth to advantage their respective merits.

Not Quite O. K.—The New York *Telegram* says of the Newport electric lights:—"Whenever the moon ought to shine, then it is supposed to shine, and the lights are turned out, and the greater part of the city left in darkness. If a dense fog should roll in and obscure the moon, or a heavy rain storm take place, and make everything of an inky blackness, then that, as they say in the law, is the 'act of God,' and it would be flying in the face of Providence to have light where He means darkness to prevail."

Intercommunication on Railway Trains.—A French Ministerial circular, dated 15th April, 1884, obliges railway companies to provide means of communication between passengers and guard in all express trains or those running 25 kilometeres (15½ miles) or upwards without stopping; and a sign, preferably outside the carriages, must indicate the compartment whence the signal has proceeded, without its being possible for the passengers to suppress the indication. This is to be carried into effect by 1st July, 1885.

Careless Writing.—This is the title of an article, reprinted from the *Penman's Art Journal*, in the *Telegraphers' Advocate*, a New York journal having aims somewhat similar to those of its contemporary, *The Operator*. The article referred to shows how easily carelessly written words may be taken for other words, giving examples of good or bad writing. In writing a message for telegraphic despatch, care in the formation of the letters should always be a *sine quâ non*, as the operators have sufficient evils to contend against besides having to deal with "such outlandish and meaningless scrawls," which are a nuisance, and discreditable to their authors.

The Telephone in Italy.—The following figures give the total number of subscribers to the Italian General Telephone Company in the various towns of Italy and Sicily up to the end of August last, the figures in parentheses representing the increase during the year:—Turin, 1,140 (563); Milan, 1,087 (567); Genoa, 828 (313); Florence, 742 (221); Bologna, 436 (118); Leghorn, 317 (77); Rome, 1,351 (428); Naples, 641 (102); Venice, 190 (5); Palermo, 333 (80); Messina, 124 (11); Catania, 181 (51); totals, 7,370 (2,536). In Turin, Milan, Genoa, Florence, and Bologna amalgamations have been made during the year with competing companies.

Scientific Discoveries.—On the occasion of distributing prizes to the successful students of the Derby School of Science, the Home Secretary said that England was fortunate in being the cradle of science. No other nation could boast of a Newton, who laid the foundation of all that had since been discovered in physical force. To these great scientific discoveries and to the development of the uses that had since been found for steam, coal, iron, and electricity, England owed as much as she did to her victories on the battlefield. We must not, however, rest on our oars, and rely upon what had already been accomplished if we wish to compete with Continental nations.

New York and New Jersey Telephone Company.—The subscribers' list of this Company is before us, and makes a fair sized book. The Company has in operation a number of offices for casual customers—such offices have been advocated in London—but with perhaps the exception of the National Company, the English companies have lost touch of their customers. The English have much to learn from American and Continental managers—not, perhaps, in the matter of finance, but in the matter of obtaining and keeping customers. The telephone is rapidly becoming a necessity in every house in America, and should certainly receive as warm a support here were the conditions as favourable.

Electric Light at Llanelly.—An Art Loan Exhibition was opened in the Mechanics' Institute, Llanelly, last week, when the electric lighting, carried out by Mr. J. C. Howell, formed by no means the least of its attractions. A Crompton-Bürgin 50-light dynamo is driven by a portable engine, supplied by Mr. C. D. Phillips, of Newport, and maintains 70 lamps, a series of storage batteries serving to regulate the light. The large hall is illuminated by 34 incandescent lamps, with tinted venetian shades; and in the vestibule Mr. Tayler Smith shows some of his new domestic fittings for incandescent lamps that may be removed from, and replaced on, various "shoes" placed in the circuit, and which transmit the current to the lamps.

New Source of Indiarubber.—The attention of the Indian Government has lately been drawn to a new plant, common in southern India, which gives an abundant supply of pure caoutchouc. It belongs to the class of the *Apocynaceæ*, and is called *Prameria glandulifera*; it is a native of the forests

Digitized by Google

of Cochin China, and its sap is often used medicinally. When the branches are broken, a large quantity of caoutchouc is seen in the interior, and can be drawn out in threads, as in the *landelphia* of eastern Africa. The plant may be propagated from young shoots; and M. Pierre, director of the botanical garden of Saigon, thinks that it can be transplanted until it is about ten years old, and that it may constitute an addition of great value to the forest products of India.

ELECTRIC LIGHT IN HUNGARY.—With respect to our note bearing this heading, in *The Electrician* of the 4th instant, the information of which was obtained from the *Standard's* correspondent at Buda-Pesth, we have received some further particulars, by which it appears that though the dynamos are of the Brush type, the lighting is effected by incandescent lamps. Temesvár is the town of third importance in Hungary; and although the plant is put down for permanent illumination, it is not at present in regular operation, the trials hitherto having merely the object of ensuring everything being in a satisfactory condition for the official opening in a few weeks' time. The work has been carried out by the International Electric Company (Limited), whose general office is in the Getreidmarkt, Vienna.

THE APPROACHING TELEGRAPH CONFERENCE.—The following letter from Mr. Lewis Wells, secretary to the Joint Committee of the Submarine Cable Administrations, appeared in *The Times* of Oct. 8, in reply to the letter of Mr. Meyer, given in our last issue:—"In *The Times* of the 6th inst. there is a letter from Mr. Meyer, of Liverpool, respecting the approaching Telegraph Conference, in which he says 'he is given to understand that a strong effort is to be made by the cable companies to reduce the limit for code words from ten letters to eight,' &c. I shall be glad if you will contradict this statement, which is incorrect. It is not the intention of the cable companies at the approaching conference to propose an alteration of the present rules or method of counting which would have the effect of enhancing the cost of telegrams."

COTTON COVERING OF DYNAMO LEADS.—Herr Uppenborn, of the *Centralblatt für Elektrotechnik*, has investigated the rules to be followed in making the wires which serve for the conductors of dynamo-electric machines. With regard to their insulation, he advises a double covering of cotton threads, coated outside with spirit varnish. The special object of the insulating substance is to prevent contact between the wires. The cotton covering should not, therefore, be thicker than is strictly necessary for preventing an exposure of the metal when the wire is bent. This is secured by adopting the following thicknesses of cotton covering for the respective diameters of wire:—1 mm. and under of wire, 0·5 mm. of covering, 2 and 3 mm. (0·6 mm.), 4 mm. (0·7 mm.), 5 mm. (0·8 mm.), 6 and 7 mm. (0·9 mm.), 8 mm. (1 mm.), 9 and 10mm. (1·1 mm.).

TISSANDIER STEERING BALLOON.—The following is, according to the inventors, MM. Tissandier, an exact description of the most distinctive portion of their new balloon, that is to say, the helm:—"This organ, made of glazed calico, is placed at the hindermost point, whence it projects considerably. It is divided into two distinct portions. About half its surface is kept rigid, and constitutes the keel of the aerial vessel, while the rudder proper, which forms an addition to the keel, may be inclined to the right or left, so as to determine, when the propeller is revolving, a corresponding movement of the whole apparatus. The rudder and the keel, stretched by cords, are mounted on a bamboo frame connected on one side with the longitudinal shafts (*brancards*) of the balloon, and on the other with a strong piece of walnut wood fixed below the propeller to the lower portion of the car."

THE INTERNATIONAL INVENTIONS EXHIBITION, 1885.—With reference to this forthcoming exhibition, Messrs. Henry Milward and Sons, of Redditch, suggest that there is ample room for an attractive and useful exhibition upon parallel lines to this, viz., the exhibition of those inventions which have hitherto met with no market. "To judge by the letters and offers we receive in our particular industry, there are hundreds, nay thousands, of inventors, with clever and striking machines, and articles of general usefulness, who are unable to *exploit* their inventions for want of capital or for want of publicity. To this class an exhibition of inventions would be a real boon, and a national and an international object would be served by enabling them to see the light. With the addition of manufactured articles which are the subjects of patents, and of music in all its varied forms, an exhibition commanding all the elements of success would be insured.

THE ELECTRIC LIGHT AND THE FRANCHISE BILL.—On Saturday last a demonstration in favour of the Frenchise Bill was carried out at Perth, when amongst other models, &c., in the procession (which numbered over 6,000) there was a lorry fitted up with a complete installation of incandescent electric light. There was a vertical steam boiler working at 50lb., driving a small engine, double cylinder, 3in. by 6½in., running 300 revolutions per minute, driving a Phœnix dynamo at 1,300 revolutions, supplying current to 16 Woodhouse and Rawson 100 volt 20 candle-power lamps. The engine was designed and built by Mr. Albert Pullar, and the whole apparatus arranged by the *employés* of the Messrs. Pullar and Sons. Shining from amongst the evergreens, the lights looked very pretty, and worked most successfully over the whole length of the route, which was between two and three miles. This, we believe, is the first time such a display has been made.

THE FIRST TELEGRAPHIC INSTRUMENT.—At the Electrical Exhibition, a large display of models from the Patent Office, under the charge of Mr. J. M. Churchill, are exhibited. Among the two hundred and fifty pieces, is the original Morse telegraphic apparatus, patented April 11, 1846. The transmitter is mounted on a pine block, and is very crude. The armatures are wound with very coarse and poorly insulated wire, and the sounder consists of an ordinary piece of stick, which strikes against a piece of iron. The clockwork which operates the cylinder, about which the perforated paper was wrapped, is of a more improved pattern. On the card attached to the exhibit is the following, said to be an effusion of a clerk at the Washington office:

"The steed called Lightning, says the Fates,
Was tamed in the United States.
'Twas Franklin's hand that caught that horse
That was harnessed by Professor Morse."

—*Scientific American.*

TRAMWAY WORKED BY ELECTRICITY.—The Alps Hotel at Chillon has been connected by a tramway with the Mont Fleury Hotel, which is situated above it, at a vertical distance of 180 metres (590ft.). Some trials have been made on a gradient of 1 in 3⅓, with a ½-metre gauge, for a length of 50 metres. Between the rails is a strong rack; and the car carries a dynamo, which puts in motion a spur-wheel gearing with it. An ordinary brake, supplemented by an electric brake, permits of regulating the speed. During the trials, the 5 horse-power dynamo was driven by a portable engine; but for definite working it is intended to use a turbine, as water is abundant. The current is led by copper cables laid between the rails by the side of the central rack, and against which rub

Digitized by Google

the collectors of the dynamo. The car, weighing from 300 to 500 kilograms (6 to 10 cwt.), is capable of carrying three and even four persons, at the rate of 1 to 2 metres per second.—*Centralblatt für Electrotechnik.*

GAMBLING BY TELEGRAPH.—Mr. H. P. Gurney, of Cambridge, writes to *The Times* as follows:—"Sir: It is hardly surprising that gambling is permitted in railway carriages while special facilities are afforded to gamblers by the Post-master-General. It is notorious that betting telegrams are allowed to be freely sent through the Post Office wires. Gamblers are allowed the benefit of the reduced rates offered to Press telegrams. At all great races public servants are officially employed at the public expense to make every possible arrangement to facilitate gambling. Betting is forbidden by Act of Parliament in any public place. Wagering has blasted many a promising career, and brought ruin and misery into many a happy home. The convenience of sixpenny telegrams is withheld on the ground that the Department has already as much business as it can undertake. Sir, I beg your powerful advocacy to protest against this wanton and wicked prostitution of a great public monopoly to the injury of morality, in defiance to the expressed wishes of the nation."

TELEPHONIC SYNCHRONIZATION.—A marine chronometer is placed in a cabinet, 21 cm. wide, 31 cm. deep, and 28 cm. high, attached to the walls of the Berlin magnetic observatory. The cover and two faces of the cabinet are made of looking glass, which resounds well. The microphone is placed against the door opposite the wall, and permits of distinguishing the beating of the chronometer more distinctly than if it be placed to the ear. The chronometer beats the half-second, and is regulated by the mean time, while the clock beats the second, and indicates the astronomical time. Consequently the interval which separates two coincidences is 3 min. 2½ sec. of mean time, or 3 sec. of astronomical time. The observer perceives through the cover the hour shown by the dial, the beating of the chronometer, and that of the astronomical clock. The correction is therefore made by taking as a starting point the interval between two coincidences. Daily and repeated experiments have proved that the irregularities of the chronometer are much more important than the probable errors caused by delay due to the telephonic transmission.—*Centralblatt für Elektrotechnik.*

THE ELECTRICAL WORKING OF UNDERGROUND RAILWAYS.—*Apropos* of the Paris Metropolitan Railway, which it appears is about to be conceded to a syndicate patronised by the Northern Company, the *Bulletin de la Compagnie Internationale des Téléphones* observes very justly that the occasion is a capital one for trying electrical traction. Hot air or compressed air locomotives would not be sufficiently powerful, unless of excessive size and weight; and we are persuaded that the Parisians would never stand the disgusting atmosphere that Londoners put up with in their sewer line. Our contemporary thinks that the experiments that are being arranged at Creil, connected with the transmission of current for a long distance, will come in most opportunely in view of solving the question of underground traction. The *Bulletin* speaks of having lately seen the *locomotives* for supplying the current already *en marche*, and only waiting for the generating machine and the leads for transmitting to Paris the current, which will supply two or three receivers. But does not our contemporary mean rather *locomobiles*—that is to say, portable engines, rather than *locomotives?*

TECHNICAL ELECTRICITY AT OWENS COLLEGE.—The class in technical electricity, under the direction of Professor A. Schuster, F.R.S., commenced its third session last Thursday evening (October 16th). The class meets for two hours, one hour being devoted to lecture and one hour to laboratory work. The lectures deal with the leading scientific principles of electricity and their direct technical applications. In the laboratory elementary students commence with the construction of a mirror galvanometer, a Wheatstone bridge, a standard resistance coil, and a Daniell cell. All materials being provided, the student is required to put them together and to make simple tests with the constructed apparatus. Afterwards the student proceeds to a course of electrical measurements with the apparatus provided in the physical laboratory. This course includes testing for faults and the chief measurements relating to the strong currents used in electric lighting. Arrangements will also be made this session so that former and advanced students may devote nearly the whole of their time to work in the laboratory, which will be occasionally supplemented by short special lectures relating to practical work.

THE LATE PANIC ON THE NEW YORK STOCK EXCHANGE AND THE TELEGRAPH.—At the meeting of the Institute of Bankers, held on the evening of the 15th inst., a paper was read by Mr. Robert W. Barnett on the action of the New York Clearing House Association during the recent crisis, in which he alluded to the rapid subsidence of the panic. In the discussion which followed, Mr. L. Handard (manager to Messrs. Martins) said he thought the rapid manner in which the panic had subsided might be attributed to a large extent to the telegraph. It was known that large sums were ordered to be remitted by telegraphic transfers, not only from London, but also from various cities in America to New York. This money was to be lent out at the very high rates of interest which could be obtained at the time, or to be used for purchasing stocks at the very low prices then quoted on the Stock Exchange. All this, he considered, had helped to make the panic of so much shorter duration than previously, or of panics which occurred before the establishment of the different cables. He thought the lesson to be derived from this was that when we had a panic here it would not be of the same duration as former ones.

ELECTRIC MOTORS AT THE PARIS HOTEL DE VILLE.—The ventilators for the various halls and rooms of the Hôtel de Ville, Paris, are a considerable distance apart, and, instead of a motor for driving each separately, it has been decided to generate sufficient current at a central station to work an electric motor in connection with each ventilator. The Compagnie Electrique put down the plant, including two double-wound No. 6 Gramme dynamos, each absorbing about 4 horse-power. These latter maintain five separate circuits, on which are placed the different motors, working together or separately, according to requirements. They may even, in some cases, be substituted one for another. They run at 1,250 revolutions a minute, each giving out 50 amperes, with an E.M.F. of 110 volts. The electric motors which drive the ventilators are also Gramme machines, all of the No. 3 size, for convenience. Their resistance has been determined by the work which each has to do, and they make 1,450 to 1,780 revolutions per minute. Some of the electric motors are as much as 150 metres from the generators. There are 35 ventilators, requiring from 40 to 80 kilogrammètres, or 290 to 580 foot-pounds to actuate, and two 15 horse-power steam engines drive the electric generators, besides doing other work.

TELEGRAPHIC EXTENSION.—Some time ago the Scottish Fishery Board entered into communication with the Post-master-General with the view of having the telegraph extended

Digitized by Google

to a number of remote fishery districts; and arrangements have now been concluded under which such extension has been made to several of these outlying places. They are Castle Bay, Barra; St. Margaret's Hope, Burra; St. Mary's, Orkney; Walls and Reawick, Shetland. In connection with this matter it may be stated that it is all important, in prosecuting the herring fishery, that means should exist for communicating at once to the different fishing stations the places where shoals of herrings appear, in order that fishermen may remove to these localities with all despatch; and also where there is a heavy and unexpected catch of herrings, it is most desirable to have a supply of salt and barrels as quickly as possible on the spot. It is only by the increase of telegraph stations that these advantages can be obtained. As an illustration of the benefits to be thus realised, it may be stated that recently, in the Orkney Islands, when there was little or no fishing going on in the south isles, the fishermen there got information by telegram that herrings had appeared in large numbers in the fishing grounds upon the north isles, and proceeding there landed in one week £1,800 worth of fish.

THE FUTURE OF ELECTRICITY AND GAS.—*Chambers's Journal*, in an article upon this subject, says:—"That the electric light has not proved a failure may be gleaned from a rough survey of what has been done during the past two years, in spite of unmerited depression and depreciation. In this country, permanent installations have been established at several theatres in London and the provinces; the Royal Courts of Justice, the Houses of Parliament, Buckingham Palace, Windsor Castle, the Bank of England, and other well-known buildings; while numerous railway stations, hotels, clubs, factories, and private mansions throughout the country have also adopted the new light either entirely or in part. In addition to this, over forty steamships have been fitted with the electric light during the past year; and the Holborn Viaduct, with its shops and buildings, has been lighted without interruption for the past two years. On the Continent, in addition to a large nnmber of factories, private houses, and public buildings, numerous theatres at Paris, Munich, Stuttgart, Brunn, Vienna, Berlin, Prague, and Milan have been electrically lighted. In New York an installation of ten thousand lights has been successfully running for the last year or two. Any one wishing to see the electric light to advantage, and its suitability to interior decoration, should visit the Holborn Restaurant. This building, with its finely decorated rooms, its architectural beauties, and ornamental designs in the renaissance style, when viewed by the electric light, is without doubt one of the chief sights of London."

THE TELEGRAPH CONFERENCE AND CABLES TO AUSTRALIA.—A letter in *The Times*, Oct. 1, signed "J. H. H.," discussed somewhat the charges to Australia, the errors which sometimes arise in cable messages, and the laying of a cable *viâ* the Cape, Mauritius, &c. Upon these subjects Sir James Anderson wrote to *The Times*, Oct. 9, as follows:—"Sir: Will you kindly allow me space to correct a statement made by 'J. H. H.' in *The Times* of the 8th inst.? 'J. H. H.' says 'No doubt Sir James Anderson will say it is impossible to lay a cable by the Cape to Australia.' I have never said and would not say anything of the kind. What I have said is, that where there is a long stretch of stormy ocean, with winds almost constantly prevailing in one direction, which is characteristic of the track between the Cape, Mauritius, and Australia, and where there is seldom any calm weather such as we can depend upon in the summer months in the Atlantic, and added to this where there are very great depths of water, then, under these conditions, it must always be at best very costly and next to impossible to effect repairs. The interruptions would be of very long duration, and every cable is liable to interruptions from causes known and unknown. No cable, in my opinion, should be laid unless the maintenance can be relied upon at a reasonable cost and repairs effected within a reasonable time. The 12,000 miles 'J. H. H.' estimates would only give one cable, and it would have to compete with existing and duplicated lines. It could not, therefore, obtain all the traffic, and if it did it would not pay 5 per cent. with the necessary maintenance, reserve fund, and working expenses. But 'J. H. H.' knows as well as I do that we have studied the question for years with abundant data, and that if the companies could see their way to adopt tariffs which would increase traffic without serious loss to their existing revenues they would be only too glad to do so. The allegation that the Press are spending £20,000 per annum was true in 1878, but in 1879 we reduced the tariff from 10s. 8d. to 6s. 5d. per word, the result being a falling off of more than 50 per cent. in the number of words. The traffic, however, gradually increased, until in 1883 there was an increase of 11 per cent. in the number of words transmitted, but a loss of £6,000 of revenue as compared with 1878."

SELF-INDUCTION IN ALTERNATE-CURRENT MACHINES.—The following are the conclusions at which M. E. Hospitalier arrives in an article on this subject, in *L'Electricien* of 1st inst:—The coefficient of self-induction of the circuit, both external and internal, plays an important part in alternate-current machines; and all the efforts of constructors should be directed to reduce it as much as possible. This result would be attained, in the external circuit, by using straight wires and always bringing the conductor and the return wire as near together as possible. Twists and spirals should be carefully avoided, as they increase the coefficient of self-induction in the external circuit, and tend to weaken the current, while at the same time needlessly increasing the expense. In the internal circuit an endeavour should be made to diminish the coefficient of self-induction by reducing to a minimum the length of wire necessary—that is to say, by employing intense, contracted, and high-velocity fields. From these different points of view, the Ferranti machine has made a distinct step in advance, and is beginning to find imitators. The iron cores, supposed to be necessary in certain machines, for concentrating the magnetic fields and increasing the electromotive force, should disappear, to give place to means which attain the same object, without introducing disturbances due to an increased self-induction and the creation of intense Foucault currents. In some machines, such as that of Gramme, for instance, the soft-iron armature of the induced (*l'induit*) is necessary for protecting the external portion of the wire from the action of the field, and for destroying the electromotive force of contrary direction which may be there developed; but this is a difficulty which it will be possible to remedy by modifying the winding and construction of the machine. The suppression of soft-iron armatures is therefore an improvement which should be introduced into all alternate-current or continuous-current machines, inasmuch as modifications in their magnetism always resolve themselves, in the long run, into a more or less considerable consumption of energy, and because an increase in the coefficient of self-induction, which is the result, is itself a fresh cause of loss. This is an established fact as regards alternate-current machines; and a future article will deal with it in connection with those of continuous current.

OLD CABLE STORIES RETOLD.—VI.

BY F. C. WEBB.

SOME "REPAIRS" AND "RECOVERIES" IN THE MEDITERRANEAN IN 1858.

The Cagliari (or rather Chia) and Bona cable did not give results that satisfied the officers of the Mediterranean Telegraph Company and the French Government; and it was decided that we should proceed to work at it in the "Elba." We had also to pick up all the cable remains of four attempts made by Mr. Brett to lay cables from Chia to Algeria. These consisted of two pieces of heavy 6-conductor cable and two pieces of 3-conductor cable. The 6-conductor cable had been laid from shore in the sailing ship "Result" in tow to some 30 miles; then there had been a run, and the cable had to be cut. They then under-run a few miles from shore, cut, and spliced on, and paid out about 22 knots, and then had a run and cut. The 3-conductor cable, laid from the "Dutchman" steamer, had been laid to some 60 miles, when there had been a run, and cable was broken or cut. Then they under-run from shore some 20 miles, cut and spliced on, and paid out till they ran short of cable near a small island on the coast of Algeria. They then hung on for some days till the cable chafed through on the rough bottom. We had therefore to try to pick up four different sections, two of which had ends on the beach, the other two lying isolated from the shore.

The "Elba" was fitted with a picking-up machine designed by Mr. Fleeming Jenkin, under the superintendence of Messrs. Newall, Liddell, and Gordon. On March 1st we had a discussion about the machine. It was thus arranged: drum 6ft. diameter; spur-wheel, 9ft.; pinion, 2ft. 6in. Brake drum to be loose on shaft, but connected by palls to the cable drum, so that, if cable overpowered engine, pawls brought the brake into play, and as near as I recollect this was all carried out. The drum, spur gear, and brake were all between the bearings; the bow sheave was also properly fitted; and wooden buoys, designed by me and made by Cooper, of Hull, were supplied for the work, as also buoy and grapnel ropes of Manilla.

I left to take charge of the work until Mr. Liddell could come out to us, and arrived at Bona on the 2nd of June. The "Elba" arrived there on the 3rd. There was much correspondence with Government officials, and some tests that detained us there till the 5th. Whilst lying off Bona, an English tug, with a crowd of gentlemen on board, came steaming up to us, and an Englishman in his shirt sleeves dashed on board and asked us for a ton of coals, as they had run short and could not fetch Bona without them. I found in the Englishman an old friend, Mr. J. Player, a civil engineer, who, with Mr. T. Snowden, of Middlesboro', had an interest in some mines near Bona. On board the tug was M. Thalabout (the Stephenson of France), and a number of French engineers and financiers. As a slight courtesy in return for ours, M. Thalabout sent us two bottles of brandy that had been kept for seven years on the roof of his house at Marseilles. It was so superfine that we only treated ourselves to a small liqueur glass of it after dinner; but when the first bottle was exhausted we found that the steward had consumed the other in making his own nightly grog.

We arrived at Cagliari on the 6th. Mr. Liddell arrived the next day, and we started that night for Chia, and arrived there the next morning. We had with us Mr. Fleeming Jenkin, Mr. Francesi, Mr. Ternant, and Mr. Löffler. After various tests, it was determined to pick up some of the Bona cable, and on the 9th we got the end off the beach and began picking up, and picked up to 30·25 miles by the 12th, when we were in about 800 fathoms and had cut out a slight fault. We hung on till the 15th, in a fresh breeze, putting cable to rights, and then got cable aft and began paying out. We anchored with kedge when 4½ miles from shore to splice on some shore end, and again at one mile from shore, to splice on a new shore end, and then landed end. This was all the practical work we performed on the Bona cable; but we afterwards had ten days' testing from a martello tower at Chia, as I shall relate further on.

On the 16th we grappled close to shore for Brett's 6-conductor cable, got it, hove it up, and buoyed end of seaward part, and picked up shore part into three fathoms, and then cut it. Went off to Cagliari, back again next day, and made some more official tests of Bona cable, and then got end we had buoyed onboard, and began picking up. Had some difficulty in getting the slack carried away from drum. Rigged up a pulley to press on cable and keep it tight on drum, as the cable was a very stiff one, and the men could not keep it tight. We came to a splice which marked the spot where the 20 mile length began. Picked up to 14 miles, and came to a crossing of the 3-conductor cable, which we had been given to understand did not overlay it. We cut and buoyed with two nun buoys and Manilla rope, and put flag buoy near. We then went to work to get the end of the 3-conductor cable off the beach, but, after expending much labour in digging up ashore, we suddenly caught sight of it from the ship, just under us, and hove it up and cut it, and got end onboard on June 21st. We picked up to our buoys on the 6-conductor cable, and then found the 3-conductor cable we were picking up was chafed through by the thick one, and the end came on board. We then picked up 6-conductor cable again, and picked up about a mile, so as to be clear of our 3-conductor, and cut and buoyed again. This brought us to the 23rd, when we commenced dredging for the 3-conductor. Got it on 24th, cut it, buoyed sea end, and picked up short piece. Blowing too hard for work till 27th, when we picked up buoy on our 3-conductor length, and commenced picking up again. Came to splice that marked the shoremost end of the 40 mile length of 3-conductor cable in 105 fathoms. Took angles to mark position. Kinks now kept coming in at the rate of 40 to the mile. Picked up 13 miles, when cable parted (in about 600 fathoms) just as a bunch of bends and kinks came to the bows. We did not try to grapple for the rest of this section. On the 28th we grappled for the shoremost end of the 40 mile length of three conductors. Hooked it one mile outside end, cut it and buoyed shoremost end of seaward section. Picked up the one mile; back to buoy, got end up, and commenced picking up. Got forty-two kinks in two and a half miles. At seven and a half miles, cable broke at a kink in about 400 fathoms. On the 29th we got hold of buoys on the 6-conductor section we had been working at. At 7:15 p.m. came to a heavy lift. Belt got off, but the pawls prevented drum from paying out; and Mr. Fleeming Jenkin was pleased, for he had strongly insisted on the pawls, although I was against them. When we had got the belt on we gradually hove in an immense skein of cable, consisting of three bights and a loose end. We had to stop it together and coil it down just as it was, and it covered the whole floor of the main cable hold. I have no note of the exact length of this skein, but it was at the end of the section which was twenty-two knots long. On the 30th we dredged near shore for the second portion of the 6-conductor cable. Got it, cut it, and buoyed short piece, and commenced picking up seawards. We continued picking up steadily until 4 a.m. of July 2nd, when, having twenty-seven miles in, we came to a grand kinkation, evidently at the end, although in cutting some of it away to get it on board we cut the actual old end off. We had to get tackles on mast end and yard arms to get it in. A photograph of this kinkation was to be seen for several years in the shop window of Mr. R. S. Newall in the Strand. In picking up one of our buoys the ship drifted on to the boat that was unshackling the buoy, and the fluke of the anchor caught on the back a poor fellow named Oliver, who was formerly mate of the old "Monarch," and hurt him seriously. We went off to Cagliari, and the Italian doctors said no bones were broken, but they resorted to their favourite remedy—they bled him. He was ill for many weeks at Cagliari.

More tests had to be taken of the Bona cable, as its state was under dispute; and on the 7th of July I landed at Chia with Messrs. Francesi, Cavalli, and Pacetti. There was a martello tower perched up on a high promontory, and this was to be our abode. It had not been inhabited for years. The entrance was about 18 or 20 feet from the ground, and we had to procure a ladder to get in. When we went in an old owl and a falcon flew out, and we found a nest of young falcons inside. Into this tower we took provisions and some

Digitized by Google

bedding, and stopped there altogether 10 days. I slept in the casemate the first night, but the feeling that all sorts of slimy things were dropping about from the walls caused me to move the next night on to the roof, where we always took our meals. We had rigged up a sail, and tried to keep it quiet with numerous crossings of No. 8 wire; but from the exposed position of the tower the wind generally kept it flapping about in such a furious way that we could hardly hear one another speak at times. We used to go down the grassy slope of the hill in our night gear to a little cove to bathe; but when we were coming away I noticed the dorsal fin of a shark right in this little cove, and I do not think I should have bathed if I had seen him before. We were pretty jolly, and got on very well together. I learnt some more Italian; and, by the time we left, my three Italian friends knew considerably more pieces of recitatives from Italian opera than they did before, and were constantly bursting out with them. We had the wires led up into the tower and made experiments on them every day, Mr. Liddell, Mr. France, and Mr. Löffler being at Fort Genois, near Bona, at the other end of the cable. A *procès verbal* was finally drawn up, but I do not know how matters ended. I should have mentioned that Spartivento and Chia are considered to be most deadly, unhealthy places. In fact, they used to say that Italian men-of-war would always sheer away from the land when obliged to pass near there, and it was considered fearfully dangerous to sleep ashore. Nevertheless, Mr. Liddell, and Mr. Löffler, and a whole party of men were caught ashore there one night by its coming on to blow, and had to pass the night in the open air. When they came off to the ship, all took some quinine in case of accidents, but nothing occurred. Of our party in the Chia Tower, one of the servants got the fever, but the rest of us escaped. There were certainly some nasty stagnant looking ponds near; and very likely it was the strong sea breeze that prevented Mr. Liddell's party from getting the fever.

In 1858 the Cagliari and Malta cable broke down, and I repaired it in January, 1859, in the "Elba." The fault was near Adventure Bank in 175 fathoms; but there was nothing in the case that would be of interest now, as the repair of cables of that type and lying away from others is now constantly being carried out.

THE PHILADELPHIA EXHIBITION.—IV.

(FROM OUR SPECIAL CORRESPONDENT.)

PHILADELPHIA, Oct. 3.

Argument in the great telephone suit of the Bell against the People's Telephone Company was ended yesterday, and the case is held under advisement. The exhibit of the People's Company, comprising duplicate models of Daniel Drawbaugh's inventions, can now be uncovered. They have been exceedingly well advertised heretofore by being covered. The suit itself is so interesting that a brief description of the 10,000 pages of printed testimony with the theories and arguments of counsel will probably be more appreciated by readers of *The Electrician* than a description of the exhibits themselves.

First, for Daniel Drawbaugh's story. He began to think of telephones, he says, in 1861, and as early as November 20, 1866, he had wrought out the general principles, and embodied them in crude instruments. In 1867 or 1868 he had invented an improved form of transmitter or receiver, by means of which he succeeded in transmitting articulate speech. These instruments he produced in court. They include a carbon resistance transmitter—the invention (it has been supposed) of Edison. In 1870 or 1871 he used a magneto transmitter. Drawbaugh's explanation of the reason why he had not patented or used his invention is that he was impoverished and burdened with debt, and that up to 1880 he was obliged to maintain his family by doing odd jobs of repairing, and that his devotion to telephonic researches had helped to impoverish him. In 1880 he sold one half interest in these inventions to the Klemm Telephone Company. This company, in defending the suit brought against it, declared that Drawbaugh's telephones were not infringements on the Bell Company's patents, but after Klemm had organised the People's Company, the line of defence was changed, and it was then declared that the Bell patents were invalid by reason of Drawbaugh's prior invention and use of the instruments. In support of Drawbaugh's story a great many witnesses were called. They were chiefly friends and neighbours, who had very hazy remembrances of a talking machine which they had seen or heard tell of. Few of them were able to fix dates definitely. He had, however, some witnesses who swore positively that they had seen and talked through his telephones before the date of Bell's inventions. Chance made me acquainted with two of these witnesses, who told me the same story they related in court. They fixed the date when they saw the telephone very definitely; it was, I think, in 1875—certainly before Bell's invention. A party had gone out on a fishing excursion from Harrisburg, and had camped near Drawbaugh's workshop. Hearing that the man at the shop (to them unknown) had this remarkable invention they called upon him, had it described to them, and examined and talked through it. This is pretty strong testimony; at the same time, knowing as I do the adventurous character of the witnesses, I should like to have it corroborated, especially in view of the strange silence of the inventor regarding his wonderful instrument.

The complainants (the Bell company) make a strong case against Drawbaugh. They show that he was a prolific and successful inventor; that between the time of his alleged invention of the telephone and the date of Bell's patents he took out four patents for other things, for which he received 10,000 dollars; that he owned his house, had the use of a well equipped workshop, was associated in business with wealthy men, and repeatedly exhibited his inventions at State Faire, and yet never patented, exhibited, or in any way made public his alleged invention of the telephone until a few years ago. Another strong point against Drawbaugh's claims is found in the models themselves. They are so nearly like other forms of telephones that it seems incredible that they should have been independently invented. Drawbaugh, it has been shown, visited the Centennial Exhibition, where Bell's invention was one of the chief wonders of the day, but he does not appear to have even casually mentioned his claim to priority at that time. The theory of the complainant is that Drawbaugh made the telephones immediately after reading descriptions of those made by Bell and others; that this accounts for their similarity to other forms, and also for some of the hazy testimony in support of his claims by witnesses who could not fix definite dates. Drawbaugh's other inventions are chiefly mechanical contrivances and modifications of existing inventions. He is evidently an ingenious mechanic, but there is nothing to show that he had ever made any study of the principles of sound or electricity, or that he had such knowledge as would suggest the invention or enable him to invent a telephone. It will be seen that the case is a very interesting one, and it involves enormous interests. If the Bell patents should be broken down it will open the door to the free use of the telephone to scores of waiting companies.

Another company is preparing to contest the rights of the Bell Company. This is the Globe, which has purchased the patents of a man named Antonio Meucci for a "speaking telegraph," patented in 1857. Meucci's invention has, of course, been improved since, until it is now practically the same thing as the telephones in use. Whether it was originally of any practical value I have not been able to learn. The Globe Company does not, of course, assume the aggressive. It is now trying to introduce its system, and if it should succeed or give signs of being about to succeed, the Bell Company will interfere no doubt, as with the People's Company, and another long trial will follow.

Bell, by the way, exhibits his apparatus for telephoning by means of a ray of light, instead of by wire conductor. It is represented that conversation has been carried on by this means over a distance of 500ft. By means of a suitable arrangement of reflectors and lenses a beam of light is trans-

Digitized by Google

mitted to the diaphragm of a telephone, and thence reflected to a parabolic reflector at the distant station, where the light is concentrated upon a piece of selenium. The property of this matter, whose resistance varies with the amount of light thrown upon it, is used to control the vibrations of a receiving telephone. If now the transmitting diaphragm is made to vibrate by sound waves, the beam of light concentrated on the selenium cell will respond to the vibrations, varying the resistance of the selenium, and the vibrations of the receiving diaphragm, controlled thereby, will correspond with those of the transmitter. It is a very curious and interesting scientific toy.

The Exhibition is prospering greatly, and is likely to be a financial success. The daily attendance now reaches from 8,000 to 10,000. Sir William Thomson lectured at the Academy of Music on Monday evening on the "Wave Theory of Light," but did not create a very favourable impression as a popular lecturer. The audience was not large, and the lecture simply paid expenses.

W. Curtis Taylor is taking photographs at the Exhibition by the electric light with marked success, although his appliances are of the crudest description. There are two arc lights suspended in line between the sitter and the camera. Directly under them is a screen of transparent paper with the effect of ground glass, sloping to one side like a skylight. This screen does not extend over the full width of the room, thus permitting the direct rays of the electric lights (covered with ground glass globes) to fall upon adjustable side screens of white muslin, which are used to modify the lights on the sitter's face. The effect of this simple arrangement is that of sunlight, and the pictures could not be told even by an expert from those made by daylight in an ordinary gallery. The light is well diffused and is concentrated for effect by the side-screens, as in ordinary gallery practice.

THE CARY TELEPHONE SIGNAL.

A growing evil in the rapidly-extending electrical business is the multiplicity of wires over and under ground. Already our large cities begin to present a very unsightly appearance, and in many of them the wires, like the Scythian arrows, begin to darken the sun. Danger in case of fire is a very important consideration, and several instances have shown how great an impediment the hot falling wires are to the firemen. Heavy fixtures may in a storm be blown into the street, endangering the lives of passers. All these evils must as far as possible be remedied, and any device tending to that end should be welcome. One way of avoiding trouble is to place the wires underground. This has been made to answer for the telegraph, but thus far we have no very extended system of underground telephone wires. Invention has been exercised to make the overhead wires do more service, and this is the end sought to be attained by the Cary telephone signal. It has stood a long practical test, and thus far done its work well. It is unnecessary to say that numerous attempts have been made to find a good individual system for circuit lines, and that many devices have been tried for this purpose. Nearly all have failed in practical results, the causes being generally uncertainty of action and complex mechanism.

Mr. T. D. Lockwood, electrician, of the American Bell Telephone Company, in his book, "Practical Information for Telephonists," says: The essential points that every individual signal instrument should possess are the following:—

1. They should be able to call up the station required.

2. This must be done to the exclusion of all the other bells or stations on the line.

3. When a station is to be called on a line, and other stations are between the station calling and the station called, those between must not be rung up in passing.

4. A unison, zero, or initial point, and a method for bringing each apparatus to such point, so that all the instruments may commence each operation together.

The Cary telephone signal, which is now to be seen at 17, Devonshire-square, has these four essential qualities, and is, moreover, exceedingly simple, so that it seems almost impossible to get out of order. In addition, it shows when the line is or is not in use, and can easily be attached to any existing system of lines.

A description of the instrument, as shown by Mr. Stetson, in its essential parts follows:—

Fig. 1 shows the instrument with the cover removed. M is an electro-magnet, B a neutral armature hung on pivots, and kept

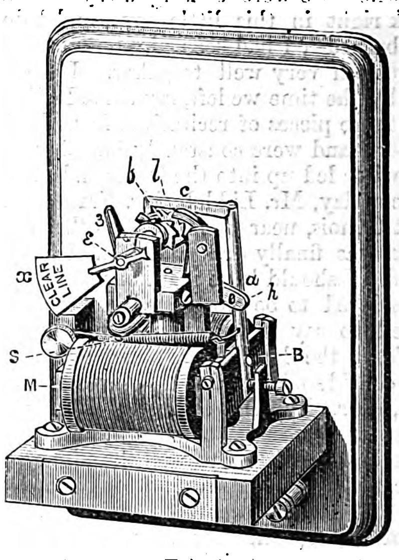

Fig. 1.

from the electro-magnet by the retractile spring *s*. The armature B has attached to its upper side the lever *a*, carrying on a pivot the notched arm *c*. *e* is a horizontal shaft, resting in standard bearings at each end. *l* is a rachet secured to the shaft *e*, arranged to be rotated step by step by means of the hooked end of the arm *c*. *f* is a ratchet secured to the shaft *e*, and

Fig. 2.

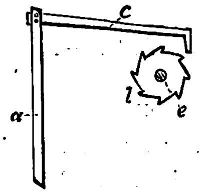

Fig. 3.

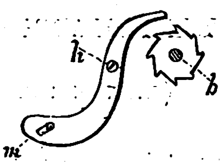

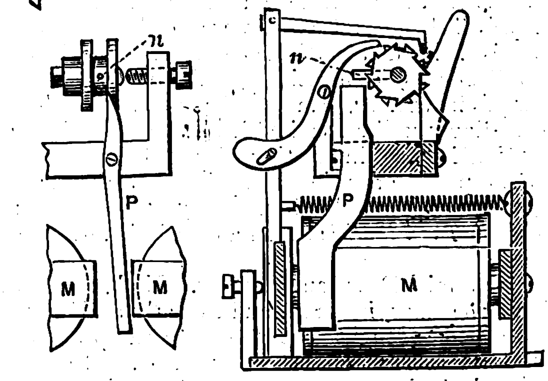

Fig. 4.

having its teeth arranged opposite in direction to the teeth of the ratchet *l*. Against the shaft *e* press two springs, one of which, shown at 3, automatically throws in the subscriber's bell, as shown in Fig. 5. *x* is a signal showing when the line is in use.

Fig. 2 shows more plainly the action of the arm *c*, and Fig. 3 the action of the pawl *h*. *m* (Fig. 3) is a slot in which slides a pin, fastened to the lever *a* (Fig. 2), so that one attraction of the magnet M moves both *a* and *h*, thereby preventing more than one step at one time.

Fig. 4 presents a side elevation of the instrument, and shows the action of the polarised armature P. P's action is as follows:—A positive current sent to line throws P to one of the poles of the magnet M. When the ratchet wheels have turned the axle around to the proper point, the polarised armature P catches in each of the instruments on the pin n, thereby preventing them from rotating further, and furnishing

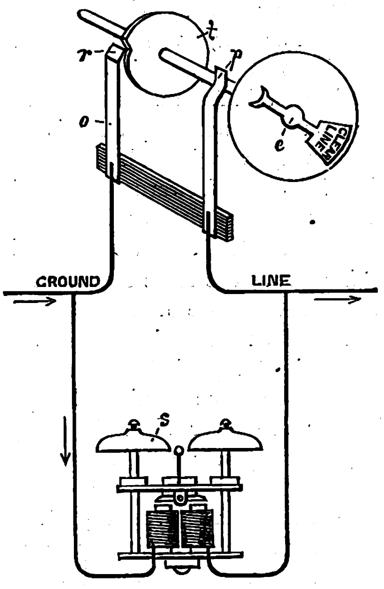

FIG. 5.

the unison point. From this unison point they are released by a current of opposite polarity.

Fig. 5 shows the manner in which the subscriber's bell is rung. Fastened to the shaft e, and revolving with it, is a wheel, t, having on its circumference a notch, r. This notch r occupies a different position on each subscriber's wheel in reference to the unison point. For instance, in subscriber No. 1's

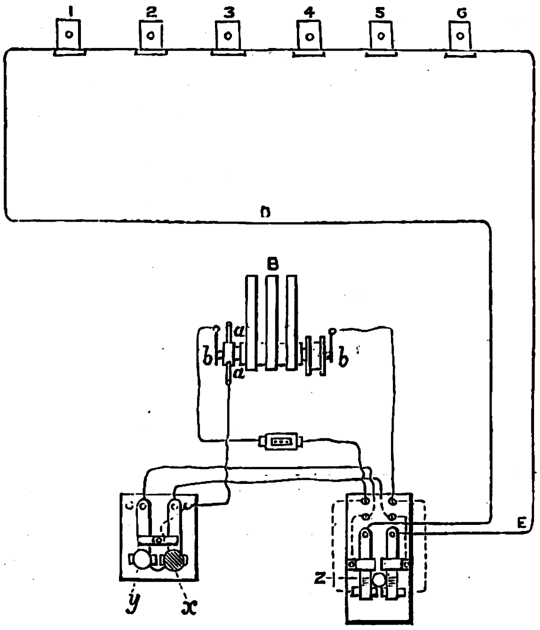

FIG. 6.

instrument one depression of the positive key in the central office brings the spring o opposite the notch r. A current now sent down the line must pass through the magneto bell s, as shown in Fig. 5. If the current be a vibratory one, it must ring the bell s. At this time all the other instruments, except the one desired to be called, are in such a position that the current's course must be line-spring o, axle e, spring p, to line, and thus only one station is disturbed. This takes place because the resistance of the axle e, and the springs p and o, is so small (except in the position shown in Fig. 5) that only a small portion of the current passes through s, much too small to cause it to ring.

Fig. 6 shows the complete connections fitted to get the two kinds of currents required—the continuous for moving the signal around, and alternating for ringing the subscribers' ring. B is the dynamo, worked by foot or power; $a\ a$ the commutator brushes giving the continuous current; $b\ b$ springs pressing against the two ends of the axle of the armature, furnishing the alternating current.

Suppose, now, No. 1 calls the central office, and desires to be put in communication with No. 4. The operator at central office presses the key x four times, turning all the instruments along four points, when No. 4's instrument is in the position shown in Fig. 5. If, now, the operator press the key Z, an alternating current is sent to line and No. 4's bell rung. It will be seen that the object arrived at is simplification and cheapening of the telephone system. A somewhat similar apparatus is that of Brown and Saunder's, as shown at the Crystal Palace Exhibition, and which has been greatly simplified since.

ELECTRIC LIGHT AT THE DAIRY SHOW.

While strolling through the gallieries of the Agricultural Hall on the closing day of the Dairy Show held last week, we could not help remarking the dejected look of the pigeons and poultry, and even of the usually cocky game fowls. The cause was not far to seek. The poor birds had been subjected during four evenings, from night-fall to past ten o'clock, not only to the products of respiration from the visitors and the animals below, but also to the foul emanations, to say nothing of abstraction of oxygen, from the numerous gas jets which illuminate the building. We could not help wondering when there is a pure wholesome light available—witness the Healtheries—that it should not be adopted. Besides, the Agricultural Hall would lend itself so readily to a comprehensive system of electric lighting. There is plenty of room for motors and dynamos. A few arc lights, judiciously disposed, would illuminate the ground floor effectually, while incandescent lamps in the bays under the galleries, and in the galleries themselves, would set off the individual exhibits, and the atmosphere would not be so vitiated as it is at present. On descending to the ground floor, we were agreeably surprised to find that a praiseworthy attempt had been made by two electric lighting companies to supply a partial illumination to individual exhibitors. The Electric Light Supply and Fitting Company, of 28, York-street, Westminster, had arranged to maintain three 2,000-candle arc lamps; but in this they were frustrated, as they could only run one of their two dynamos, owing to the portable engine they had hired falling short of their requirements. They, however, maintained a number of 55 incandescent lamps, some of which were provided with opal reflectors. Gerard's Company, of 82, Hatton-garden, maintained four of their 20-candle elongated incandescent lamps by a dynamo, driven by a small horizontal engine, and giving out 10 amperes at 35 volts.

CABLE COMPLETED.—At the moment of going to press we are informed that on the 9th inst. the ss. "International," of the Silvertown Telegraph Works, completed the laying of a cable connecting St. Vincent with St. Jago, Cape de Verde Islands.

NEW MICROPHONE.—Dr. Hipp, manager of the telegraph and electric apparatus factory at Neuchatel, has patented a microphone, which will be very useful on telephone lines. The instrument works without induction coil, and is directly connected with the telephone line. A single range of batteries at the central station is therefore sufficient for working all the stations; and there is no need of a battery in connection with the subscribers' instruments. In addition to this diminished first cost, it is said that there is a saving in maintenance, while the sounds are clear and distinct.

INTERNATIONAL PATENT RIGHTS.

Some correspondence which is appearing in *The Times* relating to the International Exhibition of Inventions to be held in London next year has no doubt awakened misgivings in the minds of intending exhibitors. It is feared that in the present state of the laws relating to patented inventions severally prevailing in the various countries which may be expected to contribute to the show, and which in any case will be certain to swell the number of foreign visitors to inspect what is to be seen there, that the moral rights of exhibitors to proprietorship in their products, processes, or inventions, will not be so religiously respected as could be wished; and that, in short, the display will afford a grand opportunity for foreigners to appropriate free of charge, and export free of duty, ideas which are not legally or morally their own.

In one sense the proceeding here deprecated is in reality one of the, at least, ostensible objects of all such exhibitions. They are got up with the avowed aim to spread information, to help one set of people to learn something from another set of people, to encourage ingenuity by showing what ingenuity has already accomplished, to stimulate improvements by showing where improvements are wanted, and generally to help on the inventive faculty for the good of mankind. These are the ideal objects; and for the purpose of the present discussion we may leave out of account all lower or less disinterested motives. What, however, holds good for the country in which the exhibition takes place, holds also for the other countries which patronise it; and it would be impossible to open any exhibition of the kind if free access to every corner of it were restricted for fear of foreign piracy. It would be a narrow, insular, and selfish view to take of these exhibitions —which are now becoming common in every capital of the civilised world—that they are to benefit only the country in which they are held. It is, moreover, an impracticable view, and therefore no more need be said about it.

But it must be granted that the fears which have found expression in *The Times* are not wholly without foundation. So far as there is real danger, however, every inventor may be trusted to guard his own property in the way he thinks best. Some will no doubt abstain from open exhibition, and nobody can blame them; but the necessity for this extreme caution must, we think, be very rare indeed, and we strongly deprecate the alarmist views put forward by *The Times'* correspondents. For one chance they risk of illegitimate piracy they may lose by abstention a dozen chances of legitimate trade.

The risk which actually has to be run at these international gatherings is due to the absence of any complete international understanding as to the rights of patentees. There are still one or two countries in Europe that have no patent laws at all; and of course there are some outside Europe whose newly awakened industries are ever alert in adopting, without acknowledgment, the superior appliances of heathens who believe in patents. But, broadly speaking, the world in general is agreed that some form of protection should be accorded to the man who invents a thing or a process that is at once useful and new. No universal agreement is to be expected yet awhile on the nature and duration of this protection, nor can we ever hope that exactly similar views will obtain as to what is entitled to protection and what is not. In some countries—in Germany, for example—it is difficult to obtain protection; in others, for example in England, it is now perhaps too easy. But there ought to be no disagreement as to the rights of protected inventions as between one nation and another. The punishment for theft may be heavier in one country than in another, and their definition of the crime may even differ materially; but the laws of extradition between civilised nations are framed on the basis that for what one nation holds to be a crime the other will yield up the criminal on proof of his having committed it.

Apart from certain niceties this rule prevails very generally, and the tendency is towards uniformity. We see no reason why similar principles should not apply to international industrial law. A great stride has been taken, we are glad to notify, in this direction by the International Convention for the Protection of Industrial Property, signed at Paris in March, 1883. To this Convention Her Majesty's Government, somewhat tardily, gave in their adhesion a few months ago; and it now includes France, Belgium, Italy, Spain, Portugal, Holland, Switzerland, Servia, Brazil, and one or two South American Republics. The adhesion of Germany, Austria, Russia, and the United States is still wanting, but not for long it may be hoped; and meanwhile the attention of inventors may properly be drawn to the provisions of this Convention—a copy of which may be obtained of Hansard at the small cost of twopence—and to the fact, in view of the forthcoming Exhibition, that in respect to certain countries the English patentee is perfectly safe, whilst he is not so safe in respect to certain other countries. The general scope of this international agreement is sufficiently indicated in Art. II., which declares that "the subjects or citizens of each of the contracting States shall, in all the other States, as regards patents, industrial designs or models, trade marks and trade names, enjoy the advantages that their respective laws now grant, or shall hereafter grant to their own subjects or citizens." One useful provision relieves the inventor from the necessity of simultaneous patenting in

Digitized by Google

foreign countries, six months' grace being allowed, during which period the inventor possesses prior claims in all the countries embraced by the Convention. Temporary protection is also given to patentable inventions exhibited at officially recognised International Exhibitions.

It should be the business of inventors to get this most valuable Convention extended to the rest of the great industrial nations of the world as speedily as possible. Meanwhile, however, we have very little doubt as to the point of English law raised by our correspondent "A. F." A patent in this country, whatever it may do in Germany, concedes the exclusive privilege to "make, use, and vend;" a privilege which, we take it, excludes the importation of the same article made in another country to be sold and used in this. The question may arise whether the article *is* the same, but that is one on which the patentee can set the law in motion to decide. When there is no doubt on this point, imported infringements of patents are liable to confiscation; and as a matter of fact such confiscations at the port of landing are by no means infrequent. It is a rule of this kind which is to be desired for all countries in the interests of inventors, and which is secured to a considerable though still only partial extent by the Paris Convention

CORRESPONDENCE.

A "NEW" FORM OF ELECTRO-MAGNET.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: In your "Notes," p. 466, is mentioned a form of electro-magnet which is credited to Signor Ricco, of Palermo, and which form you mention has been in use for some years in this country. The mere fact that I devised and made for my own use this type of magnet 30 years ago would not entitle me to claim them; however, the fact that they were devised as a necessary consequence of the theory of magnetism explained in my "Electricity" gives me a better title to their paternity. They were, in fact, deliberately made, not on a guess or experiment, but because I saw that an iron conductor carrying a current must become a magnet and require no separate core. However, my best title to the device is that it is fully described in my patent, No. 4,762, of 1878, and applied to dynamo machines for the express purpose of generating and utilising the so-called "Foucault currents," instead of trying as usual to prevent their formation. I have also used the principle in making electro-magnets for other uses, though it is not often that they will have any advantage over the usual form of construction when it is the magnetic force or field that we have to utilise.—Yours, &c.,

J. T. SPRAGUE.

[We have a strong impression that we have read of similar magnets being used in America by Henry and others even earlier than the time mentioned by Mr. Sprague.—ED. *E.*]

A CURIOUS CASE OF INDUCTION.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: Whilst testing the Blake transmitters which are manufactured by the American Telephone Company, I discovered a curious case of, I believe, induction. I had just laid my receiver on the shelf to which the transmitters are affixed so as to adjust the switch spring of the magneto call bell. I had occasion to put my ear rather close to the instrument, and I was surprised to hear the men talking at the other end of the line. I then hung my receiver on the switch hook, and placed my ear again against the instrument. I still heard the same voices. After this I summoned a man to talk and whistle very close to the instrument, whose voice (the man's) I heard very faint but very distinctly. I then placed a small piece of paper between the platinum spring and the carbon button of the transmitter, with the result that I could not hear the man's voice at all, but as soon as I took the piece of paper out I could again hear him talking. If any of you will explain this to me I shall be very much obliged. Will you insert this in your next issue? F. L. C.

London, October 13th.

THE USE OF TELEPHONES.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: Would some reader inform me if—

(1) I can use a pair of telephones that are purchased in Germany between my own and my father's house?

(2) If I can supply to other parties for use in England telephonic apparatus made in Germany?

I find that I can obtain what I want from Germany better and cheaper than I can in England; and our telephone companies, instead of crediting the Government with the stopping of the use of their apparatus, should rather credit their own short-sighted action in asking an exorbitant price for their instruments.—Yours, &c., A. F.

BALL'S UNIPOLAR DYNAMO.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: Among other interesting notes from your special correspondent at the Philadelphia Exhibition (published in the last number of *The Electrician*) is a description of the results obtained with five horse-power from a machine of the above type. The statement that 17 arc lights are actually obtained reads well; but then, of course, arc lights differ as to power. The fact that we usually get five lights with as many horse-power does not prove that we cannot get 17 with the same source; only what is the definition of an arc light as to photometric power?

If your correspondent would kindly furnish us with results in volt amperes, I am sure it would interest many of your readers who, like myself, are quite unable to visit the Exhibition and see for themselves.—Yours, &c.,

H. A. KENT.

154, Culford-road, N., Oct. 11th, 1884.

PATENT LAW.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: Having in the practice of my profession observed that exhibitors of unpatented inventions at international and industrial exhibitions are not generally aware that their position is affected by certain provisions of the Patents Designs and Trade Marks Act, 1883, I beg to point out through the medium of your paper that the six months' protection of unpatented inventions so exhibited is no longer accorded unconditionally, such protection being now obtainable only by compliance with the requirements stated in Section 39 of the above mentioned Act and Rule 17 of the Patents Rules.

Information as to the mode of procedure may be obtained from the proper official sources, or I will supply information without charge on application.—Yours, &c.,

W. T. WHITEMAN,
Fellow of the Institute of Patent Agents.

7, Staple-inn, W.C., October 15, 1884.

THE ELECTRIC LIGHTING ACT.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: A case arises under the Electric Lighting Act which I should like discussed in yours if you can find space.

The Local Authority of A. invited tenders for the lighting of part of their district as required under the Public Health Act. Tenders are sent in for lighting by gas, oil, and electric light, the latter of which is successful, and the tender is accepted subject to the approval of the Local Government Board. On application to the Local Government Board for a loan to cover erection of lighting system they state that A. must first obtain a license or provisional order from the Board

Digitized by Google

of Trade. A. has been advised that as they are their own Local Authority and only want to light the streets they are not required to have a license or provisional order. It appears, however, that although they may not purchase the plant and do their own work, yet they may contract for the lighting and pay out of the rates an annual charge for same, the plant remaining the property of the contractor. Now, if the Local Authority are willing that the contractor carry out the work and give him permission to erect the necessary plant throughout their district, must the contractor before doing so obtain a license?

From a note in yours of last week it appears that the Local Authority can give permission for the erection of plant, and this without either a license or provisional order. If so, how is it that they cannot light their own district themselves unless they have either license or order? It seems there is a want of consistency somewhere.—Yours, &c., OHM.

Kent-road, Glasgow, 14th Oct., 1884.

SIMS'S MECHANICAL TELEPHONE.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: On page 445 of your issue of September 27, you mention Mr. John F. Sims's invention of a mechanical telephone. Should you know the number and date of this patent, would you oblige by favouring me with it?—Yours, &c.,

H. F. LEWIS.

Bristol, October 6, 1884.

[We have searched the patent registers for this and last year without finding a record of the patent. If the invention is patented, perhaps Mr. Sims or one of our readers will kindly supply the information.—ED. *E.*]

ELECTRICITY AT THE ANTWERP EXHIBITION, 1885.

The classification adopted for the forthcoming Antwerp Exhibition, the buildings of which are making rapid progress, comprises five sections, of which the fourth is devoted to electricity, its applications, and the necessary motors for driving the machines that generate current. This section is subdivided into six groups, and these groups again into nineteen classes, as given below. An English edition of the classification is published, but it requires revision, or those unacquainted with the French language might be at sea; for we do not generally use the term "pile" for battery, "bobbins of induction" for induction coils, nor "drums of resistance" for resistance coils.

GROUP X.—*General Mechanism.*

Class 84.—Boilers, steam engines, gas engines, hydraulic motors.

GROUP XI.—*Production of Electric Current.*

Class 85.—Hydro-electric, thermo-electric, and secondary batteries.

Class 86.—Magneto-electric and Dynamo-electric Machines and Induction Coils.

GROUP XII.—*Electric Conductors.*

Class 87.—Cables, Wires, and Accessories.

Class 88.—Lightning Conductors.

GROUP XIII.—*The Study and Tuition of Electrical Science, and its Scientific Application.*

Class 89.—Instruments used in experiments and demonstrations, *e.g.* electrical machines depending on friction or induction, condensers, electrophores, apparatus for electro-dynamic or electro-magnetic experiments, apparatus for the study of induced currents, &c.

Class 90.—Measuring Instruments: Mariners' compasses, rheometers, galvanometers, electro-dynamometers, standards of capacity and of resistance, resistance coils, rheostats, electrometers, &c.

Class 91.—Electricity Applied to Astronomy, Geodesy, and Meteorology.

Class 92.—Electricity Applied to Mechanics, Ballistics, Physics, and Chemistry.

Class 93.—Electricity Applied to the Biological Sciences; Medical Electricity.

Class 94.—History and Tuition of Electrical Science; Books, Drawings and Models; Retrospective Collections of Apparatus.

GROUP XIV.—*Transmission of Signals and Speech by Electricity.*

Class 95.—Telegraphs.

Class 96.—Telephones, Microphones, and Photophones.

Class 97.—Electricity Applied to Railways.

Class 98.—Electrical Signals for Various Purposes; Indicators of Levels, Pressure, Temperature, &c. House Telegraphs; Electric Clocks.

GROUP XV.—*Electric Current applied to Industry; Various Applications.*

Class 99.—Electric lights; photometers.

Class 100.—Electric motors; transmission of power.

Class 101.—Eletrotyping.

Class 102.—Miscellaneous applications.

The catalogue will be printed in both French and Flemish (which is almost the same as Dutch). Exhibitors have the right, for every group in which they are entered, to four lines of description free, and may pay for more space at a uniformly progressive rate, viz., 5f. (4s.) for the first extra line, 2f. for the second, and so on. We reproduce in its native quaintness some excellent practical advice given by the management:—

"The success of an exhibition depends in a great measure on the complete installation of the products at the time of its opening. Experience has proved that the delay which the installation has suffered on many occasions was principally due to the exhibitors, who either sent in tardily their demand for admission or neglected the timely forwarding of their products. We beg, therefore, to invite exhibitors to comply strictly with the periods fixed in the regulations."

THE THEORY OF THE DYNAMO-ELECTRIC MACHINE.*

BY PROFESSOR ROWLAND.

I have prepared here a skeleton of the theory of the dynamo machines. I don't claim for it perfection. I only claim to give a few points in the theory of the dynamo machine which may be of interest and possibly of value to those who are constructing these machines. Mr. Fitzgerald was to second me in this discussion and give some important points on the subject, and the discussion will be more or less imperfect unless he arrives.

The principal losses of the machine are put down under these heads:—

1st. Mechanical friction.
2nd. Foucault currents in the armature.
3rd. Energy arrested in magnetising the magnets.
4th. Self-induction of the currents.

These are the number of losses which I, at least, intend to discuss.

Of course the efficiency of the machines would then be equal to the whole work of the machine minus the different losses divided by w, namely $E = \frac{w - l_1 - l_2}{w}$.

Thus when these losses are obtained the efficiency of the machine is known.

The mechanical friction I shall not discuss.

With respect to the loss from Foucault currents in the armature, by dividing up the armature in the proper way we

* A paper read at the Congress of Electricians at Philadelphia.

can get rid of most of these Foucault currents. It is a method very often effected in the Siemens armature by dividing up the armature into discs. The greater portion of the currents are got rid of in that way.

I have purposely omitted the loss due to the change of magnetism of the armature. As the armature revolves in one of these machines the iron changes in magnetism. It has been recently experimented upon and been found that although there is some small heating effect, yet it is very small indeed. I drew attention to this fact several years ago, and experiments have been made upon this subject by makers of the dynamo machines, and Edison, for instance, has evolved a dynamo made up in this manner so that the Foucault currents do not exist, so that practically this loss amounts to nothing. I think that that question has been discussed enough, and I shall therefore take up the third loss, which is in the current, or rather in the energy, used in sustaining the magnet.

If the magnet were of steel there would of course be no loss due to this third cause, and the only reason for not using a steel magnet is that they cannot get sufficient field; the field is moderately weak. I cannot give you the ratio, but I suppose it is at least one-third of that due to an electro-magnet. Perhaps this point may be brought up in the discussion, and somebody can give us the results. But so far as I know now the field from a permanent magnet is generally less than one-third of that from a good electro-magnet. It could not be made equal to it by any possible means. Therefore, in most dynamo machines that are used on a large scale the magnet is produced by the current.

It is a question what the form of a magnet and the position of these coils should be in order to get the greatest field with the least expenditure of energy. I have one or two

FIG. 1.

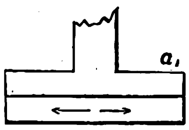

FIG. 2.

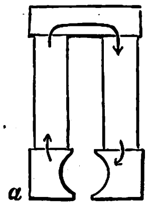

FIG. 3.

propositions to make on this subject which I think are, I will not say of vital importance to makers of machines, but of some interest.

The first proposition I have to make is that a round magnet is better than one of an elongated cross section. Those who have used the old Siemens machine will recollect that the magnets there were formed on a system of bars around which the wire was placed. If the coils are long (I do not know that it is necessary to assume that they are long if they are long enough for the purpose, and the coils are generally long enough—the theory assumes an infinite length of wire) the magnetic force at any time acting on a round iron core is exactly the same as on an elongated core; but the area of a circular section is much greater than that of an elongated section for the same circumference, and therefore the same amount of wire which would be used to go around the elongated magnet could be extended further on a circular section, and would obtain very much more work. Some people say that the principal object of making an elongated magnet is that it may include the whole length of the armature. Suppose we were constructing a dynamo machine with a very elongated magnet, we have to elongate it here (Fig. 1) and make a pole-piece in which the armature might revolve. Most makers who adopt this form think that it is better to elongate this (A, Fig. 2) out in these directions (arrows, Fig. 2). But we have seen that the round form is more efficient in general than the elongated form, and the only question is whether it will be more efficient in this particular case. I shall proceed on this theory upon the known fact that you can consider lines of force as if they were conducted by the iron and the air outside. The conductivity of the iron for the lines of force is very great—much greater than that of air. I experimented on it many years ago, and my idea is that the greatest value of the conductivity was something like five thousand times that of air. It depends upon the magnetic force, and of course it is a variable quantity.

I think it varies from several hundred up to five thousand times that of air. The conductivity is very great, especially of wrought iron; for cast iron it is probably less.

Therefore the lines of force will be conducted from any point over a circular cross section very nearly as easily as they are over an elongated cross section, and the saving in the wire will be considerable.

I have another proposition to make with respect to the magnet, and that is that one circuit of the lines of force is better than a number. Some makers might connect the pole pieces of the armature to a number of electro-magnets, and even if they were round there is loss from having a number. For this reason, that the same amount of wire produces the same magnetic force in each of these coil pieces provided there is the same number of wires per unit of length; and that same amount of wire might be made to go nine times around the iron instead of three times. Therefore you would get inside your magnet three times as much iron as you would do, and yet have the same magnetising force going on the magnet. The proposition is that one circuit is better than two, and that

FIG. 4.

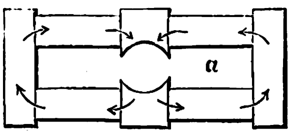

FIG. 6.

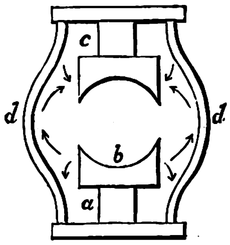

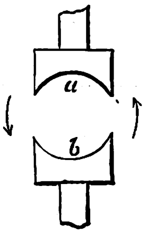

FIG. 5.

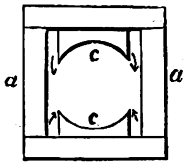

FIG. 7.

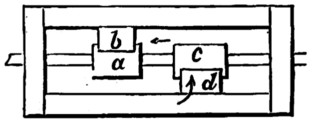

FIG. 8.

not only applies to this form of magnet (Fig. 3), but it also applies to the form where we have the armature revolving between two magnets like this (Fig. 4). Because if we should turn this section around (*a*, Fig. 4), and bring the two together, and we would have two sections. The circuit of the lines of force is around in this direction and in this (arrows, Fig. 4). So that there are two circuits of the lines of force instead of one. The working energy expended with a given amount of work will be less with this form (Fig. 3) than in the form where you have two circuits like that (Fig. 4); that is of very great value to makers of machines.

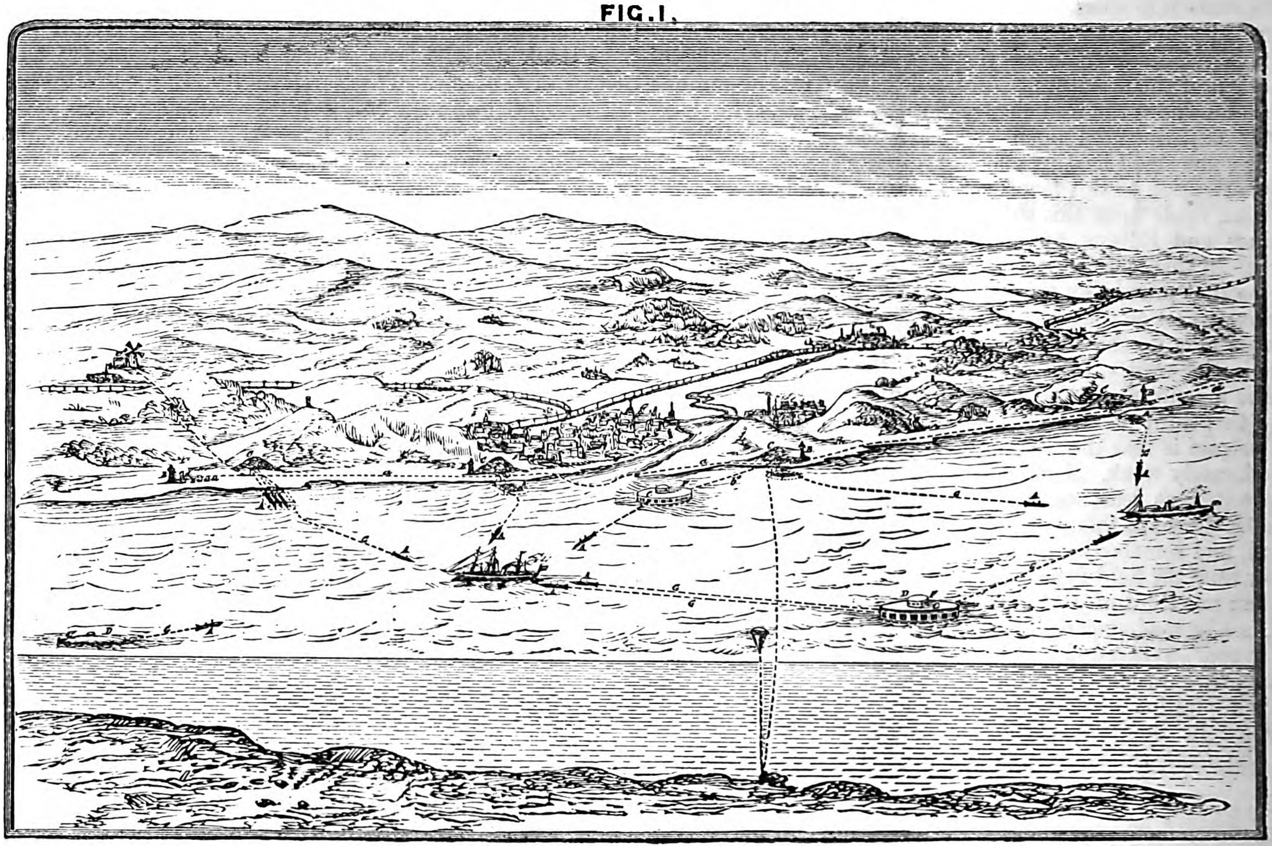
I had a number of drawings made simply of magnets in the Electrical Exhibition, and I find very great difference in this respect. There is more difference in this respect where Siemens armatures are used than in any other kind of armatures. In discussing these drawings I do not give any names nor say whether any one machine is better or worse than another; but I merely discuss the aspects of the case, and illustrate by some machines which are found in the Electrical Exhibition.

First, I will discuss in general the forms of the magnet, and I wish to say something in respect to the form of the poles that enclose the armature. Of course these forms belong both to the Gramme ring and the Siemens armature, and you may consider them both one if you wish. This magnet (Fig. 2) belongs to both of these forms and almost any form. I may mention once more that of course that theorem with regard to the number of magnets applies to a number of those old machines where there was a very large number of little magnets revolving around other little magnets. More work is used in sustaining the magnets in that form of machine than in the more modern form, where we have only a few circuits.

Digitized by Google

An Electrical System for Coast Defence. General Plan.

FIG. I.



We will now proceed with respect to the field in this (Fig. 5).

The lines of force proceed down the magnet and are supposed to go across here (*a* to *b*, Fig. 5). Wires are wound around the armature and revolve around across the lines of force, and so produce a current. It is evident that any lines which escape across this part (arrows, Fig. 5) are lost. If there was any leakage of the wire around the magnet, that would be lost. In case the wires touch there would not be much loss, but if there was a leakage in the wire the current, instead of going around the magnet, would go off somewhere else, and we should consider the machine defective because there was a loss of the current. If these lines of force, instead of going across there (*a* to *b*), go across here (arrows), as they naturally would do, all those lines of force are lost, and we would have to add so much more current in order to make up for this outside loss. I have an illustration of this from the drawing which I will give you (Fig. 6).

(TO BE CONTINUED.)

AN ELECTRICAL SYSTEM FOR COAST DEFENCE.

The Williams system of electrical torpedoes and coast and harbour defence, which we illustrate this week, will be tolerably clear to our technical readers from an examination of the illustrations given.

The torpedo is a decided advance upon anything which has hitherto been proposed in the class of movable and controllable torpedoes, which are by far the most effective kind of submarine engines of destruction. Hitherto the weak points of locomotive torpedoes, as exemplified in the "Whitehead" and the "fish" torpedoes, have been that when once launched they pass beyond control, and in the event of meeting adverse currents, or in the case of a change of position in the object attacked, are likely to miss their mark, and can rarely be recovered. In the torpedo of Colonel Lay, which is controlled through an electrical cable, the means employed for producing motive power constituted a hindrance to its being extensively adopted, and imposed limits to the attainment of a great degree of speed. The motor in this case was an engine constructed like a steam engine (and of about equal weight per horse-power with steam engines), and worked by means of compressed carbonic acid, the manufacture and preparation of which are chemical operations necessarily unsuited for being carried on on board ship or without special precautions on shore. In the Williams torpedo electric motors are used, the employment of which obviates all those difficulties in the working of the torpedoes, and the use of electricity as the source of motion and of control gives with suitable arrangements the means of constructing and operating an extended system of operation, as reserve stations may be distributed and worked with the smallest practicable outlay.

As to the propelling power of the torpedoes, this is provided by accumulators specially designed with large active surface and storage capacity, but with minimum weight, to rapidly discharge the power required to propel the torpedo at a speed of twenty-five miles an hour or more.

A device between the accumulators and the motor regulates the necessary supply of electric energy to the motor, which consists of a series of discs on the shaft, both the magnets and the armatures having a disc form, this giving a maximum of power with minimum of weight. The position of the rudder is controlled by devices operated electrically through a paying-out cable, through which the current is passed and regulated by circuit closers and variable resistances upon the switch-board at the base of operations.

The current regulator (worked automatically or by hand) placed in the discharging circuit gives approximate uniformity in the operation of the mechanism throughout the entire run of the torpedo, except when such automatic working is changed by the operator at the switch-board—when, for instance, he wishes to alter the speed of the torpedo.

The mechanism for working the rudder consists of solenoids, having their armatures connected with a lever on the rudder head, or of an electric motor working worm gearing combined with the rudder head, springs or counterbalance weights being used to return the rudder to midship or normal position when no current is passed through the electric mechanism.

Guide rods are also raised and lowered through the medium of a current passed through the paying out cable, operating solenoids, or other suitable devices. These rods carry hooded incandescent lamps, which are thrown into circuit either automatically by the

raising of the rods, or by hand at the will of the manipulator at the switch-board.

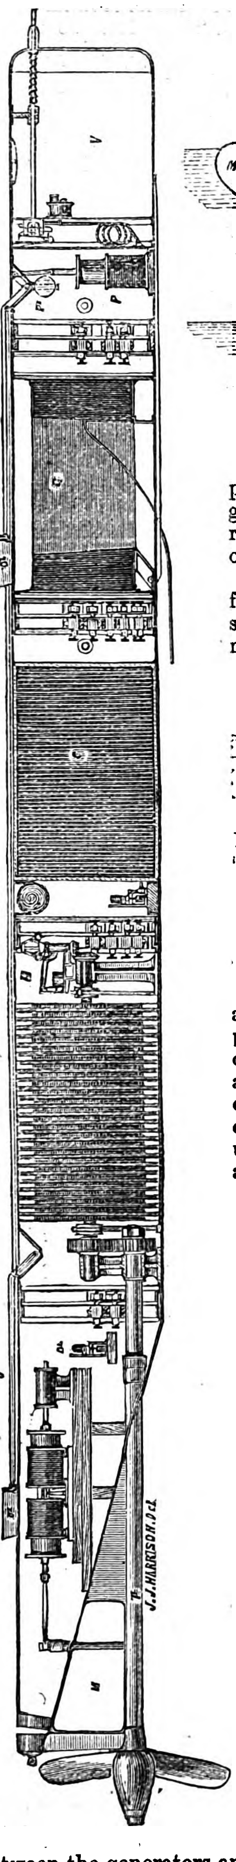


FIG. 2

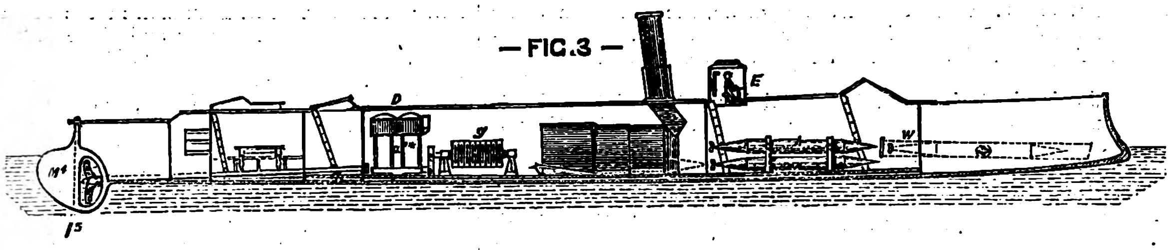
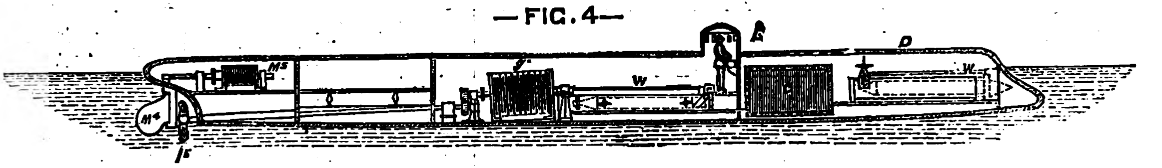


— FIG. 3 —

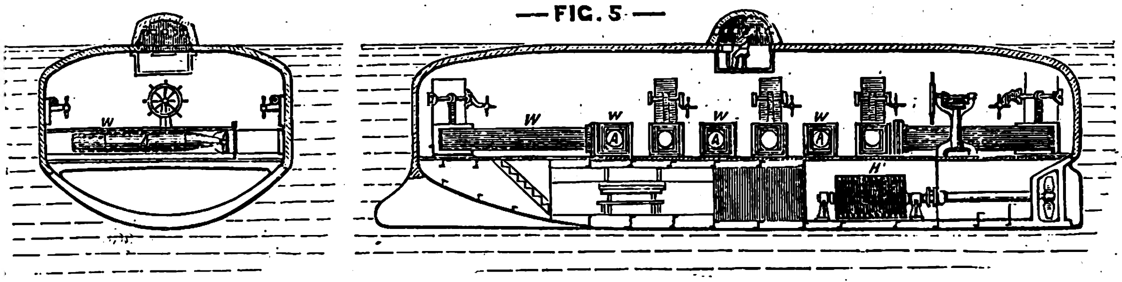


— FIG. 4 —

The position and direction of the torpedo are shown to the operator by the guide rods, and he manipulates the currents for controlling the propelling and other mechanism accordingly.

The general system, as will be seen from the drawing (Fig. 1), provides for a supply of electricity stored up in accumulators stationed at fixed points along a line of coast to be defended, which supply may be developed from wind, water, or coal power, whichever is cheapest in any given district, and conveyed by means of suitable cables of light section. In carrying out this system of distribution the use of automatic pressure regulators, variable resistances, and cut-offs, interposed between the generators and accumulators and between the accumulators and the appliances in the working circuits, secures the operation of all the various parts of the system without conflict, and of the appliances in the discharging or working circuits independent of the condition of the developing or reserve source when required.

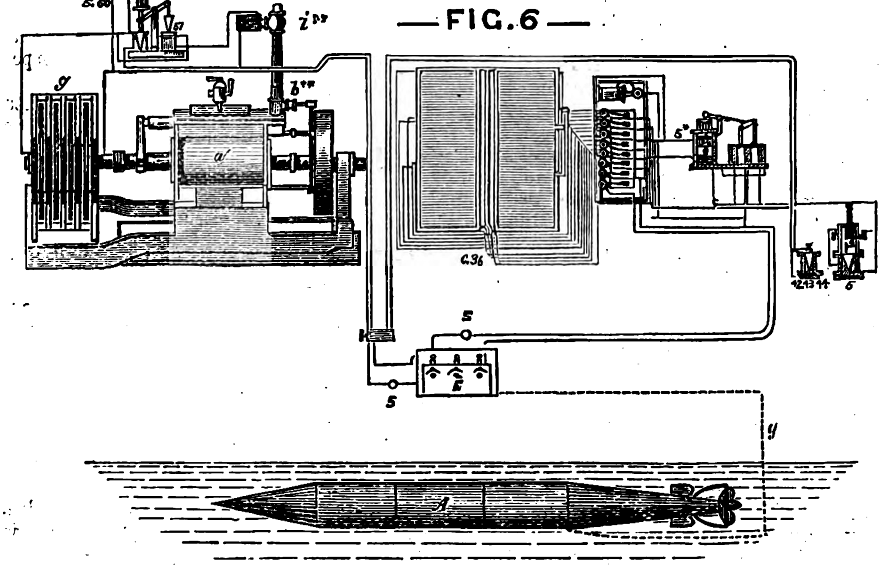
This enables the generating or producing plant to be used to its full capacity, and the main cables or conductors to be kept constantly employed for the transmission of the energy to the distant points where it is held in reserve, and as the E.M.F. of the current in such main circuits may be high, the cables used may be of lighter section than is practicable with any other method of working.



— FIG. 5 —

The accumulators are safeguarded by having means to disconnect them automatically or by hand from the charging circuit when they are fully charged, and devices are provided for preventing the backward flow of the current towards the source.

Torpedo launches (Figs. 3 and 4), worked by electricity as well as the torpedoes themselves (Fig. 2), can be constantly kept charged and in readiness for work at the fixed points, and it is easy to lead branch cables to buoys moored off the shore, so as to provide floating stations where accumulators on board of vessels can be recharged.



— FIG. 6 —

A great advantage the torpedo has is that the accumulators can be kept charged by a small plant, as shown at Fig. 6, worked from the main boilers of an ordinary war ship or launch, or the torpedo motor can be driven direct from the dynamo, the operation being under control by the use of current regulators and variable resistances. Any man-of-war or steam launch can carry and work this plant.

The floating batteries (Fig. 5), (containing a store of torpedoes), which can be moored off a harbour or port, combined with the use of torpedo boats and the submerged batteries close in shore, render it practically impossible to approach for bombarding purposes.

The result of the practical application of this system will be that, at far less cost than that which the country goes to for ironclads, unarmoured cruisers, &c., it will be possible to protect our harbours, ports, coaling stations, &c., in a manner that will bid defiance to any war machinery existent.

JUSTICE TO ALL.

This is the title of an article in the *Warrnambool Independent*, which some kind correspondent has forwarded to us, and which we reprint below. There are in the article some sentences not quite accurate historically or scientifically, but we hardly think the *Independent* realised the statement that without Davy certain news would not be in its columns. Great praise, great honour, as well as justice, are due to Davy; but then many minds were investigating "electric telegraphs," and the required apparatus was soon to come. However this may be, our views as regards Davy's position as a pioneer in the work have long been known, and we should like to see his claims duly acknowledged, and a just meed of praise and honour given to him before time has taken the opportunity from us to give to him personally. The article we refer to is as follows:—

"Justice to All."

Justice is seldom done to the scientific benefactors of mankind during the currency of their own times, although in most cases the memories of those who have discovered wonders, or who have accomplished great things, is preserved after all that is mortal of them has passed into the oblivion of the grave. It appears, indeed, almost to be an accepted principle fully borne out in practice, that until a man who rises pre-eminent has himself paid the debt of nature, his fellow men neglect or refuse to satisfy the just claims he has upon their gratitude for services rendered. Why this is so it would be difficult to explain, except upon the theoretic grounds applicable to the case of the typic prophet who, we know, upon indisputable authority, has no honour in his own country. Death is a great leveller, and, amongst other things, sweeps away all jealous feeling, so that communities of men do not hesitate, after the great change, to do homage to the departed intellect or genius of a fellow being, even though while the philosopher or poet lived he were allowed to live as best he might, or to die for want of bread, if his ill fortune so decreed. It nevertheless does seem hard, when particular cases come under our notice, that this rule should always obtain, and that there should be no exceptions by which the closing years of a man who has made his mark might be gladdened with a generous recognition of his worth. Dr. Edward Davy, now eighty years of age, the man to whom the world is indebted for the electric telegraph to-day, unnoticed and unthought of, while messages flash from hemisphere to hemisphere, is ending his days quietly, unobtrusively, but still usefully, as a practising physician, in the unpretending Victorian town of Malmsbury. But for his discoveries in relation to, and his successful practical application of, one of the most wonderful powers in nature, not one item of the European, foreign, intercolonial, or city news of yesterday, which appears in our columns to-day, would be available for Warrnambool readers. Briefly these are the facts; with the addition, that no properly concerted, enthusiastic, or sufficiently comprehensive movement is afoot, here or in the old country, to do common justice to Dr. Davy. We are sure that when he is dead a monument will be raised to his memory. The work of his hands and of his head has supplied undying material for it. But why should not the fast fading moments of his ripe old age be cheered and made happy by some expression of tangible and unmistakable acknowledgment and approval by the nations of the earth? Not many people, in these selfish, busy times, care to spend the time to think about, much less to take action in such matters. Yet there are a few, and one of these is our townsman, Mr. John Flaxman. We published, a little time since, an answer sent by Mr. Murray Smith, the agent-general of Victoria, to a communication received from the gentleman named; and since then letters and articles have appeared in the Melbourne press, and action has been taken which will result, we hope, in the subject being remitted to Parliament at an early date. Parliament's business will be, not simply to vote an inconsiderable money grant, but to instruct Mr. Smith so that he, acting for and on behalf of Victorian opinion, will be enabled to place the movement upon an international footing. Mr. Flaxman, in the meantime, is indefatigable to promote the good cause; and, indeed, there is little time to spare. In regard to the history of telegraphy, as it leads up to and affects Dr. Davy's claim, we may submit a short statement of facts. It cannot, upon any known data, be claimed by anyone in particular that he invented the electric telegraph. It has progressively developed out of the contributions of numerous inventors. All these, prior to 1820, depended on the use of frictional electricity, and, including the ingenious proposals of Mr. Ronald, did not admit of being made very useful. Œrsted's discovery of electro-magnetism, in 1820, opened a different prospect. Ampère was probably the first to propose its use in this way. The first idea was to use 24 if not 48 wires, to work alphabetically. Cooke and Wheatstone, and at the same time Davy, showed how this might be done with five or six. Steinheil, of Munich, soon after showed how, by making use of the earth as a conductor, communications might be effected with one wire only. But still there was the unsolved problem—How far would the electricity go without losing so much of its energy by dissipation as to become inefficient for producing signals? *At this point* comes in Davy's invention of the renewer, or the relay, which solved the problem. Steinheil's one-wire improvement was one of the greatest approaches to practical perfection that had been made, and the relay principle was certainly not second to it. Both these are now in daily use all over the world. Founded on these was introduced Morse's excellent invention of dot and dash telegraphy. Davy's relay was first patented, and sold to the Electric Telegraph Company for £600, the agent with whom it was left in England not properly appreciating its value, so that, practically, Davy never got anything for his inestimable invention. Other earnest friends besides Mr. Flaxman are at work to do something that will bring about a recognition, while the doctor lives; but as "Audeo," writing to the *Argus*, says:—"Individual efforts must be superseded by collective efforts, and, although I agree that the subject should be national, yet if only the local friends and admirers were to combine to do honour to the nan of genius who has so long and worthily lived among us, not a little could be achieved in this colony alone, and it would be a centre around which the other parts would gravitate, and thus grow into national, nay, even international dimensions." We commend the subject to those who, like ourselves, desire to see shams put down and real merit rewarded. And if there are any who could and would assist, but that they are unaware of the merits of Dr. Davy's undoubted claim, we hope they will read Mr. J. J. Fahie's pamphlet, reprinted from *The Electrician*, entitled "Honour to Whom Honour is Due," and giving an account of Edward Davy and the telegraph from 1836 to 1839.

ELECTRIC LIGHTING FROM A SANITARY POINT OF VIEW.

At the Congress meeting of the Sanitary Institute of Great Britain, held in Dublin last week, the following paper on "Electric Lighting, considered from a Sanitary Point of View," by J. Angelo Fahie, C.E., Member of the Society of Telegraph Engineers and Electricians, was read before the Engineering Section.

Sir Robert Rawlinson, C.B., President of the Institute, presided.

It may be asked at the outset, What relation is there between Electric Lighting and Sanitary Science? The author hopes to be able to show that the question of artificial lighting, and especially electric lighting, has a most important bearing on sanitation, although hitherto it has not received very serious attention from this point of view. Recollecting that foremost amongst the objects of the Sanitary Institute of Great Britain are the discussion and consideration of all questions affecting, directly or indirectly, our general health, the question of the good or evil influence exercised by artificial light thereon is of the highest importance, and is, in every respect, worthy the consideration of this Congress. When we reflect what a considerable portion of time is spent by modern society under light other than natural light, and how much more injurious are all modes of artificial lighting in comparison with sun light, it is essential that we should consider anxiously the most desirable form of light which shall exercise the least ill effects on our bodily health and comfort.

In olden times man paid little attention to the subject of artificial illumination. Content to work during the day by the light of Nature, he spent his life after sunset in semi-darkness, or in the imperfect light emitted by the rude fire which served to warm his dwelling.

To the inhabitants of the East may be ascribed the first attempts at producing light by artificial means, which consisted in burning fluid bitumen in rude vessels of baked earth. Attempts were also made to utilise the fat of fish and animals for the purpose, and later on the primitive pine torch came into almost universal use as the only means of affording light after sunset. It need hardly be said that these early attempts served to fill with odour rather than light the dwellings it was sought to illuminate.

Digitized by Google

Since the object of this paper is to consider the subject of electric lighting from a sanitary point of view, and since it is only with the general introduction of gas and petroleum the danger of injury to health arose, it is not necessary to dwell on the forms of lighting in vogue prior to the illuminants now so universally used. Nor is it necessary for our present purpose to enter into the consideration of the theory or nature of light; suffice it to say that light is the medium by which bodies are rendered perceptible to the sight. Every form of matter when sufficiently heated has the power of emitting rays of light, and thus becomes self-luminous. All artificial sources of light depend on the development of light during incandescence.

The conditions of life under all kinds of artificial light are less favourable to health than under daylight. During the day we have abundance of soft, pure, white light. The air we breathe is pure and unvitiated; it contains the heat only necessary for health. All nature delights in sunlight, the animal and vegetable organisms flourish under its influence; our energies are in a state of activity during the day. Under artificial light these conditions are completely altered; light which would be considered excessive at night is far inferior to ordinary daylight. The heat produced by all forms of light exceeds the temperature of the atmosphere in average daylight, and the air is vitiated to an extent proportional to the amount of light produced. How desirable, therefore, is it that we should seek, and by every effort in our power assist in, the development of that form of artificial light which approaches nearest the conditions existing under sunlight.

As will be seen hereafter, the light afforded by means of electricity is far superior to all other illuminants in the fulfilment of these conditions.

All forms of artificial light hitherto in use depend on combustion, in order to sustain which a good and plentiful supply of air is necessary.

Gas, for example, the chief constituent of which is a combination of carbon and hydrogen, will not burn without the aid of the oxygen in the atmosphere. In the process of combustion the particles of carbon contained in the gas come into contact with the oxygen of the air, and float in an incandescent state in the interior of the burning vapour, and this constitutes the flame. The presence of the carbon in a finely-divided state may be easily shown by holding some refractory substance in the flame, when the carbon will be deposited upon it in the form of soot.

TABLE—Showing the oxygen consumed, the carbonic acid produced, and the air vitiated, by the combustion of certain bodies burnt so as to give the light of 12 standard sperm candles, each candle burning at the rate of 120 grains per hour:—

Burnt to give light of 12 candles, equal to 120 grains per hour.	Cubic feet of oxygen consumed.	Cubic feet of air consumed.	Cubic feet of carbonic acid produced.	Cubic feet of air vitiated.	Heat produced in lbs. of water raised 10° F.

Electric light.	none	none	none	none	13·8

Should, however, the supply of oxygen be insufficient, partial combustion only takes place, the carbon escaping in an unburnt condition in the form of a dark cloud, when the flame is said to smoke.

The brightness of the flame, therefore, depends on the supply of air necessary for perfect combustion.

To show that oxygen is absolutely necessary for combustion, here we have a tumbler placed over a taper, which burns nicely at first, but soon a change will be observed; gradually the flame diminishes, and at length goes out. This result is caused by the enclosed oxygen combining with a portion of the material forming the taper, producing a poisonous compound called carbonic acid, which suffocates the flame. Similarly, if we take an Argand burner and stop the aperture in the centre, the gas burns poorly because there is a restraint to the supply of air.

The light afforded by candles and lamps does not differ essentially from that of the ordinary gas burner. The same elements which constitute the one are present in the other—they all owe their luminosity to combustion. A petroleum lamp burns imperfectly without a chimney, but when this is put on, a strong draft is caused, supplying the air necessary for thorough combustion, and the brilliancy of the flame is thus materially exalted.

From what has been said it is obvious that in order to obtain the highest illuminating power of a flame, a plentiful—and what is more, a fresh—supply of air is essential. Thus it will be seen that wherever light is obtained by combustion, it deprives the air of oxygen, that element which has justly been termed the "ærial" food of animal life. Moreover, in the process of combustion the air is contaminated with certain poisonous compounds, such as carbonic acid, carbonic oxide, and sulphur, which, when breathed even in a limited quantity, are injurious to the human frame. Another effect of combustion is the production of vapour, formed by the oxygen of the air combining with the hydrogen, which constitutes a portion of the material consumed. The presence of this vapour will readily be detected if a decanter of cold or iced water is brought into a room where a number of lights are burning. The surface of the decanter will be speedily covered with a thick dew, caused by the vapour floating in the air being condensed by the action of the cold water within.

As we all desire to live in pure air, is it not strange that we should be content to use a light which not only robs the atmosphere of oxygen, thus destroying its life-supporting virtue, but actually loads it with noxious vapours, the products of combustion?

Considering the comparative merits of the various artificial lights now in use, the above table from Dr. Tidy's "Handbook of Modern Chemistry" will afford some idea of the heat-producing and air-vitiating effects of the different bodies enumerated. To this table Mr. R. H. Hammond has added the effects produced by a 12-candle incandescent electric lamp.

From this table it follows that an ordinary gas burner consuming 5 cubic feet per hour absorbs nearly 5¼ cubic feet of oxygen per hour, or, in other words, it deprives 17 cubic feet of air of its oxygen in an hour. But, as has been already pointed out, gas not only deprives the air of its health-giving oxygen, but it contaminates it with poisonous compounds which are more or less—according to the extent to which they exist—injurious to animal life. Dr. Tidy considers that the contamination of the atmosphere in a crowded theatre at the end of the performance may be regarded as distressing, and many of us experience a disinclination to go to the theatre because of the inconvenience suffered from the heat and vitiation of the air caused by the gas, producing headache and oftentimes giddiness. The effects of heat and vapour from combustion will be readily detected in a wareroom or shop, the lower portion of which may be only at a temperature of 60° to 70°; in consequence of the hot air ascending, the temperature near the ceiling will probably be from 130° to 140°. When, therefore, goods, books, &c., are placed in such high localities it cannot be wondered at that they become injured or destroyed.

Turning to the table above quoted, we find that electric lighting by incandescence produces absolutely none of the evil effects just enumerated. There is no oxygen consumed, no carbonic acid or other compounds given off, and, consequently, there is no vitiation whatever of the atmosphere; and, as to the heat-producing effects, the table shows that the air of a room lighted by gas is twenty times more heated than if lighted by incandescent electric lamps. From this it will be readily seen how conducive to health and bodily comfort are the conditions fulfilled by electric light in contrast with all other illuminants. And not only is the health and bodily comfort affected by the influence of artificial light, but the temperament also; and it is very remarkable to notice the difference in the effect produced by gaslight and electric light on the spirits of those obliged to work long hours at night. A brilliant light, we all know, exercises a cheerful influence on the animal spirits, and electric lighting affords unusual facilities for acquiring a higher degree of illumination without the accompanying heating and air-vitiating evils inseparable from gas and petroleum.

It has been said, as an argument against the use of electric light, that it is injurious to the eyesight, and, therefore, cannot be considered as conducive to health. This argument is more imaginary than real, and has no foundation in fact. As compared with other lights, electric light is less injurious, when used under proper conditions. True, an unsteady or flickering light has an ill effect on the sight, and electric lighting on the *arc* system is open to this objection, a defect which, however, will doubtless be remedied in time. But the *incandescent* system leaves nothing to be desired; the light is pure, soft, and white, and is absolutely steady in its action.

It is this system which concerns us at present, since it is the most suitable for indoor purposes, and consequently bears directly on the question of health.

The flame of a candle, or a gas flame, is not absolutely steady, although considerable improvements have been made in gas lighting, during recent years, by the introduction of better burners and more suitable globes; but in some cases—for instance, in factories—globes cannot be conveniently used, and the flame is ever subject to drafts, causing a disagreeable wavering or flickering in the light. It is impossible that the light of the incandescent electric lamp can be affected in this way.

The glare of the electric light is also commented on as being objectionable; but this is only applicable to the arc light, and even this form readily admits of being shielded in ground globes; and as it is only suitable for outdoor use and for large buildings, it is not necessary here to say much about it. It might, however, be said *en passant* that we have no right to stare at the electric arc any more than we have to stare at the sun, which makes our eyes weak, and otherwise inconveniences us. A strange story is told in the newspapers a few days ago, of a boy, aged about 14 years, who, for a wager, stared at the sun for some time and died the same night in great agony. Professor Pickering, a German *savant*, recently made an investigation into the cause of weak sight amongst the students of his university, and traced it to the heat given off by their reading lamps, which dried up the humours of the eye. Seeing that the electric light gives off but a trifling degree of heat it is, therefore, far preferable in this respect, and far less injurious to the sight than gas, oil, or candle light.

Many institutions throughout the country are now lighted by electricity, and in every single instance with the most beneficial results to the health and comfort of the people who work by its aid.

It would be impossible in a small space to describe the lighting arrangements in these institutions, but the author may be permitted to refer to one installation which has been working under his charge for the past nine months, and which will serve as an illustration for many others. The installation referred to is that of the offices of the *Irish Times*. The composing room here forms one large apartment, measuring some 60ft. by 40ft. by 70ft. in height. Before the introduction of the electric light, this

Digitized by Google

apartment was lighted by 100 gas jets, and, remembering that one gas jet consumes as much oxygen as five individuals, and adding to this the effects resulting from the breathing of the compositors, together with the long hours of night during which the work is carried on, we can readily conceive how extremely unwholesome and unhealthy must have been the air of this apartment. Indeed, as a matter of fact, the *employés* frequently suffered from ill health and discomfort, which they usually attributed to the vitiated state of the atmosphere, and it was not unusual to have several out on sick leave at one time. This was especially noticeable in summer. The temperature of the apartment frequently ran as high as 85° in winter, and 95° in summer. The discomfort occasioned sometimes in summer was very serious indeed, oftentimes rendering it impossible for some of the men to carry on their business for the usual number of working hours.

Since the introduction of the electric light the condition of things is entirely changed. The atmosphere is pure and healthy, the thermometer rarely marks higher than 70° during the night, the light is bright and perfectly steady in its action, the health of the *employés* is good, and their spirits cheerful and buoyant, many of them being able to work for considerably longer hours now than formerly, and the sick list has all but disappeared.

This proves that not only from a sanitary but also from a *commercial* point of view is the introduction of the electric light beneficial.

It may be argued that a proper system of ventilation would render the use of gas harmless; but the question of ventilation, although apparently so simple, is difficult to deal with. Sometimes arrangements adopted to ensure a good supply of fresh air may be admirable in calm or warm weather, and just the opposite in cold or boisterous weather. Again, a means of ventilation may work well for a period, and unexpectedly, perhaps, owing to a change in the wind, instead of the noxious products of combustion passing off, the wind rushes in with occasional gusts, causing the flame to become agitated and smoky, and the air is vitiated to even a greater extent than otherwise. With the electric light the difficulty of ventilation is reduced to a minimum.

Amongst other advantages of the electric light which, although not strictly relating to its sanitary aspect, have nevertheless an indirect effect on health, may be mentioned the following:—Plants grow in rooms lighted by it, and cut flowers exhibit their true colours, and do not quickly wither; paintings show their natural tints and colours to better advantage. Its influence on the health of children is incalculable. An electrically lighted nursery, even if the light remains on all night long, is free from the noxious vapours produced by candles or gas. The electric light also lends itself to artistic treatment in the most admirable way.

In the adoption of the electric light, therefore, we fulfil the following important considerations:—We do not deprive the air of oxygen, so necessary for our health and comfort; we do not adulterate the air with pernicious compounds of any kind; we avoid the accumulation of vapour; only a small degree of heat is produced; and we facilitate the means of ventilation.

In fact, by means of electricity, we have at last obtained an artificial light which is nearly all that could be desired; and, regarded from a sanitary point of view alone, its development and introduction should command our warmest sympathy and earnest support.

It may be expected that some reference might be made here concerning the expense of the electric light, but since the subject has been dealt with chiefly from a sanitary point of view, and as the question of first cost and maintenance involves considerations which could scarcely be fairly treated in a paper of this kind, the author may be excused for not entering into details or comparisons of cost.

So long as electric lighting is carried on in isolated installations, it will be found difficult, no doubt, to compete with its older rival, although there are cases where the cost of such installations compares favourably with gas. The expense of maintenance by isolated lighting is governed entirely by local considerations. Where the light is required only to a limited extent—say 100 incandescent lamps burning for less than 1,000 hours per annum—the cost will probably exceed that of gas; but where the number of lamps reaches 200 and the number of working hours amounts to about 2,000 per year, then electricity will undoubtedly beat gas. It is, however, unfair to compare the expense of lighting by isolated installations with that of lighting by means of a well-established and elaborate system, whose existence is founded on the experience of half a century. However, in considering the question of expense, the superior advantages which we have endeavoured to point out, inherent in the electric system, should entitle it to a higher price than all other systems of artificial illumination.

The time will come, however, when the electric current will be supplied on a large and comprehensive scale, and when its merits will be fully appreciated by all; then the question of cost will no longer form an insuperable barrier to its universal adoption.

A discussion followed, and

Sir ROBERT RAWLINSON, in summing up, spoke as to the purity, brilliancy, and wholesomeness of the atmosphere wherever the electric light was used. He thought that its advantages over all other illuminants would sooner or later recommend its universal adoption. But there were still difficulties to be got over in order to make it a perfectly safe and certain means of illumination. He referred to the fact of its having gone out at the Health Exhibition, where it was worked under the most favourable conditions, and also alluded to the unfortunate accident which occurred the other day, resulting in the death of one of the attendants on a dynamo used for arc lighting.

Mr. FAHIE, in reply, said that no doubt there were still some difficulties which impeded the successful and economical application of the electric light, but it should be remembered that difficulties had always to be overcome in the introduction of every new industry, and those attending electric lighting were being removed from time to time, as electricians gained experience by actual practical work. As to the accident which occurred at the Health Exhibition, it simply arose from the attendant incautiously placing both his hands at one time on or in connection with the opposite brushes of the dynamo, thus receiving through his body the current which was being generated to feed some 23 arc lamps. It appears that the unhappy man had been cautioned against placing both hands on the machine, and the accident was wholly due to negligence.

During the reading of the paper Mr. Fahie exhibited a specimen of the spectacles or goggles recently devised by Dr. W. H. Stone for the use of electrical engineers and others connected with electric lighting. These goggles have blue glasses in the front, and are provided with side glasses tinted red. When looking at the incandescent light the blue glasses are used and the red rays neutralised, while for the purpose of examining the arc light the red side glasses are turned down and both are used, by which means any danger to the eye arising from excess of blue rays is obviated.

COMPANIES' MEETINGS & REPORTS.

The Eastern Extension, Australasia, and China Telegraph Company (Limited).

The twenty-second ordinary general meeting of this Company was held on Wednesday, the 15th inst., at the City Terminus Hotel, Cannon-street, under the presidency of John Pender, Esq., M.P.

The SECRETARY (Mr. F. E. Hesse) read the notice convening the meeting and the minutes of the last meeting, which were confirmed and signed by the Chairman. The report of the Directors was taken as read.

The CHAIRMAN: Gentlemen, I have no doubt that in reading the report you have found it on the whole very satisfactory, and I have great pleasure in congratulating the shareholders on our being able to put such a satisfactory report before you. As usual, the report not having been read, I shall go over some of the figures, so as to give some little explanation. The gross receipts for the half year have been £237,672, against £213,729 for the corresponding period of 1883, showing an increase of £23,943. The working expenses for the same period amounted to £66,658, against £62,778 for the corresponding period of 1883, showing an increase of £3,880. This is practically made up by an increased expenditure of £910 on account of maintenance of the Company's lines, and to the additional salaries at foreign stations, amounting to £2,680, necessitated by the opening of new stations. The net revenue for the half year was £127,415, against £107,356 for the corresponding period of 1883, showing an increase of £20,059. Against the half year's revenue the Directors have charged £22,767 for the renewal of the teredo exposed portion of the original portion of the Java-Australian cable, by which means the whole of the work has been carried out without any charge to capital. I think you will approve of this as being a sound proceeding. In addition to this long lengths of brass-ribboned cable have been inserted in the Singapore-Saigon and Penang-Rangoon sections, where the teredo has been found troublesome; but as those renewals have been effected since the close of the half year, they will be dealt with in further detail in the current half year's report. With respect to the dividends, one interim dividend for the half year, at the rate of 5 per cent. per annum, was paid on the 15th of July, and another of a similar amount, together with a bonus of 2s. per share, was posted to the shareholders last evening, making a total payment of 3½ per cent. for the period, against 3 per cent. for the corresponding half year. The balance of £17,147 is carried forward. With respect to the 5 per cent. Australian Government Subsidy Debentures, 909 of these were drawn on the 23rd of April last in terms of the trust deed, and the necessary funds were placed at the disposal of the trustees for meeting the payment of the same. Up to the present time 654 have been lodged with the bank and paid off by the trustees, leaving 255 still outstanding. Of these only six are "registered," the balance being held "to bearer." With regard to the opening of new cables, as stated in the report, the new cables between Hong Kong and Tonquin and between Macao and Hong Kong have been successfully laid during the half year under review, and opened for traffic. It will be in the recollection of those who were present twelve months ago that I shadowed forth what was likely to take place in the negotiations we were then having with the French and Portuguese Governments, and, as just now stated, all those negotiations were successfully completed, and resulted in our establishing for the French Government a connection between Singapore, Annam, and Tonquin, for which they pay us £10,600 a year, and also a connection between Macao and Hong Kong, with a subsidy from the Portuguese Government of £500 a year. All this has been done in the twelve months, and has worked satisfactorily. Unfortunately one of the cables—that between Hong Kong and Tonquin—was interrupted, but as I have frequently said at these meetings lately we have so thoroughly mastered the mode of repairing and finding out where a fault exists, that we have now very little hesitation in dealing with it, whereas some years ago an interruption put us all into a very great flutter. The cable is now, however, repaired and at work again. Another between Saigon and Hong Kong is now interrupted, but we expect every hour to hear that it is repaired, the steamer "Agnes" being on the ground of the fault. I have men-

tioned frequently that the great object of this Company is to secure permanent and continuous telegraphic communication with the important places with which we have connected our cables. We have found that without duplicate cables interruptions are very serious; not so very serious perhaps to the Company (although the loss is very considerable, as I shall show you) as it is to the public, as a very large amount of commerce is now being carried on by means of the telegraph, and it is therefore our duty to those who support telegraphy (always having the interests of our shareholders in view), that we should make our system so thoroughly efficient that merchants may rely upon it. The principal interruptions during the half year under review were between Madras and Penang, for thirty-seven days during the south-west monsoon, and between Java and Australia for seventeen days. The traffic was transmitted by the alternative lines, and consequently there was no loss to the merchants, nor to the Company. If we had not had the duplicate lines the loss to the Company would have been £23,000 for that comparatively short number of days, so that by duplication we not only maintain our traffic but we give confidence to the merchant, who is involved in important operations at a particular time, and thus secure his confidence and increasing support. We had also an interruption on the Victoria and Tasmania cable for fifty-nine days, but not having a duplicate line, the loss, although it is only a short cable carrying comparatively speaking only local traffic, was for that short period about £1,600. It is our intention to duplicate the line, which we shall do from the cable we have taken up and replaced with brass-ribboned cable to fight the teredo. This stock cable costs us a comparatively small amount of money, and will add very little, if anything, to the capital of the Company. In that way we propose to continue the policy of duplication where now we are dependent on single cables, and thereby secure for the Company such a continuity of telegraphic communication as will best maintain our dividends, and above all serve the merchants who are depending on telegraphy. I may mention that in completing our system to China we have had, as I have frequently stated, some trouble and difficulty with the Chinese. We have had a good deal of difficulty lately through the hostilities going on between the French and the Chinese in maintaining our connection with Foochow, but I am glad to say we have been enabled to maintain the service between Sharp-Peak Station and Foochow, although under very difficult circumstances. I think that the Chinese, seeing that we are honest and in earnest, have pretty well agreed to do what we have asked them—namely, to give us a line from Foochow to connect with our cable at Sharp-Peak. In that way we have our cable worked under English supervision, which will give us all we could desire, and save us the expense of maintaining expensive Chinese offices. A good deal has been said in the newspapers, and it is a question I find even some of our shareholders take a very strong view about—about the reduction of our rates. Having been a merchant myself, and knowing something now of the value of telegraphic communication, and the expense of it to merchants, I am very anxious, whenever I see our interests can be served by a reduction in the tariffs, to give effect to it. But it is a very curious fact that the reductions we have tried have not resulted in any degree to encourage us to go on with it to any great extent. When we find that there is a response, and that it is being availed of to an extent that will recoup us for the loss we make by the reduction of the tariff, we shall only be too glad to extend the privilege. But I have learned this, that in all important transactions involving thousands of pounds—many thousands of pounds often—the question whether it is a small or large sum for telegraphy when the charge is within moderate compass does not enter so much into consideration. These operations are carried on, the telegraph must be used, and the consequence is that we get the returns. When the duplicate Australian cable was laid it was arranged that Press telegrams between England and Australia should be carried at quarter rates over the Extension Company's system, and although the privilege has been in force for five years the number of words transmitted has only increased by 11 per cent., whereas the receipts show a loss of 72 per cent. Now, that is a very conclusive argument. As a further illustration, I may mention that when the Atlantic cable companies reduced their tariff from 2s. per word to 1s. the increase in the number of words sent was only 22 per cent., whilst the loss of revenue was 37 per cent. Subsequently, when the rate was increased to 2s.—a rate which we find is about the lowest rate that can be really worked with anything like a fair return—the number of words transmitted at the lower charge only decreased 12 per cent., whilst the revenue increased 58 per cent. As an explanation of these figures, it should be mentioned that the out-payment to other administrations included in the rates of 1s. and 2s. are in some cases fixed charges. Hence the cable companies make a heavier loss at a rate of 1s. than 50 per cent. of the receipts at a 2s. rate. I mention these facts because I think it is well that the shareholders should clearly understand the question. There is a very general idea that if you only reduce the rates you will largely increase the returns. We have not found that to be the case, but I am quite prepared to say, and I believe I express the opinion of my co-Directors, that when we see good grounds for making further reductions in the rates we shall only be too glad to make them. There is another question I will take this public opportunity of referring to. I see there has been an attempt to get up an agitation in the newspapers against any alteration in what is called the coding system, and to bring this matter before the Conference which is to be held in Berlin next year. I know that these coding systems are got up at a very great expense by merchants. They have shown wonderful ability in them, and they have beaten us at all points. They have got the advantage of the fight most completely, and with a few words they can fill pages of paper; whereas we originally contemplated that with open words we should get a larger number of words. Had we got that amount of business in open words our dividends would have been very different to what they are. But the coding system has been got up at very great expense, and I may say that we have no intention whatever of proposing at the Conference any alteration in the present coding system. I wish the Press to notice this, as I think it is well that merchants should know that we are not working in antagonism to them, but that we are doing all we can to meet their wishes where those wishes can be met consistently with the best interests of the shareholders. I think I have now pretty well exhausted my remarks, and conclude by moving "That the report and accounts of the Directors now submitted be received and adopted."

The Most Hon. the Marquis of TWEEDDALE seconded the motion.

After some remarks from Mr. Newton and Mr. Griffith in reference to the reduction of tariffs, the preservation of the existing coding system, &c.,

The CHAIRMAN said: I may mention in reply to Mr. Newton that it was the Company that first suggested to the merchants a coding system, and I may also repeat what I have stated so very often, that if a coding system had not been adopted we should not have had cables enough to carry the traffic, and therefore, as you can well understand, we encouraged them, and are anxious that the merchants should do their work as cheaply as possible. I may say that they have done it so very well that they limit to a very considerable extent the dividends which we originally anticipated we should be able to pay. As I have said before, we are working hand in hand with the mercantile community, and as I have already pointed out, whenever we can reduce our rates consistently with securing our dividend we shall only be too glad to do it. There was an important conference held in Australia about a year ago, and the question of lower telegraph rates was considered at that conference, because they considered telegraphy of such great public importance. We were appealed to, and we said: "We are earning such and such a sum, which is paying such and such a dividend. You may make the rate between England and Australia what you please if you will guarantee to us the sum we now earn." That was a very fair challenge, showing that we had done everything we could to meet the colonies for political purposes and the merchants for mercantile purposes. We are prepared to repeat the offer. It is our business to preserve your interests, however, and I think we should not have had the pleasant receptions from you that we have had for the last few years if we went on reducing the tariff and the dividends at the same time. I think you must give us your confidence in so far that we will—always having a due regard to your interests—do the best we can to develop telegraphy between this and our distant stations. I think I have pretty well answered Mr. Newton's questions. As to those of Mr. Griffith, I am afraid if we carried out his views, which are generally very prudent, it would involve very considerably reduced dividends—that is, if we insured our cables as he suggests. Whatever we can insure with propriety we do, namely, our ships; and we do more, we take a certain risk on our ships. I think altogether, looking at the affairs of your Company at the present moment, I doubt if I could make any important suggestion, or if there is any suggestion by which I could place your affairs before you in a more sound or fairer light than we have done to-day. We should bear in mind the development of the traffic, and upon that development will depend the realisation of Mr. Newton's idea of an increased dividend. But we have a good deal to do, and I wish you to bear that in mind. We have some duplications still to carry out, and if we can do that out of income instead of capital I think we shall strengthen ourselves to a great extent. I shall be very glad to have an expression of opinion on the part of the shareholders on this point. Seven per cent. is a very good dividend, and if we can make that 7 per cent. doubly secure by not adding to the capital while adding to the strength of our position, I am sure you will agree that the policy of the Board is a sound one [hear, hear, and applause]. I now beg to submit the resolution.

The resolution was carried unanimously.

Mr. NEWTON: I beg to propose a vote of thanks to the Chairman for presiding over us to-day. I take this opportunity of doing so to congratulate myself on having elicited the important statement which you have just made—that you made such a splendid offer to the Australian colonies which you mentioned. I think it removes all cause of complaint on the part of the Australian colonies. I desire to include your colleagues in this vote. Although I have come into collision with you in past years, it is due from me to say that, under your management and care, telegraphy has become—taking into consideration the rate of dividend paid—the soundest and best investment in the market [hear, hear]. I don't object to your limiting the dividend to 7 per cent. when you make such substantial additions to capital account out of revenue.

Mr. GRIFFITH: I second the motion. I think we are greatly indebted to the Directors for the present position of our Company, for the large dividend we are receiving, and for the substantial state of the concern. In answering the questions which I put, there was one you omitted in connection with the auditors' certificate. I have no doubt that all our securities are perfectly in order and perfectly safe, but the auditors' signature does not include the investments and the securities. If you tell us that it was intended to do so, I shall be very much obliged to you.

The CHAIRMAN: You are aware that when auditors sign the balance-sheet it embodies all this. There is no further signature necessary. They have there given their signatures to the whole account. It is not necessary to certify separately every particular item. I am very much obliged to you for the way in which you have expressed your approval of the Board's policy. I may say that the little talk that we have had to-day elicits information, and I think strengthens the position of the Company before the public. I am always delighted to give an answer as far as I can to satisfy the questioner, and I hope if the relations between this side of the table and the shareholders' side continue as they are likely to do, we shall not go back, but become stronger and stronger, and make it appear before the public that telegraph property is really a good, sound, substantial investment.

The proceedings then terminated.

The West India and Panama Telegraph Company (Limited).

Report of the Directors to be presented to the members at the fifteenth ordinary general meeting, to be held on Wednesday, the 22nd inst.:—The accounts for the six months ended 30th June, 1884, show the amount to credit of revenue to be £50,677 5s. 10d., and the expenses £28,893 17s., leaving a balance of £21,783 8s. 10d., which, with the balance of £2,519 7s. 2d. brought from last account, make a total of £24,302 16s. Of this sum the Directors have placed £10,000 to reserve, leaving an available balance of £14,302 16s., with which it is proposed to deal as follows:—Payment of 6s. per share on account of arrears of dividend on the first preference shares, £10,368 18s.; balance to current half year's account, £3,933 18s. The traffic receipts show a decrease of £3,059 9s. 4d. on those of the corresponding period of 1883, which is partly attributable to the depression in the sugar market and the interruption of the Demerara cable referred to in the last report. It must, however, be remembered that the returns for 1883 were augmented by the exceptional traffic during an interruption of the Central and South American Company's cables, which compete with the Company's system at the Isthmus of Panama. On the other hand, the revenue for this half year has benefited by the chartering of the Company's ss. "Grappler" to the International Ocean Telegraph Company for the repairing of their Havana-Key West cables. Satisfactory progress has been made towards the restoration of the original Jamaica-Porto Rico cable, the repairs of which have now been completed from San-Juan (Porto Rico) to within 30 miles of Jamaica. The "Grappler" is now at work at the Jamaica end, and it is expected that the re-establishment of this important duplicate cable will be shortly reported. This operation, which will add materially to the security of the communications with the whole of the West Indian colonies eastward of Jamaica, has, owing to the great depth of water and the nature of the sea bottom, been both tedious and costly. It is hoped that this effort of the Company to maintain and fortify the colonial connections to an extent far in excess of that contemplated by the single line system, which formed the basis of the original contract with the colonies, will be recognised by both Imperial and Colonial Governments, and by the interests associated with West Indian possessions, whether British or foreign. The appeals to the colonies for some revision of the unfortunate arrangements entered into at the formation of the Company have resulted since the last meeting in an increase of the Grenada subsidy, from £500 to £1,000 per annum, and of the St. Lucia subsidy from £500 to £800 per annum, both to commence on 1st January, 1885. These additions to the Company's resources deserve the most grateful acknowledgment to the colonies which have granted them, and give a much needed encouragement to the Company's endeavours to maintain the telegraphic system of the region. The colony of St. Vincent declines at present to augment its subsidy on the ground of the depressed condition of the sugar trade. The situation in Barbadoes and the Leeward Islands remains unchanged. The terms for which the foreign colonies Guadeloupe, Martinique, and St. Thomas granted their subsidies expire on the 31st December next, and applications have been made to them for renewals. The severe crisis through which the commerce of the West Indian colonies is now passing, causes much anxiety to the Directors, although the traffic receipts of the current half year have not as yet been impaired. Several interruptions to the cables occurred during the half year under report, which were repaired with every possible despatch.

The Telephone Company of Ireland.

Report of Directors presented at the fourth half-yearly ordinary general meeting on the 17th inst.:—

The Directors present their report and statement of accounts for the six months ending the 30th June, 1884. The number of subscribers to the exchange system of the Dublin district, and also of the renters of private lines, as compared with the corresponding period last year, and also with the 31st December, 1883, is as follows:—June 30, 1883, exchange 411, renters 127; December 31, 1883, exchange 507, renters 140; June 30, 1884, exchange 568, renters 168. As the shareholders are aware, the business of the Company has hitherto been limited, under the Post Office licence, to the Dublin district only, within a radius of five miles from the central Post Office. The Postmaster-General has, however, now agreed to grant licences without limit as to radius, and the Directors will thus be enabled to extend the operations of the Company within their territory wherever they find the business can be made remunerative. The new licence will permit the Company to open public call-offices, and also to give intercommunication between towns. The Directors anticipate that these privileges and conveniences will tend greatly to facilitate business, and be of considerable advantage to the Company. That the telephone supplies a want not met by the telegraph—namely, that of obtaining an instantaneous reply, is demonstrated by the fact that the gross rental of the Company from the Dublin district alone is now already upwards of £8,000 per annum over an area with a radius of five miles from the central Post Office, whilst the amount received by the Post Office Department from telegrams despatched from an area with a radius of twelve miles from the Post Office to addresses within the same area, as stated by the Postmaster-General in the House of Commons on the 9th June, 1884, was only £1,390 per annum. The line to Kingstown is now practically complete, and will be opened to the public so soon as the new licence from the Post Office has been perfected. The Board have to thank the Directors of the Dublin, Wicklow, and Wexford Railway Company for the liberal spirit in which they have granted the necessary way-leave for poles to carry this line along and across a portion of their railway. With a view to provide sufficient funds for the development of the business, without using the uncalled capital, and for the reasons already explained to the shareholders, the Directors have considered it advisable to place a further portion of the unallotted shares. This they have done (after first offering said shares to the shareholders) to an extent sufficient for the present purposes of the Company without the necessity of any appeal to the public. These shares were offered as six per cent. shares, which the Directors propose to exchange into five per cent. shares, at the rate of 120 five per cent. for 100 six per cent., in accordance with the terms of the issue. Subject to the approval of the shareholders, the £2,258, being 10s. per share credited as paid on the 4,516 five per cent. shares issued during the half year ending 30th June, 1884, on conversion of the six per cent shares into five per cent. shares, in accordance with the special resolution of the 7th September, 1883, has been written off to expenditure on capital account, and the Directors propose to write off in like manner such further sum as may be credited in connection with the exchange of any six per cent. into five per cent. shares of the authorised issue of £50,000. Since the date of the last half-yearly meeting still further progress has been made in the conversion of the 25,000 old six per cent. shares. At date of last report 3,720 shares remained unconverted. This number had been reduced on 30th June last to 2,405, and the Directors propose, subject to the approval of the shareholders, to redeem and extinguish the small balance of these shares now remaining, upon the following terms:—To exchange the six per cent. shares, 10s. paid, for five per cent. shares fully paid, at the rate of five six per cent. shares, 10s. paid, for three five per cent. shares fully paid, or upon such other terms as may be agreed upon, or as in the opinion of the Directors may be most beneficial in the interests of the Company. The amount standing to the credit of profit and loss, including the balance of £259 15s. 4d. brought forward from last account, amounts to £1,362 10s. 7d. This admits of payment to the preference shareholders of the full dividend, amounting to £388 0s. 4d. upon the preference shares; also of a dividend at the rate of 1 per cent. per annum upon the ordinary shares, amounting to £875, as against nil for the corresponding half year ended 30th June, 1883, and of ½ per cent. for the last half year ended 31st December, 1883, leaving a balance of £99 10s. 3d. to be carried forward to the credit of the current half year.

NOTES.

CHINA AND JAPAN.—The cable between Haiphong and Hong Kong is repaired.

ELECTRIC LIGHT AT BRUNN.—In addition to the installation at the theatre, four cloth factories are now lighted by the Edison system, requiring about 700 A lamps.

THE TELEPHONE AT PHILADELPHIA.—The laying of an underground electric cable for telephone purposes was begun by the Philadelphia authorities on the 2nd of October.

TELEGRAPH CLERKS' GRIEVANCES.—It is stated that Professor Fawcett, M.P., Postmaster-General, has refused the country telegraphists' application to be paid for Sunday work.

WEST INDIA AND PANAMA TELEGRAPH COMPANY.—The estimated traffic receipts of this company for the half month ended the 5th October are £1,679, as compared with £2,369 in the corresponding period of 1883.

WESTERN AND BRAZILIAN TELEGRAPH COMPANY.—The traffic receipts of this company for the week ended 17th October, were £2,301, after deducting the "fifth" of the gross receipts payable to the London Platino-Brazilian Telegraph Company.

THE CHINESE TORPEDO SERVICE.—The Berlin correspondent of the *Morning Post* states that the French operations at Tamsui were in a great measure frustrated by the torpedoes which were laid by a European, Mr. Betts, of the Silvertown Company, and head of the Torpedo College at Tientsin.

ELECTRIC LIGHT IN SPINNING MILLS.—Mr. Charles Lever, of Bowdon, Cheshire, has applied his system of arc lighting to the combing and hanking room of Messrs. Blackburn and Co.'s Clarence Mill. A special Gramme machine is used to maintain six arc lights of 2,000 candle-power nominal. We learn that the light has given every satisfaction.

ELECTRIC LIGHT AND NOVEMBER FOG.—On the occasion of laying the foundation stone of the new National Liberal Club, which is fixed for Tuesday week, 4th November, it is intended to erect a large marquee, and have the electric light ready to be switched on, in case the "London particular" should throw its yellow pall over the proceedings.

ELECTRIC LIGHT AT THE BRIGHTON PAVILION. — The general lighting of the Royal Pavilion, Brighton, is now complete, the total number of lamps being about 1,400. The insurance companies have expressed themselves highly satisfied with the manner in which the work has been carried out by Mr. Magnus Volk, electrical engineer to the corporation.

ELECTRIC LIGHT FOR NEW YORK HARBOUR.—On Monday night the gigantic statue of "Liberty Enlightening the World," that forms the lighthouse at the Hell Gate entrance to New York Harbour, was illuminated by electricity on the Brush system, nine lamps being used of 6,000 candle-power each. The light is regarded as the most powerful in the world.

DOMESTIC LIGHTING BY ARC LAMPS.—We learn that Siemens Brothers have made some small arc lamps, maintained by a current of 40 volts at 10 amperes, and that the light is very steady, thanks to the use of special carbons. A few of these small lights can, of course, be run in the same circuit with those of larger size, and at a far cheaper rate than incandescent.

SHIP LIGHTING.—The steamer "Olympo," built by Messrs. A. and J. Inglis, Pointhouse, for the River Plate service, is lighted by 330 incandescent lamps of 20 candle-power each. An Elphinstone-Vincent machine generates the current; and storage batteries are used to supply 51 lamps for 12 hours while the dynamo is stopped. The lights in the cabins can be switched on or off by the occupants.

PERSONAL.—Messrs. J. E. Spagnoletti and Crookes, electrical engineers and contractors, have bought the business of Messrs. Griffith and Co., Reading, and have removed it to the Adelaide Works, Uxbridge-road, London, W. They continue to carry on the same business, viz., the making of telegraph instruments, blocks, single needles, &c., and also Barnett's accumulator, and are prepared to give estimates for any class of electric lighting.

TELEPHONE ORDERS.—The Consolidated Telephone Construction and Maintenance Company has just received a considerable order from the Portuguese Government for Gower-Bell loud-speaking telephones on the pattern of instruments supplied by the Consolidated Company to the Telephone Company of Austria. The Consolidated Company has also on hand a large order from the United Telephone Company for Gower-Bell telephones for the Postmaster-General.

BRAZILIAN SUBMARINE TELEGRAPH COMPANY.—The general meeting of this company is fixed for the 31st inst., when the directors will recommend the declaration of a final dividend of 3s. per share, payable on 1st November, making with interim dividends already paid, a total payment of 6 per cent. per annum for the year ended 30th June last. £24,000 has been transferred to the reserve fund from the profits of the half year.—The traffic receipts of this company for the week ended 17th inst. amounted to £3,561.

THE TELEPHONE ON BOARD SHIP.—The steamer "Normandie," of the Compagnie Transatlantique, recently took over to the Philadelphia Electrical Exhibition some French *savans*, including M. Berthon, Engineer-in-Chief of the Paris Telephone Company. Some trials were instituted with reference to the practicability of giving orders by telephone on board ship, a line being established between the bridge and the forecastle, and the results showed a marked superiority of the telephone over the speaking trumpet.

OVERHEAD WIRES IN AMERICA.—An Act passed by the last Legislature of the New York State requires that all telegraph, telephone, and electric light wires be removed from the streets before the 1st November, 1885, and that all new wires be laid underground. In the Supreme Court of New York State, Judge Van Brunt has upheld the injunction against the Baltimore and Ohio Telegraph Company, restraining them from maintaining telegraph poles and wires in front of the Clausen Brewery in Second Avenue, New York.

TELEGRAPH OPERATORS' ACCOMMODATION.—The authorities of the Post Office contemplate taking premises in the neighbourhood of Newgate-street, to form a subsidiary branch for the clerical staff of the Telegraph Department, so as to increase the accommodation in the head office for the operative staff. Upon this the *Civilian* reflects that the Government should have acquired a greater frontage in Newgate-street when they had the opportunity; for the building, even with its additional story, is inadequate, and its extension must now be a matter of very great expense.

INSTITUTION OF MECHANICAL ENGINEERS.—The secretary, Mr. Alfred Bache, announces that a general meeting of the institution will be held in the lecture theatre of University College, Nottingham, on Wednesday, 5th November next, at 4 p.m. Among the papers to be read will be one on "The

Digitized by Google

Application of Electro-Magnets to the Working of Railway Signals and Points," by Illius A. Timmis, of London. The locomotive works of the Midland Railway, Derby, will be thrown open to members after 10 a.m. on 6th November, by kind invitation of the locomotive superintendent, Samuel W. Johnson, Esq.

A VERY NEW DYNAMO.—We are informed that a new dynamo is in the market, somewhere in the north or south of England, which the proprietors, or their agent, or both, are recommending with a confidence that is somewhat staggering. It appears that all other machines give off an "impure current," which blackens the lamps; whereas with this new invention they "always remain clean." Further, that the wires of existing systems are "decomposed"—probably by "impure" current—whilst theirs remain intact. We believe that the discoverers of these phenomena were in the oil or leather trade, and that they have spent several weeks in the study of electricity.

LONG-DISTANCE TELEPHONY IN BELGIUM.—A recent number of the *Moniteur Belge*—the official journal of Belgium—publishes the royal decree authorising and regulating the long-distance telephoning on the Van Rysselberghe system. It appears that communication has already been established between Brussels and Antwerp, and that it will soon be effected with Ghent, Liége, Verviers, Mons, Charleroi, and Louvain. The tariff is 1fr. (10d.) for five minutes, and 1fr. 50c. (1s. 3d.) for 10 minutes' conversation, the maximum limit; and the rates are doubled during the night. Public offices are established at the Bourse and in the Parc, at Brussels, and at the Eastern Station, the National Bank, the Flemish Theatre, and the "Harmonie," at Antwerp.

AN ELECTRIC LAMP SCARE.—"Just before a ballet at Niblo's Theatre, in this city, one evening last week, a bouquet of crisp flowers hung above the stage, and, lighted by Edison lamps, took fire. A ballet girl, with much presence of mind, immediately seized it and took it off the stage. The flames were at once extinguished, and the curtain rose without the immense audience knowing anything of the accident." We read the above astounding announcement in the New York *Sanitary Engineer* of 9th October. The context leaves us rather in doubt as to what it was the ballet girl took off the stage; but if, as we suppose, the bouquet of crisp flowers is intended, we ask how the dickens they became ignited by the incandescent lamps? As they are said to be Edison lamps, perhaps that distinguished electrician will inquire into the matter and enlighten us.

GULCHER ELECTRIC LIGHT AND POWER COMPANY.—We have received the illustrated catalogue of the Gülcher Electric Light and Power Company, whose system is claimed to afford "a practical solution of some of the difficulties which have hitherto somewhat hindered the introduction of the electric light." Among the principal advantages put forward are the absence of danger to life, owing to the low E.M.F. of the Gülcher dynamo (65 volts); the simplicity of construction of the dynamo and lamps (which we lately described and illustrated); the purity and steadiness of the light due to constant feed; the ability to run arc and incandescent lamps in parallel circuit; and the absence of increased premium demanded by fire insurance companies, as the system fulfils the requirements and conditions laid down by the Council of the Society of Telegraph Engineers and Electricians. The publication of this catalogue at this moment is most opportune, and we commend it to the notice of our readers and the public.

ELECTRIC LIGHT AT THE NEW ORLEANS EXHIBITION.—The managers of the New Orleans Exposition have entered into the following contracts for lighting the buildings and grounds:—The Leavitt-Müller Electric Light Company, 800 arc lamps for the main buildings; the Brush Electric Light Company, 300 lamps for the Government and State exhibit building; the Jenny Arc Light Company, 100 lamps, with five star iron towers for the grounds and the live-stock department; Thompson and Houston, 100 arc lights for the machinery, extension, and saw-mill; Edison Incandescent Light Company, 4,800 lights for the Music Hall, Horticultural Hall, the Art Gallery, State head-quarters, and offices. Each principal entrance and wharf will be lighted by six Leavitt-Müller lamps. Fifteen hundred horse-power is required for the electric-light, which costs the exposition over 100,000dols., or about £20,000.

A MINIATURE INSTALLATION.—A very successful trial of an extremely small electric light plant took place in Manchester on the 16th inst. The steam engine was a pretty little model, with a single cylinder, 3in. diameter and 3in. stroke, driving one of Paterson and Cooper's No. 1 Phœnix dynamos, placed on a sliding foundation. The engine, which has been designed and manufactured by Messrs. Deakin and Parker, of Salford, ran smoothly and without vibration at 480 revolutions, transmitting the power to the dynamo through a Gandy belt. The dynamo, which is compound-wound and has an E.M.F. of 60 volts, maintains 16 incandescent lamps of 60 watts each, and on this occasion was also used to drive an arc lamp, using 16 amperes. This plant, which is interesting if only from its smallness, has been made to the order of a gentleman in Coventry, and will be used for lighting his observatory and billiard room. The required pressure of steam was found to be only 45lbs.

ELECTRIC LIGHT AT THE LAW COURTS.—The Courts opened yesterday, and the electric light was *non est*. Why? Is it the fault of the electrical staff? We should say not, as, from the fact of two large boilers having been lowered into the crypt at the beginning of the present week, it is hardly likely that they could be fixed, connected with the engines, the engines driving the dynamos, and the dynamos maintaining the lights, all by yesterday. We learn, on inquiry, that the electrical department is in as forward a state of preparation as circumstances permit—said circumstances being that one of the large boilers above referred to had to be passed over a space that will eventually be occupied by the dynamos. We hear that the engines are on the rail, so that the electric light will, at any rate, shine out before the end of the year. In the meantime our legal luminaries will have to be supplied with some other source of material illumination.

ELECTRIC LIGHTING AT THE BRIGHTON ART LOAN EXHIBITION.—The large picture gallery has been lighted by Maxim lamps with excellent results, the fact that these lamps will best bear an excess of current having been taken advantage of to produce a whiter light, which shows the paintings with great distinctness. The Corn Exchange, transformed *pro tem.* into an art gallery, has also been lighted by 250 20-candle-power Woodhouse and Rawson lamps, all the electrical work having been carried out by Mr. Magnus Volk. The Exhibition itself is well worth a visit, paintings and works of art, of the gross value of nearly half a million, never before exhibited in public, having been lent freely. It is a point which cannot be too strongly insisted upon that the chief inducement to the owners to lend their property, valuable intrinsically and beyond price from an artistic point of view, was the

Digitized by Google

fact that the electric light had been definitely adopted as an illuminant.

THE DEFENCE OF OUR COALING STATIONS.—Under the heading of "What Should be Done," the *Pall Mall Gazette* of last Saturday, in concluding its article on the defences of our coaling stations, puts the following as among the very first things to be undertaken. The writer says:—"The result of this hasty survey is far from satisfactory—if, indeed, it may not be described as alarming. I will therefore summarise what ought to be done: A telegraphic cable should be laid down connecting West Africa and the Cape direct with England. All our telegraphic communication with South Africa passes through Suez, and would be intercepted in case of war. From the Cape, cable communication should be established with India and Australia. A cable should also be laid to Bermuda. The telegraph stations where the cable touches ground should be placed within fortifications; and this of course applies equally to the English end of the cable. At present a single boat's crew landed at Port Darwin could sever Australia from communication with England, and keep all our commanders in the southern seas in total ignorance, until the mails arrived, whether we were at war or peace."

THE NEW SS. "ARAWA."—This splendid steamer, 420ft. in length, 46ft. in breadth, and 32ft. in depth moulded, built by Messrs. Wm. Denny and Brothers, Dumbarton, for the Shaw, Savill and Albion Company, proceeded down the Frith of Clyde last Friday, on her official trial, with a large company on board. A mean speed of 15·31 knots was obtained. The powerful main engines, designed by Mr. Brock, one of the partners of Messrs. Denny, are on the triple expansion principle, supplied with steam at a pressure of 160lb. per square inch, the highest pressure yet reached in ocean going steamers. The vessel is fitted throughout with the electric light, comprising in all 300 separate Swan lamps, the whole of the work of running the leads and fitting the lamps, switches, &c., having been executed by the builders' electrical staff, under Mr. Smillie. Two separate sets of Ferranti plant, of the slow-speed ship pattern, driven direct by Westinghouse engines, were supplied and fitted on board by the Hammond Electric Light Company. The specification for the lighting was prepared, and the official tests were carried out, by Mr. Jamieson, Principal of the Glasgow College of Science and Arts.

THE PRIME MERIDIAN CONFERENCE.—The Prime Meridian Conference at Washington has adopted a resolution providing that the universal day be the mean solar day, and to begin for the world at the moment of mean midnight of the initial meridian coinciding with the beginning of the civil day. It will be counted from zero up to twenty-four hours. There is a hope that it will soon be practicable to arrange that astronomical and nautical days shall begin everywhere at mean midnight. On the motion of M. Janssen, the French delegate, another resolution expressed the hope that technical studies to regulate and extend the decimal system to divisions of the circle and of time would be resumed, so as to permit the extension of this application to all cases where it presents real advantages. *Apropos* of a universal prime meridian and the revelations of "One Who Knows," in the *Pall Mall Gazette*, "Kosmos" advocates the meridian of Rome, once "mistress of the world," being adopted, and adds that those who desire to see chosen the meridian of the nation possessing the largest number of vessels expose themselves to hear said on the morrow of a disaster, "The hour must be changed; the prime meridian has lost its *raison d'être*."

OVERHEAD WIRES.—The General Purposes Committee of the Wandsworth Board of Works, having considered the subject of the proceedings against the United Telephone Company, letters from vestries and district boards as to contributing towards the cost of appealing against the decision in the Court of Appeal, and letter from the vestry clerk of St. Marylebone, stating that, after the decision in the action brought by the Board against the United Telephone Company, it is not proposed to proceed further with the action commenced by the Vestry of St. Marylebone against a telephone company having wires in that parish, recommended that the following vestries and district boards—viz., St. Marylebone, St. James's, Westminster, St. Mary, Islington, St. James and St. John, Clerkenwell, St. Martin-in-the-Fields, and St. Giles-in-the-Fields and St. George, Bloomsbury—be each invited to send five delegates to attend a meeting to be held at the Charing-cross Hotel, with the view of appointing a deputation to present a memorial to the Government, asking them to fulfil their promise to introduce a Bill to confer upon the local authorities control over the erection and maintenance of overhead wires.

ELECTRIC LIGHT AT WORKS.—Messrs. George Richards and Co., who are introducing American types of wood-working machinery into this country, have lately erected some fine new shops, called the "Atlantic Works," at Broadheath, near Manchester. As the roof is arranged at a great height, and the shafting is all carried beneath the floor, they have been enabled to carry out a most effective system of electric lighting, giving a result that would hardly be possible in works of ordinary construction, where the line shafting and belts are all overhead. There are three Gramme dynamos, excited by a smaller machine, for working the 21 arc lights, and a small Phœnix machine for working 30 Gramme incandescent lamps, used in the store rooms, offices, and dining room. In the fitting shops there are 14 Lever arc lights of 2,000 candle-power each, arranged so as to avoid shadows. In the foundry are placed six arc lights, also on the Lever system, and one in the yard. A Manchester contemporary says that the effect of the light is to give a result equal to daylight on a bright day, and a superior light to daylight on a dull or foggy day. The different circuits of the lamps in the workshop, offices, and foundry are driven by three separate engines of small power, so as to permit of their being worked only as required. The plant has been erected by Mr. Charles Lever, of Bowdon; and the results are highly satisfactory, both in working and as compared with gas.

TOLEDO ELECTRIC COMPANY, U.S.A.—The Citizens' Electric Light Company, capital $50,000, which had been doing business in this city for about two years with moderate success, recently became somewhat embarrassed by some claims immediately pressing, so that a change was necessary. Accordingly, within a few days a reorganisation has been effected. The new company, the Toledo Electric Company, with a capital of $150,000, will take the assets of the Citizens and assume the liabilities. President, L. S. Baumgartner; Secretary, F. B. Dodge. The two electric light companies of this place, the Citizens and the Brush, have been rapidly extending their business; but their officers claim they have been doing it at too low rates. Something of a contest has been going on between the gas company and the two electric light companies of this place, especially with reference to lighting the new Cherry-street bridge, and occupying the territory of the sixth ward, East Toledo. When bids were first called for on the bridge, the gas company and the Citizens' Electric Light Com-

Digitized by Google

pany put in bids at the same figure, 800 dols. per year. The committee considered this too high and called for more bids, when the gas company failed to respond. The two electric light companies proposed to furnish lights at 60 cents and 70 cents each per night respectively. One of these was recommended by the committee; but the council failed to confirm the contract.—*Sanitary Engineer.*

GAS ON ELECTRICITY.—"The disinterested electricians who are not connected with systems of electrical supply at high potentials have been 'making capital' out of the unfortunate fatality at the Health Exhibition. In this they have been well supported by *The Times*, which has published several letters too slightly distinguished from advertisements for the difference to be perceptible to any one out of Printing House-square. The writers of these effusions have all the same tale to tell:—'It would be unfortunate if popular prejudice should be excited against all electric lighting systems; because there are some which are absolutely harmless,' &c. These people will rejoice because the last fatality in connection with lighting is a gas explosion." So writes the *Journal of Gas Lighting*; and it is almost exactly what in our last week's leader we predicted. We would point out, however, that although a statement of fact may serve as a recommendation—or advertisement if you will—it is no reason why the fact should be withheld. It is a fact that there are electric lighting currents which are harmless, and there is no harm in saying so, if only for the instruction of Gas Lighting journalists. It would be more to the point if the *Journal of Gas Lighting* could say as much for gas explosions. We do not notice that any interested electricians have "rejoiced" at the "latest fatality" for which gas is responsible; whereas there is an evident tone of satisfaction in our contemporary's remarks on the misfortune of its rival.

ELECTRICAL TRANSMISSION AT CREIL.—Last week, in a note on "The Electrical Working of Underground Railways," we quoted from the *Bulletin* of the Compagnie Internationale des Téléphones, and, with reference to the preparations now being made at Creil for the generation of electricity to be transmitted to Paris, asked if our contemporary did not mean that portable engines rather than locomotives were put down for driving the generators. An administrator, or, as we should say, director, of the International Telephone Company has most obligingly sent us the following account of the motive power to be used:—"The two engines put down at Creil for supplying the motive power are two of the Northern Company's ordinary locomotives; they drive an intermediate shaft, which will constitute the starting point of the power in the experiments, and the point where it will be measured. During the experiments, care will be taken that this shaft revolve at a speed about equal to that of the turbines; it will make from 100 to 120 revolutions a minute, while, according to present intentions, the speed of the dynamo-electric machines will not exceed 400 revolutions." This week the *p'tit bleu*—as the company's organ is familiarly styled on account of its complexion, just as the *Globe* was once spoken of by a morning paper as "our blushing contemporary"—says that, in all probability, there will be three receiving machines at the Gare du Nord, Paris, where 20 horse-power is required for the electric lighting; and it is natural to suppose that the current will be taken for the Creil generators. From 30 to 40 horse-power might be absorbed by the hydraulic capstans; and a further 20 horse-power, by the machine-tools at La Chapelle.

THE NEW ATLANTIC CABLE.—The Bennett-Mackay cable was landed at Coney Island at 12.15 on Saturday afternoon; and at 1 o'clock the end was placed in the cable station, being carried through the trench on the shoulders of twenty men. As the end of the cable was dropped on the beach, loud hurrahs went up from a crowd of 200 persons congregated at the entrance of the trench through which the cable passes. The tugs, the locomotives of the Manhattan Beach line, and the "Faraday" blew whistles for several minutes. The general superintendent, Mr. Ward, of the Commercial Cable Co., and the electrician, Mr. Brittle, of Siemens Bros., were heartily congratulated. The landing, according to a *Daily News* telegram, was an entire success, although the wind was north-west, blowing a quarter gale. Telegraphic communication was completed between the "Faraday" and the shore on Saturday evening for the first time. There is now a direct connection between New York and Europe, for the Commercial Cable Company lands almost at the gateway of the city, and carries its cable underground to Wall-street, within two doors of the Stock Exchange. It is believed that this will be an advantage in many ways, the chief of which will be the certainty of instantaneous transmission, without the risk of the delays incidental to land lines from atmospheric disturbances. It will furthermore give the public the benefit of competition, by offering for its use cables outside the Gould combination. It is announced that the new company have applied Muirhead's duplex system to their cables, and have independent stations at all the prominent points in Great Britain, Ireland, and France, and give all these countries the benefit of direct cable communication with New York.—*The Globe.*

TELEGRAPHIC COMMUNICATION.—With reference to communication for outlying portions of the kingdom, the following letter has been addressed, on behalf of Lloyd's Committee, to the Secretary, General Post Office:—"Lloyd's, E.C., Oct. 14. Sir: I am instructed by the Committee of Lloyd's to beg that you will be good enough to inform the Postmaster-General that many more vessels than was formerly the case now make the passage from America round the north coast of Scotland; so much so that, in consequence of the increased use made of this route, Lloyd's have lately established a signal station on the Pentland Firth. It appears that, in case of distress or heavy weather, vessels compelled to put in for refuge on this voyage, when near the coast of the United Kingdom, would probably make for Loch Eribol; and it has been pointed out that at present there is no telegraphic communication with Loch Eribol, so that, when ships arrive there with reports of derelicts or vessels in distress, communication cannot be speedily made with tugowners, shipowners, or underwriters interested; and thus assistance cannot be rapidly sent for the saving of life and property. The Committee of Lloyd's have addressed the Board of Trade upon this subject, and I am to beg that you will be good enough also to bring the matter to the serious attention of Mr. Fawcett. At the same time the committee would wish to suggest that the maintenance of the telegraphic communication of the country as Government monopoly would appear to have prevented the extension of telegraphic communication as widely as might have been expected had the construction of telegraphs been left to private enterprise stimulated by public competition. I am to beg that you will be good enough to move Mr. Fawcett, to allow it to be considered whether some measures might not be taken, by which licenses should be granted to private companies to institute telegraphic communication at their own risk, in districts to which the Government system has not been extended. I am further to remark that it would appear in many countries, which are believed to be financially less prosperous than Great Britain, the benefits of telegraphic

Digitized by Google

communication are more widely extended than in this country, as it seems that in Switzerland and Norway there are few villages which are not connected by wire with the telegraphic system of the State."

ELECTRIC LIGHTING IN CARDIFF.—At a recent meeting of the Cardiff Town Council, a report of the Highway Committee was brought up, recommending that the tender of the Great Western Electric Light and Power Company for lighting St. Mary-street with six electric lamps of 2,000 candle-power each, at a cost of £27 per lamp per annum, be accepted. Alderman Duncan moved the adoption of the report; and the motion was duly seconded. The Mayor, however, considered the recommendation condemned by the engineer's report, which stated that the proposed electric lighting would cost £162 a year, against £31 7s., the present cost of gas lighting. Although they would get 12,000 instead of 167 candle-power, this light would not be so evenly distributed. As the gas company had reduced their light by 1s. a lamp, and the price of gas to ordinary consumers by about 6 per cent., so that it was now the cheapest in Wales, and of a quality and purity second to none, he thought it would be better to defer the electric lighting experiment. Alderman Duncan, in reply, thought the present was a very opportune occasion for the council to make a small experiment in St. Mary-street, so that the electric light could be compared with that from Bray's lamps in the High-street. The Highway Committee considered that every corporation, especially that of a rising town like Cardiff, ought to make fair experiments of this kind. He did not think there was any doubt but that the electric light had a great future before it; but unless they made experiments, unless they gave some opportunity for electric light companies to come into the town, so as to see what they could do both in the way of illuminating power and comparative cost, how was the corporation to arrive at a conclusion? As a public body, the council should consider how they could light the town best and at the lowest price; and he thought it was no unreasonable thing for the committee to ask the corporation to expend a few pounds for one year upon an experiment of this kind. The Mayor's amendment, altered as follows:—"That the recommendation of the Highway Committee be deferred until the Corporation have conferred with the Gas Company upon the terms on which they will light St. Mary-street with a light equal to that given in High-street," was then put and carried; and the committee's minutes, as altered, were adopted.

LONG-DISTANCE ELECTRIC LIGHTING.—At the Turin Exhibition, the electrical section of which is international, M. Tresca, curator of the Paris Arts et Métiers collections, has communicated to the *Académie des Sciences* the following facts with regard to the 80-kilometre (50-mile) circuit (including return) established between Turin and Lanzo for electric lighting:—A chrome bronze wire, 3·7 mm. (a full ⅛in.) in diameter, uncovered, conducts the alternate current produced by a Siemens dynamo-electric machine, of the 30 horse-power type, in such a manner that it may be utilised simultaneously for various methods of electric lighting—at the Exhibition itself, at the Turin station, at the Lanzo terminal station, or at the intermediate stations, by its transformation at each point, of the two factors which constitute its energy, by means of new secondary generators exhibited by Gaulard and Gibbs. On the 25th of September, the working was simultaneously found to be regular:—1. At the Exhibition, but a short distance off, of nine Bernstein lamps, one Sun lamp, one Siemens lamp, nine Swan lamps, and five other Bernstein lamps, which necessarily required very different potentials; and 2. At the Turin-Lanzo station, 10 kilometres (6 miles) distant, thirty-four 16-candle Edison lamps, forty-eight 8-candle ditto, and one Siemens arc light. On the 29th September the trials were still more conclusive, the system having been completed to the Lanzo station, 40 kilometres (25 miles) distant, when twenty-four Swan lamps of 100 volts were maintained with absolute regularity. The multiple transformations required by the variety of these various modes of lighting are effected with safety; and, although precise figures cannot yet be given, it is fully proved that the secondary generators must, at any rate within certain limits, be considered as transformers, with a relatively high duty, of the energy of alternate currents. The lighting and extinction were effected, without any disturbance, by means of simple commutators. M. Tresca's principal object was to put on record the complete success of a distribution of various methods of electric lighting over a 40-kilometre (25-mile) circuit (not including return); but these experiments are quite independent of the transport by electric current of mechanical energy, to which the distinguished *savan* has of late directed his attention.

ELECTRIC LIGHT ON MEN-OF-WAR.—It is not often that the *Journal of Gaslighting* has such a good word to say of the electric light as what follows:—"Although, during the last two or three years, electric lighting has made great progress in the direction for which it is pre-eminently suited—the lighting of steamships—very little has transpired as to the cost of this method of illumination when compared with the ordinary method. There are sufficient inducements for the use of the incandescent light on board ship to cast into the background the mere item of expense, even if it should be greatly in excess of the cost of oil. Everyone who has seen the work of the lamp room of a large ship must have been struck with wonderment that more vessels are not set on fire through the necessary provision of means for lighting. A dirty cell, saturated with oil, and littered with oily rags, cotton wicks, and matches, is a real danger on board ship in rough weather and warm climates. Whatever may be the danger of electric lighting currents, it cannot be so great as that of the lamp room. The expense of vegetable oil lamps is also very considerable, as railway companies know full well. Still, it would be satisfactory to learn how the account stands as between oil and electricity; and this idea has struck the Lords of the Admiralty, for in the case of one of the last ironclads fitted with arc and incandescent lamps—the "Colossus," now at Portsmouth—it has been decided to carry out competitive trials of the two systems, for the special purpose of ascertaining the comparative cost. It is to be hoped that the result will be published, and that it will show not only the capital and working charges, but also the cost of breakages; which, in the case of incandescent lamps in a fighting ship, must be serious." The "Colossus" is the only vessel of the first class as yet fitted throughout with the electric light, having powerful search lamps fore and aft, besides 400 incandescent lamps of 10 and 20 c.-p. for lighting the whole of the interior, including stokeholes and coal bunkers. The current is generated by three Victoria dynamos, making only 400 revolutions per minute, placed near the engine room and driven by three-cylinder Brotherhood direct-acting engines. The E.M.F. is only 80 volts, so that no dangerous shock would ensure from inadvertently touching the conductors. The lighting of each portion of the vessel is made independent of the others, and can be controlled from the dynamo room. The whole of the work has been carried out by the Anglo-American Brush Electric Light Company.

ELECTRICAL TRANSMISSION OF POWER.*

The work produced by a mechanical motor can be converted into electricity by means of dynamo-electric machines, and conversely by the aid of these same machines, which should in this case be called electro-dynamic machines, we can again transform into mechanical work the electric current derived from any source we please. As an example of this, we may take the Gramme machine, and represented diagrammatically in Fig. 1. The current in this machine is universally admitted to be produced by the action of the coils A, passing over the poles N_2 S_2 of the ring. As these coils, with the current circulating through them, approach one or the other pole of the ring, they are attracted by one pole and repelled by the other in such a way that the ring tends to carry the coils round in a direction opposed to that of the motor which turns it, thus absorbing the energy of the motor.

The current produced in machine I. is led into machine II., and flows through the coils of the electro-magnets and the soft iron ring. The result is that in this second machine the coils are similarly repelled and attracted by the now magnetised ring, and the second machine moves round in the opposite direction to the first.

Let the electromotive force of the current produced by machine I. be E_1. The second machine, being precisely similar to the first, itself produces a current as it revolves; let the electromotive force of this current be E_2.

The directions of the currents produced by the two machines are directly opposite, as the machines revolve in contrary

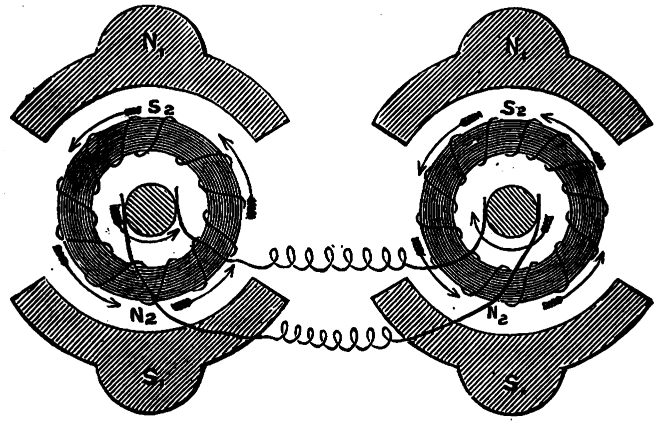

FIG. 1.

directions; the currents accordingly partially neutralise each other, and we obtain in the whole system a current whose electromotive force is equal to $E_1 - E_2$. The work W_1 (in kilogrammetres) expended in machine I. to produce the electric current is, by Joule's law, $W_1 = \frac{E_1 C}{g}$, where g = the intensity of gravity = 9·81, E_1 = E.M.F. of machine I. in volts, C = the strength of the current in the whole system.

Thus $C = \frac{E_1 - E_2}{R}$ = the difference of the electromotive forces of the two machines divided by the sum of the resistances of the coils of both machines and the external conductors.

Now, substituting this value of C in the former equation, we obtain (1)

$$W_1 = \frac{E_1 C}{g} = \frac{E_1 (E_1 - E_2)}{g R}.$$

The work W_2 which is obtained from machine II., and may be described as available work, we can calculate from the formula (2)

$$W_2 = \frac{E_2 C}{g} = \frac{E_2 (E_1 - E_2)}{g R}.$$

The work supplied to the generator is always greater than the available work W_2, as a loss of power occurs owing to the heating of the machine coils and conductors.*

The work expended in heat is by Joule's law (3)

$$W = \frac{R J^2}{g} = \frac{(E_1 - E_2)^2}{g R}.$$

The efficiency K of the power transmitted electrically can now be calculated from the formula,

$$K = \frac{W_2}{W_1} = \frac{E_2 (E_1 - E_2)}{g R} \div \frac{E_1 (E_1 - E_2)}{g R} = \frac{E_2}{E_1}.$$

The efficiency K is thus equal to the ratio of the electromotive forces of the two machines, and thus, with similar machines, similar arrangement of commutators, and perfect insulation of the current, $\frac{E_2}{E_1} = \frac{V_2}{V_1}$, where V_1 V_2 represent the velocities of the two machines respectively. Thus the efficiency K is proportional to the speeds of the two machines, and can in many cases be thus determined.

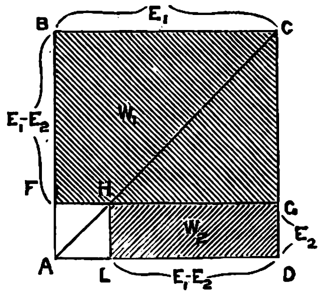

FIG. 2.

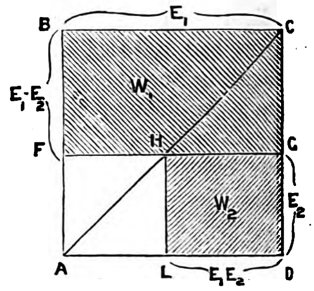

FIG. 3.

The former equation,

$$\frac{W_2}{W_1} = \frac{E_2(E_1 - E_2)}{g R} \div \frac{E_1(E_1 - E_2)}{g R},$$

can be more easily demonstrated by the following graphic method suggested by Professor Silvanus Thompson:

In Fig. 2 let the constant electromotive force E_1 be represented by the line A B, and let the square A B C D be described upon it. From A B cut off A F, equal to E_2, the value of the variable electromotive force, and draw, as in the figure, the lines F G, A C, and H L.

We now have $LD = BF = E_1 - E_2$.

And the area B C G F represents the amount of the work $E_1 (E_1 - E_2)$ absorbed by machine I., and the area L H G D the amount of available work $E_2 (E_1 - E_2)$ obtained from machine II., the constant $\frac{1}{Rg}$, which does not affect the ratios of these amounts, not being taken into consideration.

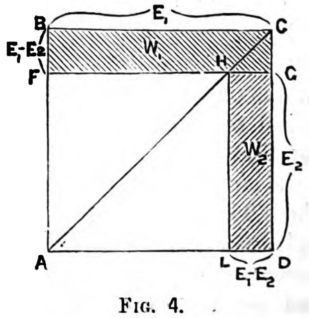

FIG. 4.

It is now evident, on comparing these areas in Fig. 2, that the efficiency, corresponding to the former equation $K = \frac{E_2}{E_1}$, is very small, as E_2 is small compared with E_1.

* Abstracted from an article by Oscar von Müller, in the official report of the International Electrical Exhibition at Munich, 1882.

* A further loss of power takes place owing to the friction of the machine and the existence in the iron of the armature (whether annular or cylindrical) of prejudicial currents, which expend themselves in heating it. Very interesting experiments on this loss of power, which takes place principally in the case of weak currents, have been published by Dr. Fröhlich in the *Electrotechnische Zeitschrift* for 1881, pp. 134 and 170. The consideration of these, however, for the sake of simplicity and brevity, must be omitted from all the following calculations.

Digitized by Google

If $E_2 = \frac{1}{2} E_1$ (Fig. 3), the area of F B C G becomes twice that of L H G D; thus the efficiency becomes 50 per cent., and the work obtained from machine II. has now its greatest absolute value.

As the value of E_2 approaches that of E_1 (Fig. 4), though the efficiency is certainly greater, the area L H G D is less than the corresponding area in Fig. 3; thus the absolute value of the available work is less than in the second case.

The amount of work expended in the actual transmission of the power, as also the efficiency, is independent of the diameter of the conductors, provided that where thinner wires are used the electromotive forces of the dynamo machines be increased proportionately to the increase of resistance.

Suppose, for example, the dimensions and speeds of the machines for the transmission of a given force to a given distance, and the proportion of resistance of the coils of the machine to that of the conductor (assuming the cross section of the wire to be of a given dimension) be so arranged that the desired efficiency is produced. Now, instead of the diameter originally used as the basis of calculation, suppose a smaller be selected, so that the resistance is n times as great as before, we have only to increase the electromotive force till it is $\sqrt{n}$ times as much as before in order to transmit the same amount of work with the same efficiency as before.

For by the former equations (1), (2), (3), (4), $W_1 = W_2 + W$, where W is the work lost in heat,

or
$$E_1 \frac{(E - E_2)}{g R} = E_2 \frac{(E_1 - E_2)}{g R} + \frac{(E_1 - E_2)^2}{g R}.$$

If we now employ thinner and longer wire for the machine coils and the conductors, so that the united resistances amount to n R, taking care that in winding the machine with this longer and thinner wire we thereby raise the electromotive forces to $\sqrt{n}\, E_1$ and $\sqrt{n}\, E_2$ respectively, we obtain the equation

$$\frac{\sqrt{n} E_1 (\sqrt{n} E_1 - \sqrt{n} E_2)}{g n R} = \frac{\sqrt{n} E_2 (\sqrt{n} E_1 - \sqrt{n} E_2)}{g n R} + \frac{(\sqrt{n} E_1 - \sqrt{n} E_2)^2}{g n R}$$

which is identical with equation 4.

Thus the increase of resistance affects neither the work absorbed by machine I. nor the available work obtained from machine II., nor the loss of power through heating of the wires, the only result being an increase of the electromotive force, the amount of electromotive force which can be employed with the hitherto invented means of insulation fixing the limit to the increase of resistance.

Deprez employed in the Munich experiments electromotive forces up to 2,200 volts, this being the highest potential hitherto used for electrical transmission of power.

In the Munich International Electrical Exhibition could be seen several examples of electrical transmission of power.

Schönemann worked an autographic press, Schuckert a Zettler's mechanical workshop, and the Société de la Lumiere Electrique Edison a dairy exhibit by means of electrical transmission of power. In these three cases both dynamo-electric and electro-dynamic machines were erected in the exhibition rooms themselves.

A perfectly successful installation over a great distance was carried out by Schukert between the manufactory at Hirschan and the Exhibition. The two electric machines were connected by a copper wire of 10 kilometres long and 4 millimetres in diameter, the machine at Hirschan absorbing about 9 horse-power, while that in the Exhibition supplied about 3 used to work two threshing machines running empty.

The greatest attention could reasonably be claimed for the experiments of Marcel Deprez, who, with ordinary telegraph wires 114 kilometres long, succeeded in the electrical transmission of power to the greatest distance hitherto obtained.

Though the theories of electrical transmission of power, thoroughly developed by Deprez, Frölich, Siemens, Thompson, and several others had been long known to all engaged in the science, Deprez was certainly the first who, acceding to the request of the committee, established, by means of an experiment on a large scale and one intelligible to the general public, the practicability of his calculations on the transmission of power to great distances, though these calculations were frequently considered to be nothing more than interesting scientific speculations. Deprez's experiments have also shown that, if only moderate care be exercised, the much dreaded high potential currents, which must be employed for transmission of power to great distances by means of thin wire, are not absolutely dangerous even in exhibitions, with all the throngs of people and the various manipulations of machines and wire necessary to the carrying out of the experiments.

The machines employed by Deprez in the Murbach at a distance of some 35 miles from Munich absorbed about 1·5 horse-power, while the available work obtained in the Exhibition amounted to about ·4 of a horse-power employed in setting in motion by means of a centrifugal pump a waterfall eight feet in height.

ELECTRICITY AS A NATURAL FORCE.

BY E. L. VOICE.

The writer will endeavour to treat this subject in a manner that all may understand, without the necessity of their having previous electrical knowledge; at the same time, perhaps, some of the remarks may be interesting to scientists.

Faraday's discovery may be classed under two heads: (1) The movement of an electrical conductor round about the pole of a magnet, so as to intersect or cut the external magnetism, thus producing a current. (2) Causing a wire to be under the influence of periodical magnetic change, this change being brought about either by mechanical or electrical means. The latter proposition will only be dealt with in the present article.

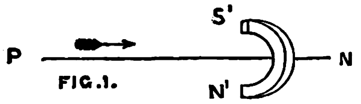

FIG. 1.

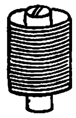

FIG. 2

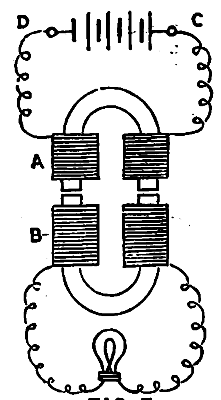

FIG. 3

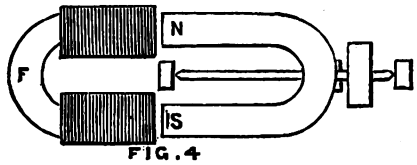

FIG. 4

Let P R (Fig. 1) represent a wire conveying a current in the direction of the arrow, no matter from what source. The wire will be immediately surrounded by magnetism, which may be imagined to consist of a series of magnetic rings or whirls. To make it plain the half of one of these imaginary rings is shown, and it will be seen to resemble a horseshoe permanent magnet, with its two poles N S. In fact, if a piece of soft iron be bent and placed in a similar position, it is rendered magnetic by the action of the current.

From this it may be inferred that an electric current in a wire produces an invisible something round about it. That something is called magnetism. The thought occurred to Faraday that if electricity produced magnetism, then magnetism would produce electricity. He found that it was so, hence his marvellous discovery.

This may be proved by having a powerful permanent magnet at N S. (Fig. 1). If, at a point some distance from the wire, the magnet be moved towards it, say, to the position N S, a current will be generated whose direction will be the reverse of that indicated by the arrow. An *extra* current in this reverse direction also occurs when an initial current from a battery is caused to suddenly exist periodically in the wire. This inverse current or counter E.M.F. plays an important part in the systems to be presently explained.

It has already been said that if an iron rod be bent round

Digitized by Google

the wire it is rendered magnetic. The same thing occurs if the rod is straight and laid across the wire. The small area which it covers, however, makes its power very weak; but if the whole length of wire be wound on the rod, then a great power may be developed, and we have an electromagnet (Fig. 2). When a current is passed in the coils of this magnet, the latter will attract masses of iron towards its poles, and cause them also to become magnetic by induction; moreover, if one of these masses be coiled with wire as at B (Fig. 3), it will induce a current in its coil which may be felt by the hands—it may light a Swan lamp. There can be no induced current in the coil B, however, unless the inducing magnet A undergoes a state of magnetic change. This change may be produced by either causing the inducing magnet to periodically lose or reverse its magnetism by breaking the circuit at C, or by reversing the battery connections at C and D. Here, then, a current is induced in the coil B by simply changing the direction of battery current in the inducing magnet A. This is a remark able fact; and, although it is as old as electro-magnetism, time will show it to be one of the chief causes that are destined to revolutionise electricity for industrial purposes.

It has now been shown that a current is generated by mechanically moving a magnet in the neighbourhood of a wire, as at Fig. 1, and that the same result may be obtained electrically by reversing the battery connections, as at Fig. 3.

In 1832 Hippolyte Pixii, of Paris, was the first to apply Faraday's discovery, but it was the mechanical mode of production that he took up. Fig. 4 is a rough sketch of the Pixii machine. The electro-magnet or armature F is fixed,

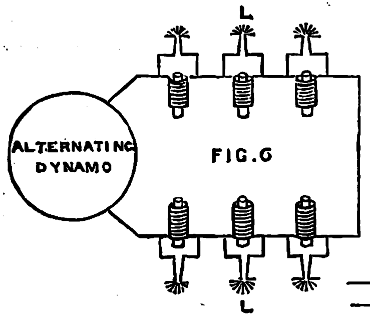

FIG. 6

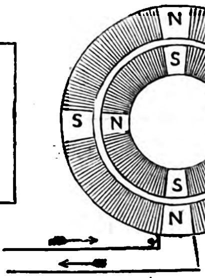

FIG. 5

and is made to undergo a state of magnetic change, and consequently currents are set up in its coils. Now, this change is brought about in this case by pivoting a movable permanent magnet and rotating it by suitable motive power. The induced current, however, sets up a magnetic repelling force to the rotating magnet, and this force, in all modern dynamos, has to be overcome by a steam engine. But what says the sceptic to this?

S. You say that in order to generate a current in Pixii's machine the coils must be subject to magnetic change?—*A.* Quite so.

S. And this change is brought about by the rotation of a permanent magnet before the coils; and moreover you say that this rotation entails a mechanical resistance, requiring in large machines enormous power to overcome it?—*A.* That is so.

S. You appear to have shown that the coil B in Fig. 3 will also develop a current when subject to magnetic change, this result being obtained by simply reversing the battery connections of the inducing magnet A, and requiring practically no mechanical power?—*A.* Quite right.

S. Then it seems in Fig. 3 that the battery takes the place of the steam engine.—*A.* To a certain extent it does; but, assuming the electrical capacity or output of the two machines to be equal, it takes far less power to magnetise the inducing magnet A to saturation than it does to rotate the magnet in the Pixii machine. The whole of the field magnets of modern alternating dynamos are magnetically saturated by the expenditure of two or three horse-power.

S. If all this is true, then why not take the permanent magnet away from the Pixii machine, and put the inducing magnet and battery (Fig. 3) in its place?—*A.* Happy thought!

S. But what about the inverse current? You said just now that any change in direction of inducing current produced an extra current, and in Fig. 3 it seems necessary to be continually changing the initial current. Is it not detrimental?—*A.* At first sight it appears so, but, fortunately, the greater part of this inverse current takes place in the induced coils that form the consumption circuit, in which the lamps may be placed, and is therefore transformed into heat and light. The remainder which exists in the inducing circuit is in no way a mechanical loss to the generator, supposing the apparatus is supplied by a dynamo. There seems be an erroneous impression regarding this inverse current, as if it formed a resistance to the initial current. In reality the two currents are totally distinct from each other, and as they are in inverse directions, the reactionary power which they exert on the armature of a primary generator is as the difference between the two, and is precisely similar to the action of the two inverse currents on the needle of a differential galvanometer.

S. The above machines seem to be well adapted for making an analogy, but for practical application there seems room for improvement.—*A.* Yes. Fig. 5 is a diagram of a recent invention involving precisely similar phenomena. It consists of two circular magnets, placed one within the other. One of the machines may be fixed in each house, and the lamps joined to the inner ring, the outer magnet ring being connected to the main wires in the streets. By an arrangement of movable commutators actuated mechanically the outer magnet is made to rapidly alter its magnetic state, and, in accordance with the above principles, induced currents are set up in the inner magnet for the lamp circuit. The requirements of the Board of Trade are easily followed in this case, inasmuch as the outer magnet may be wound for high tension currents and the inner one for quantity. In this arrangement both the inducing and induced currents are continuous—in fact, it is a continuous current system.

A somewhat simpler arrangement for an alternating system is shown at Fig. 6. A number of electro-magnets are placed in a circuit that is supplied by Gramme, Siemens, or Gordon alternating dynamos; the currents consisting of electrical impulses in alternately opposite directions. The lamp circuit is connected up on each side of each respective magnet so as to enclose it. The electrical resistance of these magnets is very much less than that of the lamp circuits, and therefore the bulk of the initial current passes through them. There is, however, a counter E.M.F. produced in each of the magnets, and this would also tend to expend itself throughout the main circuit. It is easy to see that in a large installation—one with 2,000 magnets, for instance—the resistance of the main circuit would be practically infinite with regard to one of the lamp circuits. It follows, therefore, that the counter E.M.F. finds the path of least resistance by passing in the lamp circuit of each respective magnet, and develops light.

The advantage of these inventions may be summed up in a few words. They demonstrate, both theoretically and practically, that electricity is no longer a mere medium or deputy for the transmission of power, but one of Nature's original forces applicable in endless ways for the benefit of mankind.

[This matter has already been published in a fragmentary form in the columns of a contemporary journal, but as it has been carefully ignored by those who pose as electrical historians, the writer will endeavour to more fully show how the above continuous current system may be practically applied to electric lighting, motive power, the propulsion of ships, railway locomotion, tramcars and tricycles, with a suggestion—a suggestion without much faith—for propelling and steering balloons.—E. L. V.]

Electric Lighting of Hospital Ships.—It will be seen from our advertisement columns that the Metropolitan Asylums Board invite tenders, from electrical engineers and electric light companies, for lighting by electricity the three hospital ships now moored in the Thames at Long Reach, near Dartford, and also the administrative buildings on shore. Mr. J. Hopkinson, F.R.S., M.I.C.E., has prepared the specification, which, with forms of tender, may be obtained at his offices, 4, Westminster-chambers, S.W.

CORRESPONDENCE.

THE ELECTRIC LIGHTING ACT.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: The point raised by your correspondent, "Ohm," is one of considerable interest and importance, and I welcome his letter because it is by a discussion of such points that, pending our being able to obtain a repeal or an amendment of the obnoxious Electric Lighting Act, which has proved, for all practical purposes, a dead letter, we may be able to see a way of avoiding some at least of the many barriers to the carrying out of house-to-house lighting, and with this view I venture to submit one or two considerations in regard to the question asked by "Ohm."

The Act of 1882 lays down the conditions upon which compulsory powers to break up streets for purposes of supplying electricity may be granted. It did not extinguish any existing rights, and as many local authorities hold special Acts of Parliament entitling them to break up streets for various purposes, it is, I think, an open question whether they have not this right for purposes of electric lighting. Whether or not this right is possessed by any particular local authority is of course best determined by a legal adviser acquainted with all the local circumstances. The Public Health Act alone does not authorise any one to break up the streets for these purposes. It states that "any urban authority may contract with any person for the supply of gas or other means of lighting the streets, markets, and public buildings in their district," and the person who so contracts for the supply of the means of electric lighting would undoubtedly have to provide himself with a license or provisional order, unless (as I believe is the case in many instances) the local authorities are able to maintain that they have the power to break up the streets for this purpose independent of the Electric Lighting Act, and are prepared to give the contractors the benefit of this right.—Yours, &c., E. G.

Oct. 23, 1884.

A CURIOUS CASE OF INDUCTION.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: I am not sure that I understand "F. L. C.'s" letter—that part of it about "summoning a man" being rather obscure; but if he means that voices were reproduced by the microphonic portion of his apparatus, this is by no means a new although still a curious phenomenon. It has been contended, from almost the very first discovery of the microphone, that it not only transmitted sounds but accurately reproduced them; and several receiving telephones have been constructed on this principle, their non-adoption in practice being due to their comparative feebleness for want of that resonant element which a diaphragm supplies in the magneto telephone.—Yours, &c., J. L.

London, 20th Oct., 1884.

HONOUR TO WHOM HONOUR IS DUE!

TO THE EDITOR OF THE ELECTRICIAN.

SIR: The following extracts are from a letter addressed to the editor of the Melbourne *Argus*, and printed in the issue of that paper for July 23, 1884:—

"You were good enough to insert, in November last, a letter from me on Dr. Davy's early connection with the electric telegraph; and other letters on the same subject followed in your columns. Mr. Ellery, the Astronomer Royal, read on November 15, before the Royal Society (of which he is president), an eulogistic paper, after which the Society conferred on Dr. Davy the distinction of honorary life membership . . . . .

"Dr. Davy's friends are not content that the matter should rest here; and Mr. C. Young, the member for his district, has kindly and most readily promised to ask the Legislative Assembly at once to appoint a committee to inquire into the validity of the Doctor's claims, with a view to making suitable representations to the Imperial Government.

"The House will, no doubt, for the honour of the colony, and in the interests of an old and respected colonist, gladly grant such an inquiry. Dr. Davy has, we may well suppose, at the age of 80, arrived near the end of life's journey; and if anything is to be done for his personal benefit it should be done at once."

Dr. Davy's claims to our recognition have been so recently set forth by me, in Vol. XI. of your journal, and in Chapters XIII., XIV., and XV. of my "History of Electric Telegraphy," that I need not recapitulate them here. In the early days of the electric telegraph, 1836-39, Dr. Davy was, to use Mr. Latimer Clark's expressive words, "neck and neck with Cooke and Wheatstone;" and had not circumstances compelled his withdrawal from the race, when almost in sight of the goal, he would, without doubt, have shared with them the prize. As it is, Cooke and Wheatstone have had riches and honours showered upon them, and have died leaving behind them imperishable names, while Edward Davy lives —but how?, unknown and unhonoured, outside a small circle of colonial friends, dependent for his subsistence on the drudgery of an up-country doctor's practice in a far-off colony. So for forty-five years he has been content to live, and so would he have been content to die; but his early inventions and discoveries in electric telegraphy having lately come to light, his fellow colonists have determined, even though it be the eleventh hour, to do him all the honour they can, and to make easier the last years, it may be days, of the venerable pioneer.

Some recognition on the part of the telegraph engineers of England would now be useful, as it would strengthen the hands of Dr. Davy's colonial friends; and it is with a view of eliciting this recognition that I write these lines.

As long ago as last October (1883) I brought Dr. Davy's case before the council of the Society of Telegraph Engineers and Electricians, but—but, no decision has yet been come to.—Yours, &c., J. J. FAHIE.

Teheran, Persia, Sept. 29, 1884.

LIGHTNING CONDUCTORS.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: Will you kindly favour me with your opinion if, in fixing a lightning conductor to a church tower, it is either safe or proper to secure it to the *gas* main, and that only some six inches underground. It is only about six years since the church (a new one) was totally destroyed by fire within a fortnight of the flues being tampered with, and now the vicar &c., appears to be inviting another disaster.

A reply in your columns or otherwise will greatly oblige.—Yours, &c., A SUBSCRIBER.

[It is neither safe nor proper.—ED. *E.*]

TELEPHONY.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: In reply to "Curiosity's" letter in your impression of the 4th of October I would refer your correspondent to the *Dundee Advertiser* of the 16th and 17th September, 1884, containing two lengthy illustrated articles on the telephone, which will give him all the information he can require.—Yours, &c.,

3, Great Winchester-street, E.C., E. A. B.
4th October, 1884.

A LEGAL QUESTION.

A subscriber writes us:—"Some three years ago I purchased a few transmitters of the Gower-Bell type. Can I legally use these, as they were bought long before Edison sent in his disclaimer?"

ONE PHASE OF CABLE MAINTENANCE.

An ever-recurring question is found in the true relation between the mother country and her colonies. We strongly suspect, however, that no Englishman is content to think of any colony except as an integral part of the Empire. During the parliamentary recess attention has been called to the state of our navy—its unpreparedness, weakness, and inefficiency to protect our commerce. It has been shown that not only is our navy numerically weak, but that in case of war it would be further weakened in that most of our coaling stations are wholly at the mercy of an active, enterprising enemy; and there are many gaps in the continuity of telegraphic connection that should be remedied before the evil day arrives. All such discussions are valuable and interesting, but at the same time we must not be led away with the idea that the main object of ocean telegraphy is for military and political purposes. So far is this from being the case, that almost without exception cables have been made, laid, and are maintained more directly in the interests of commerce, and are only indirectly connected with military purposes. Assuming, then, that the direct object of cables is to promote commercial intercourse, while at the same time they are almost invaluable in political affairs, the question of their maintenance in good working order is one of the utmost importance. One phase in the maintenance of cables has only during the past year or two become prominent, but it is one that, in certain positions and under certain conditions, will rapidly overshadow all others. The right time to consider the whole question is before it becomes "urgent."

A cable is the property of its owners, just as a house or an estate, and the owners can recover damages from anyone wilfully injuring their property. There are many ways of injuring a cable without cutting it, and one of these has not yet received the consideration it deserves, viz., the laying of one cable too near or over another in such depths as there can be no certainty of recovering one without injury to the other. Consider for a moment the work of repairing a cable. Far down below the surface—a thousand fathoms deep, lies a thread some inch or so in diameter. This thread has to be caught by the grapnel and brought to the surface. Given every assistance—the fullest knowledge of the sea and its surface currents, the configuration of its bed, the atmospheric conditions, yet still the operation is uncertain, difficult, and dangerous. But the knowledge is generally far from perfect. The exact position of the cable is unknown, it may be miles, more or less, from where it is supposed to be. The course of the ship while grappling may be affected by currents, and instead of being at right angles to the line of cable, it may be parallel to—or at some other than a right angle. In laying a cable across the Atlantic the ship does not stop paying out because of unfavourable weather; yet this or surface currents may cause a long deviation from the course it was intended to keep. We have said sufficient to show that exactness is out of the question. A repairing vessel arrives upon the ground, and grapples over a course of five, ten, or twenty miles backwards and forwards to find the cable. Suppose two or three or more cables to be laid parallel, or are supposed to be parallel, to each other at five or ten miles' intervals, it is doubtful if the best equipped expedition ever sent out could, except by chance, grapple for a certainty one of these cables. The probability is that in attempting to find one the doctrine of cussedness or contrariety would step in, and while the one wanted would not come on the grapnels, the others not wanted would be caught, and, being caught, would be rendered for the time useless. This is no imaginary case—it has occurred—nor is it the worst case. What but disaster can happen when cables are laid over cables in deep water? The Atlantic can show more than one example of this. Let one of these cables develop a fault near the crossing point, and in the repair it is absolutely impossible to get the faulty cable without injury to the other. At the present time there are seven Atlantic cables laid at several points in such proximity, parallel one to the other, overlaid and crossed where the depth of water is very great, making it almost certain that whenever any one of these cables has to be repaired one or more of the others will be broken. The outlook to the shareholders is not good. The legal aspect of the case is fairly simple, but there is no doubt the question of injury must be decided before the legal tribunals. A concessionaire, A, has a right to lay a cable from Europe to America, so has B, but has B any right to lay his cable to the certain material injury of the cable of A? One man has a right to build a house; that being built, he has certain rights that cannot be ignored by B when building an adjacent house. The loss to a landlord is hardly comparable to the three-quarters of a million or a million which represents the loss of a cable; and the more the question is examined the more certain becomes the fact that cables crossing in deep water present almost insuperable difficulties in the way of repair.

Surely the question now to ask, and the problem to solve, is what international law or restrictions should be framed to regulate the laying of new cables. If communication with every part of the world is felt to be so important politically,

Digitized by Google

this question can hardly be allowed to rest before being finally settled. The loss to owners may be bad enough, but it is easy to foresee how infinitely greater might be the loss to civilisation if, some day, in the midst of political troubles, communication with America ceased. It is not a question of giving monopoly to existing companies. It is in the general interest of the public that the existing means of telegraphing should not be needlessly endangered. The Governments concerned in the concessions are all-powerful in the matter, in that they can make it a condition of the right to land cables that they shall be laid so as not to endanger existing lines. Such questions, so far as England is concerned, might well be determined by the Board of Trade, inasmuch as they involve neither technicalities nor other difficulties. Existing cables must, it seems to us, take their chance of interruptions; yet we think much costly litigation will be avoided if some agreement is come to by the companies interested. The law governing the protection of submarine cables is contained in the Convention signed last March at Paris. Two of the Articles in this Convention may be quoted as referring to the subject now under discussion. Art. II. says "It is a punishable offence to break or injure a submarine cable wilfully or by culpable negligence, so as to interrupt or obstruct telegraphic communication either wholly or partially . . ." Art. IV. reads, "The owner of a cable, who in laying or repairing his own cable breaks or injures another cable, must bear the cost of repairing the breakage or injury without prejudice to the application, if need be, of Art. II. of the present Convention."

We may sum up the whole question thus. It is admitted that the laying and maintenance of submarine cables is of the greatest importance, commercially and politically. At the present time the indiscriminate manner of laying the Atlantic cables has led to several cables being in close proximity, crossing one another in deep water, so that it is impossible to repair any one cable at these points without damaging one or more of the others. The remedy we suggest is an international agreement to refuse the rights to land cables unless the cables are laid at such a distance and in such a manner as not to jeopardise the maintenance of other cables; and further that no delay should occur in obtaining this agreement.

THE THEORY OF THE DYNAMO-ELECTRIC MACHINE.*

BY PROFESSOR ROWLAND.

(CONTINUED FROM PAGE 518.)

This machine has two magnets, one above and one below. The lines of force pass up there (*a*) and then out through here (*b*) and then up through there (*c*). These outside pieces (*d*) instead of being far off, are down close. Here is one pole of the magnet near this piece. The lines of force instead of passing across the field of force as they ought to do, pass off here (arrows). The circuit cannot go around, for it would go down and across this opening and up that way (arrows). In this case there is loss, due to the lines of force leaking out; and if these pieces are too near, the lines of force will pass across that opening instead of passing across the opening where the wires revolve; so that there will be a loss, and we shall have to enlarge our magnet, and therefore have more energy expended in keeping up the magnet. There is energy expended in keeping up the field outside as well as in keeping up the field of the magnet. So with respect to this machine it is important that this point should be considered. In this form of a machine (Fig. 3) where there is a small circuit, this magnet has to be attached somewhere. They usually put on a piece of brass across the poles to attach it to. Very often this magnet is turned vertically in the way shown, and then the whole thing is attached to a cast-iron bench. I have no doubt that considerable lines of force are lost in passing across this magnet to this iron piece. I do not think much is lost at that point, but some is lost. The makers of the machine, I suppose, considered this to some extent, but what is needed is measurement on that point.

How many lines of force go across the armature opening and are effective in producing the current, and how many escape and are lost?

These questions are just as important as the question of the leakage of the current in the wire?

There are defects in many of these machines in that respect. By the way, in this last form, some people may say the putting this here and there (indicating *d d*) adds to the strength of the magnet. It does undoubtedly add to the strength of the magnet, but those are useless lines of force that pass across here (arrows). If you measure it here the strength is increased, but you do not increase the strength when you take into consideration the loss.

Here is another form of magnet (Fig. 7). That machine would be defective. It has two magnets in the place of one, and it has two magnetic circuits in the place of one, and many of the lines of force probably make little private circuits of their own around in that way (arrows). Those lines of force are of course lost, and therefore it is more or less defective in that respect. There are machines which this figure represents exactly, but it is not meant for any particular machine; it is meant for a scientific drawing.

I am only giving a general idea of the principles of these machines, and I do not refer to any particular machine. It is also important that this line of magnetic induction shall find easy passage around in order to produce the most intense field. Suppose this was the pole *c*, then the opening at the sides must be made as wide as possible; everybody recognises that! The reason for it is, in order that the lines of force may find easy passage across this opening (*c* to *c*).

Suppose we had a machine made in the following manner (Fig. 8). I don't want to say that it is anybody's machine—I may not have made the drawing right—but suppose there was such a machine, and that somebody did make it, in which there was a magnet with a Gramme ring here (*a*), pole-piece here (*b*), one ring here (*c*), and pole-piece here (*d*), but not any on the other side. How are the lines of force to pass? They evidently go around here (arrow) and strike into the Gramme ring, and I suppose pass across the opening here (arrow), and go to the other side the best way they can. You see there is no easy passage for the lines of force in this case.

I have here a formula for the amount of work which one has to put upon a magnet to produce a certain effect. I will take the case which I have considered most efficient, where there is one magnetic circuit. Here you will have the lines of force going around this machine in this manner (see arrows, Fig. 3). The reason they go thus is from what I have sometimes called a magneto-motor force. It is not a very bad term to be used. It is an original idea of Faraday that these lines of force are conducted by a metal. We suppose these lines of force pass (as shown by arrows), and then they have to pass through the iron and across the opening, and are caused to do that by what may be called the magneto-motor force of the helix. The magneto-motor force of that helix is proportional to the number of coils around the magnet and proportional to the current C in the wire. I will not write down the exact expression for this quantity; I will only say the magneto-motor force is proportional to N, the number of turns around the magnet, and C, the current. The number of lines of force which pass around here we may call B. This is not the quantity which Maxwell considers, but it includes the whole number of lines of force which pass through the magnet. We may write B proportional to N the number of turns of the wire, and C the current, and inversely proportional to the resistance of these lines of force in going around this circuit. The resistance of the lines of force is proportioned to L, the length of the iron

* A paper read at the Congress of Electricians at Philadelphia.

Digitized by Google

of the system, divided by S, the surface cross section of the magnet, supposing it to be a uniform surface, into ϕ, the magnetic permeability of the iron (or you may call it the conductivity of the iron for the lines of force). This quantity ϕ varies with the current, it can readily be obtained; indeed, some years ago, I gave a formula for it. It can be expressed simply as dependent upon the magnetism of the iron and a constant depending upon the iron alone. Then to this we have something more to add.

Let l be the width of this opening (indicating) and A the area across which the line of force flows; then we have to add l ÷ A, we have still to add to this a certain quantity which we can call p, which depends upon the resistance of these lines of force which escape in all directions. It represents loss due to the escaping of the lines of force. Thus we have the final value for the magneto-motor force,

$$\frac{NC}{\frac{L}{S\phi}+\frac{l}{A}+p}.$$

This gives us an equation which may be solved with respect to ϕ. It is evident that the curve for the magnetic permeability is of this nature.

It rises to a maximum here and then decreases. It will not rise as much as this diagram (Fig. 9) indicates, but it will be a more flat form, according to the value of l and p. Therefore, increasing the magnetic force on your magnet, a certain point will be arrived at where it becomes very easy to magnetise a magnet, and after that it becomes harder and harder to magnetise the magnet. So that in practice you should get the form of this curve, so that it should produce a very strong

Fig. 9.

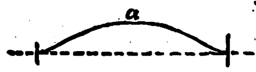

Fig. 11.

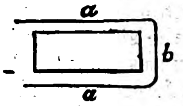

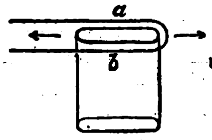

Fig. 10.

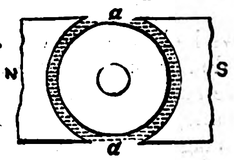

Fig. 12.

magnetic field. This can only be done by an exact calculation, or, better, by experiments on the machines, examining at each point the forces of the current, and in that way getting an idea of how these lines of force go, and we can then see whether this area is large enough to take all the lines of force necessary to pass.

I have here an expression for the work necessary to keep up a proper field in the magnet. Of course as you coil the wire on these magnets, the coil becomes thicker and thicker, and in order to have a sufficient magnetic force across this opening with sufficient velocity you must have sufficient wire. As you increase the thickness, of course you have to use more wire for a certain core. Every core acts very nearly the same as every other in producing force; therefore, if you have the magnets very short indeed, you have to pile up your wire to a very great extent. The wire is made of copper, and as iron is cheaper than copper, it might be better to lengthen out the core slightly. I suppose you would lengthen out the core until the given length of wire on the magnet may make a moderately thin layer. Of course, as you lengthen out your magnet the resistance of this circuit to magnetisation becomes greater; but that is a very small quantity, and I do not suppose it increases much, even for a considerable lengthening of the magnet.

As I said before, the magnetic conductivity of iron is many times greater than that of air, and we can lengthen out the cores without producing much loss on account of that lengthening. Some persons have suggested that there may be a slight gain from the fact that iron, after it has been magnetised a great number of times in the same direction, rather likes to be magnetised in that same direction afterward. If the core is made of any material similar to steel, such as wrought iron or anything of that sort, it might be possible to have some gain from the coercive power of the magnet. There would be a loss from that cause—you have to act against the force of the magnet at first—but, from the continual use of the machine, I think very likely the iron might get a set in the direction of the force, which might possibly aid in the production of a suitable dynamo. If the core was of steel it is evident that you could send a strong current through at first, and magnetise the steel and then diminish the current slightly. We could thus still keep up a very large force at this point and with a moderately small current. I do not know how practical that would be, but it seems to me that it would produce a very strong field. In the commencement of the operation we should have to send a powerful current to magnetise the steel, and then, without stopping the current, to diminish it; then the force of the steel would be in the same direction with the current, and produce the field with less expenditure of energy than if it were simply iron.

As far as the difference between a shunt machine and a series machine is concerned, there is no difference. The magnetising force of this magnet is proportional to the number of turns multiplied by the current; that is, proportional to the cross section of the coils multiplied by the current per unit of the section, so that the magnetising action can be the same with a machine which produces a strong current and a machine which produces a weak current. If you calculate the energy, you will find it is the same, because it depends upon the current into the cross section. If the exterior dimensions of the coils are the same in both cases, the same energy is expended in each; in order to produce the same force, therefore there is no difference between a shunt machine and a series machine. I think the energy will be the same for both. I will now refer to the heating of the armature. Of course the amount of energy expended in the heating of the armature will be dependent on the resistance of the armature, and the efficiency of the circuit will merely depend upon the relation between the resistance of the armature and the exterior resistance; that is very well known. There is one other point: There is a certain lot of dead wire, you may call it—I do not know the technical term; I think very likely that that is the technical term. In the first place, I will only discuss the Gramme and Siemens armatures. In the Gramme machine you have the armature inside of the ring, and the ends do not act at all. In the Siemens armature, we have the coils brought over the ends of the armature. It is only a question of the work of the machines and the relation between the two. In the Gramme machine, it must be that less than one-half of the wire is acting. You have the section of the Gramme ring (see Fig. 10), and when that portion, a, of the wire is active, of course this portion, b, is dead. I suppose some of the lines of force go out here, as shown by the arrows, so that we can see at least half the wire is dead wire.

In the Siemens armature one cannot say immediately how much dead wire there will be, because it depends upon the length of the armature. In the Siemens armature you have the wire wound (as shown in Fig. 11), and this portion, a, would be active and this portion, b, dead. Of course, if the armature is very thick you would have more dead wire than when it is simply long. I cannot say which has the more dead wire, but I dare say the Gramme has more than the Siemens. Furthermore, either in the Gramme ring or the Siemens armature—I will draw this figure to represent either the Gramme or Siemens armature—you have the lines of force running (Fig. 12) as shown in dotted lines. That portion is active, and this portion, a, in between the poles is dead; and when the thing revolves you have the lines of force turning around, and I think that would add more dead wire to your machines. I believe an attempt has been made to throw out these dead coils; I believe in some form of machines they are thrown out. There is no necessity to go further. Of course the efficiency of the circuit depends upon the ratio of the resistance of the armature to the resistance of the wires, and therefore, as far as this point is concerned, any machine can be just as efficient as you please by putting in greater and greater external resistance. But as the magnet

Digitized by Google

remains the same, you would find a point where the efficiency of the machine as a whole would not increase for an increase of external resistance, and the work would actually diminish.

There are other things to be taken account of; there are some losses due to the self-induction of the coils which produce sparks in them. I have requested Professor Fitzgerald to take up that point, and therefore I will leave it for him to consider. Now to consider another point with regard to the dynamo which can be treated in this simple manner with no use of the calculus. I think it can be done by very simple reasoning, if you only know the principles. I shall now attempt to construct two machines similar in all respects, but one of which is larger than the other. We can suppose that we construct one of the machines, and then see what the effect will be when that machine gradually grows and becomes very large.

The point we shall start from is that the magnetic field is constant in the two machines. Owing to the fact that there is a limit to the magnetisation of a magnet, we cannot have a field which is produced by iron, with more than certain strength. Therefore, I suppose that you get up to a reasonable strength with your iron. It cannot be up to the maximum strength, of course, but it is somewhere near it. I made some experiments many years ago upon an ordinary magnet (and the results were published, I think, in *Siemens' Journal*). It is beautifully applied to the dynamo machines, and I obtained everything with it that I have referred to here. With that apparatus, if I remember rightly, I got about one-third of the force in the field of a magnet that iron could possibly give. Of course, you could get greater. It is theoretically possible to get a force equal to the magnetisability of the iron, or the maximum magnetism of the iron; but, practically, I suppose the case is very similar to that of the ordinary dynamo machine. Therefore, we can say that the field of force in the two machines, one of which is larger than the other, shall be constant, and I will therefore write down F constant.

It is not only constant in one part of the machine, but in all parts; the magnetising force at every point of one machine is equal to that in a similar point in the other machine. Therefore, if you drew the machines on the board, it would not make any matter about the scale of dimensions of the machine; you could mark down the force at a certain point as being a certain amount, and consider the scale whatever you please.

Starting from that point, we will consider what must be the current in the wire in the two machines. The machines have the same number of turns around the magnet, and everything is the same except the dimensions of one machine are greater than the dimensions of the other. I will give you a formula for the current in the wire. Suppose you have a tangent galvanometer. Consider the current passing around its coil. If you make the circular wire of the galvanometer grow, in order to produce the same effect at the centre you must add current in direct proportion to the radius of the coil. If you make that coil twice as large, you must have the current twice as large in order to produce the same force at the centre, and not only at the centre but at every point. If the material is constant, if there is no difference in the iron, we have the current in direct proportion to the linear dimensions of the figures, so that the current in the wire varies as the linear dimensions of the machine. Make one machine twice as large as the other, and the current per unit of area in the magnet must be twice as great to produce the proper motive force. Of course the wire has increased in size. If the machine is increased to twice its original size, the cross section of the wire is increased four times. In other words, from that cause the current per unit of area will vary inversely as the square of l, the linear dimension; and since we have found the current to vary directly as l, in order to retain the same force in the field by a combination of the two results, it varies inversely as l. Therefore, as far as the magnets of a machine are concerned, if the machine grows larger in this way, its heating effect, which depends upon the current per unit of cross section, will be less, since the surface will have been increased in proportion to the square of l. There will therefore be less danger of heating in a large magnet than in a small magnet. This is only with respect to the magnet. In some cases it is practically found harder to run a large machine than a smaller one; but we shall find how that comes.

The resistance of any part of the machine and the work of the armature varies, of course, directly as the length of the wire and inversely as the cross section. The cross section varies as l square, so that the whole work varies inversely as l, or the resistance varies inversely as l. Therefore the larger you make the machine the less the resistance will be; one machine being twice as large as the other, the resistance will be half as great.

I will now consider the electromotive force. This applies not only to the work of the magnet but also to the work of the armature. We have here the current and the resistance. The electromotive force is proportional to the product of the current and the resistance, hence we may write $E = RC$. Therefore the electromotive force of this machine will be constant. We shall presently see how this is modified so as to get the electromotive force greater for the larger machine. The work done is therefore equal to $C^2 R$ in any part of the machine, or in the whole machine just as you please. But that quantity varies directly as l, the linear dimension. Therefore the one machine, which is twice as large as the other, requires twice as much power to run it, and you get twice as much electrical energy out of it. But it is to be remembered that the weight of the machine varies as l^3, and you have only got l times the work out of it as constructed in this way.

Let us see what the reason of this is. The field of the magnet is the same. There are just as many lines of force in the armature in the two machines, and when we calculate up, we shall see that the angular velocity of the armature or the number of turns per second or minute must vary inversely as l^2. In other words, in one machine twice as great as another, the velocity of the armature must be only one-fourth as great in order to produce the same current in the wires. This takes account, I think, of every irregularity in the machine—the two machines are exactly alike in every respect. I have not added the loss for the self-induction of the coil.

So far as the results go, we have constructed two machines which differ only in size. The efficiency of these two machines is a constant quantity. That will be rather startling to some who come to me constantly and say "a larger machine is more efficient than a smaller one." As far as this thing goes, we have constructed a machine which is larger than another, and in which the efficiency is the same.

Let us see the cause of the efficiency remaining constant. On what does the efficiency depend? We have got to keep our magnetic field the same in both cases; and therefore work done in sustaining the magnet will be this $C^2 R$. But here we have the angular velocity inversely as the square of the linear dimension. The question comes up again, whether we cannot increase the velocity of the armature above that point. Is it practically necessary that we should run one machine at one-fourth of the velocity if it is twice as large? It is a practical question as to what we can get. I should think it certainly was not in this proportion. I should think it would be more nearly inversely as the square of the size. Can we not then run the machine with greater angular velocity? We certainly can do so by increasing the external resistance, so that the same current flows when you run it fast as in this case. Then the driving force will be the same, and the whole machine will be increased in efficiency. We can certainly do that to a certain extent—I do not know where it will end practically—but starting with a small machine without increasing the electromotive force, which is constant in these machines, but by arranging the wire of the armature so as to increase the external resistance, we can increase the speed and yet have the current per unit of section through the armature the same as in this case. If we do that, we shall be able to increase the external resistance of the machine in comparison with the resistance of the armature, and when we do that we increase the efficiency of the machine.

I think it is from this cause that we find large machines more efficient than smaller ones. But it is also evident that there is a limit, which can only be obtained, I suppose, from practically making the machines, and seeing how fast they

Digitized by Google

may be run without flying to pieces. If we can keep them going at a greater rate of speed than I have pointed out as they are increased in size, I suppose the efficiency will be increased.

As far as this theory goes, the increase comes not from the size of the machine but from the fact that you can get a greater electromotive force with the same angular velocity, and so can increase the external resistance in proportion, so that you find in very large machines you can make the wire with one turn around the armature—not several turns—just have bars on the machines. We thus decrease the resistance of the machine and at the same time we run it above this relation which I have pointed out and so obtain the proper electromotive force. The proper electromotive force is more easily obtained from the large than the small machine, because it is not practically necessary to decrease the velocity.—*Electrical World.*

ON THE PERMANENT TEMPERATURE OF CONDUCTORS.*

The experiments of which an account is given in the following paper were commenced several months ago in connection with a theoretical investigation by Sir Wm. Thomson, "On the Effect of Clothing," showing the dependence of the effect on the relation between the dimensions of the covered body, and the dimensions and physical properties of the covering. A primary object of the experiments was the determination, for practical purposes, of the temperature of electric light conductors. The preliminary experiments have led to results which seem to be of considerable importance, and they point to the necessity for a fresh determination of the "emissivity" or "surface-conductivity" of bodies of various dimensions, and under various circumstances as to surroundings and as to air pressure.

With respect to the determination of the permanent temperatures of wires carrying electric currents very little seems to have been done experimentally. In fact, the only important experiments on the subject seem to be those of Mr. Preece, on the currents required to fuse and to raise to a dull red heat platinum wires of different diameters. These were communicated to the Royal Society in a paper read April 3, 1884. I may here remark that the results given by Mr. Preece differ in a very definite way from those which I have obtained; but it is to be noticed that the temperatures of Mr. Preece's determinations were much higher than those at which I have, up to the present, experimented.

The method which I have employed for determining the heating effect of a given current in a given wire has been to find the *resistance* of the wire, first with a very feeble current passing through it, and afterwards with the given more powerful current passing, and after it has been passing for a sufficiently long time for the wire to have acquired a temperature permanent under the given circumstances. The resistance of the wire becomes increased as the temperature rises, and from the increase of resistance the increase of temperature can be calculated.

In doing this I have used two methods of experimenting. In the first method the wire under experiment was connected in series with the battery supplying the current, an amperemeter, and a standard resistance of thick German silver wire. The German silver wire was immersed in heavy paraffin oil to keep it cool, and the wire under experiment was left freely exposed to the air, but carefully guarded by paper screens placed at safe distances, both from draughts and currents of air, and from radiation of the sun or laboratory fire, and from the persons of the observers.

To commence the experiment a very feeble current was passed through the line consisting of the copper and the German silver wire, and by means of a sensitive reflecting galvanometer of high resistance the differences of potentials at the two ends of A B, the copper wire, and of B C, the German silver wire, were determined (Fig. 1). The ratio between these differences of potentials is the same as the ratio between the resistances of A B and B C. Then, B C, the standard of German silver, being known, the resistance of A B was calculated. This experiment, therefore, gave the resistance of A B *cold.*

A much more powerful current was then caused to flow through the line, and was kept up for a sufficient time until A B had taken a permanent temperature. The terminals of the potential galvanometer were again applied, and the differences of potentials at the extremeties of A B and of B C once more determined, and thus the ratio of their resistances. If the resistance of B C had remained absolutely constant, the resist-

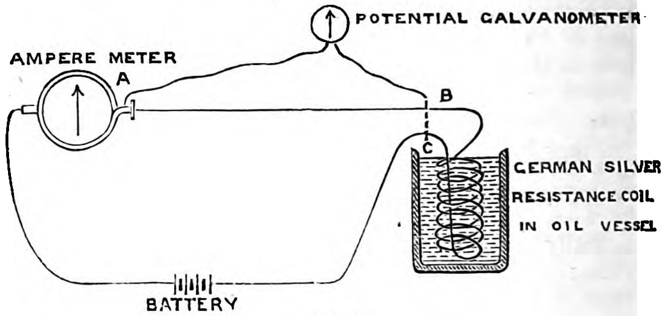

FIG. 1.

ance of A B *hot* from the effect of a current, the magnitude of which is shown by the ampere-meter, would now be known. This was practically the case. The quantity of oil surrounding the German silver wire was so considerable that the temperature rose but little, and the change of resistance of German silver with temperature is so small that it was unnecessary to apply any correction. It would be easy to keep the temperature of the oil quite constant by occasionally passing a test tube containing a little ice or a small freezing mixture from place to place through it, and then stirring the whole up thoroughly.

The resistance of the copper wire first *cold* and afterwards *hot* having been determined, and the temperature of the wire

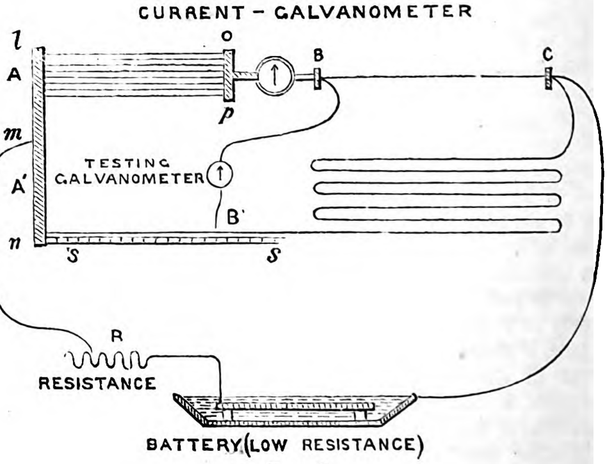

FIG. 2.

when cold being known (as at the beginning the temperature of the wire was the same as that of the air), it was easy to find the temperature of the wire hot by applying the formula for temperature correction for the resistance of copper.

I have also used latterly for passing a powerful current through a wire under experiment, and for determining the resistance of the wire while the current is flowing, a Wheatstone bridge, suitably arranged for the purpose, in accordance with a plan suggested by Sir William Thomson, and I find this method more sensitive and more generally convenient than the potential method.

The diagram (Fig. 2) explains the arrangement. A B C and A' B' C are the two branches of the Wheatstone bridge, and

* On the Permanent Temperature of Conductors through which an Electric Current is passing, and on Surface Conductivity, or Emissivity. By J. T. Bottomley. With a Note by Sir William Thomson, F.R.S.

Digitized by Google

the four conductors are made up as follows: B C is the wire under experiment as to heating by the current; *l m n* and *o p* are two bars of very stout copper, and between *o p* and the portion *l m* of the bar *l m n* there are soldered a considerable number of stout copper wires making up a compound conductor of small resistance, and having very large surface exposed to the air for cooling. Between *o p* and B a current galvanometer of very small resistance is introduced for measuring the whole current flowing in the branch A B C, and therefore through the experimental wire B C. The branch A′ B′ C is a single long wire having many times the resistance of the branch A B C, and many times the resistance of the battery used, and thus only a small portion of the current passes through it—a quantity, in fact, unable to heat this branch to any appreciable extent. The testing galvanometer is introduced between B and B′, the contact at B′ being shifted about till a "balance" is obtained; and from the position of B′ on the scale *s s* the ratio can be calculated between A′ B′ and B′ C, when the equipotential point has thus been found.

In experimenting, the wire B C is soldered between stout copper slips for the purpose, shown in the diagram at its extremities, and its resistance is taken with a very small current passing through it, the resistance R being provided for the purpose of varying the current. The current is then increased by diminishing the resistance R. When this is done, the wire B C becomes heated, and its resistance increases, but the conductor A B and the branch A′ B′ C remain unaltered, though the ratio between the parts of the latter corresponding to the "balance" is changed.

Let c be the resistance of the conductor A B; let r_1 and r_2 be the resistances of B C when respectively the weak current and the stronger current are applied; also let a_1 a_2 and b_1 b_2 be the corresponding respective lengths of the shorter and longer parts of the branch A′ B′ C,

Then

(1) $$c : r_1 :: a_1 : b_1$$

and (2) $$c : r_2 :: a_2 : b_2$$

Hence $$\frac{r_2}{r_1} = \frac{a_1 b_2}{a_2 b_1}$$

Let t be the temperature of the air of the room where the experiment is made, and let it be assumed that the temperature of the wire B C is the same as that of the air during the first experiment with the weak current; let θ be the temperature of the wire when the stronger current is passing. Let σ_t and σ_θ be the specific resistance of these substances at these temperatures.

Then, $$\frac{r_2}{r_1} = \frac{\sigma_\theta}{\sigma}$$

the change in dimensions of the wire due to heating being left out of account. The values of σ_t and σ_θ can be found, as has been remarked already, for copper and for several other substances from well known tables and experiments.

My first experiments, after some preliminary trials had been made, were on a series of copper wires, all of them cut from the same piece, and of the same length, but some of them bare and others covered with different insulating coatings. The wires were about No. 21 of the old B.W.G., 0·81 millim. in diameter and half a metre in length. The resistance of each, with only as much current passing as sufficed for the ordinary application of Wheatstone's bridge, was 0·0183 B.A. unit. These were tested by the potential method described above. Eight wires were taken, and their surfaces were prepared as follows:—

A. Surface amalgamated with tin and mercury.
B. Surface amalgamated with mercury by rubbing on mercury nitrate and washing.
C. Bare surface (dim).
D. Covered with cotton and shellac.
E. Cotton-covered.
F. Shellac varnish.
G. Bare, polished with fine emery.
H. Thick coating of lampblack.

These wires were tested successively with currents of 1·2 ampere, 3 amperes, 5 amperes from the battery; then with 10 amperes, 20 amperes, and about 30 amperes from the dynamo-electric machine, the last named current overheating both the coverings and the wires and burning some of them up. The differences of temperature were wonderfully small, but they were decided. The following table shows the wires arranged in order of coolness, and therefore of the efficiency for emission of heat of their respective coverings:—

Current—								
1·2 ampere	H	D	C	E	F	G	B	A
3 "	H	D	C	E	F	G	B	A
5 "	H	D	C	E	F	G	A	B
5 "	H	D	C	E	F	G	A	B
10 "	H	D	E	C	F	B	G	A
20 "	D*	F	H	E	C	G	B	A

With about thirty amperes—

Tin and mercury ...	A	Surface slightly fused and blistered.
Mercury	B	Wire totally dissipated.
Bare surface (dim)...	C	No visible alteration.
Cotton and shellac...	D	Coatings fused together.
Cotton covering ...	E	Covering burned off.
Shellac varnish	F	Covering fused.
Bare polished	G	No visible alteration.
Lampblack	H	No visible alteration.

It appears, therefore, that the surfaces stand as follows in order of cooling efficiency:—

H, lampblack.
D, cotton and shellac.
C, bare wire, dim—in common unaltered condition.
E, cotton covered.
F, shellac varnish.
G, polished copper.
B, mercury surface.
A, tin and mercury.

In order to show a comparison as to the amount of cooling effect, I may here quote the temperatures of these wires with a current of 5 amperes passing, and in air at 11° C. This was the highest current I was able to apply with the battery I then had at command, and with the mode of experimenting which I was using at the time these experiments were made. The temperatures were determined in all the cases mentioned in the table above, but with the higher currents there was in this series of experiments some uncertainty owing to the fluctuations of the potential of the dynamo-electric machine; and, moreover, it is the less necessary for me to quote these here as I hope shortly to make the whole investigation more thorough and more satisfactory.

Temperature of wires with 5 amperes passing, the temperature of the air being 11° C.—

A	Tin and mercury............	22·5°
B	Mercury	22·5
C	Bare wire (dim)	21·75
D	Cotton and shellac	21·5
E	Cotton-covered	21·75
F	Shellac varnish	21·8
G	Polished copper	22·0
H	Lampblack coating.........	21·0

The numbers in this table show that the permanent temperatures assumed in the various cases differ wonderfully little with so great differences as to clothing; and that, at the least, there is no tendency in the covered wires to attain a temperature higher than that taken by the uncovered wires. With stronger currents it is made much more apparent that the covering does, on the contrary, favour loss of heat by emission at the sides with a wire of the size here referred to.

The following table contains the results of experiments on five copper wires of good conductivity with various coatings. In the first five columns are given particulars regarding the

* Covering probably half burned in D and F. The wires bracketed were equally heated.

Digitized by Google

wires and the current passing through them. The sixth column shows the difference $t - \theta$ between the temperature assumed by the wire and that of the surrounding air, the latter being in all these cases about 12° C. In the seventh column is given the emissivity of the outer surface, or the quantity of heat (C.-G.-S. units) lost by the surface per second per square centimetre of cooling surface per degree centigrade of difference of temperature of cooling surface and surroundings.

Specifying number B.W.G. and nature of covering.	Length of wire. Centims.	Resist. of 100 centims. B.A. units.	Diameter of wire in millims.	Dia. of covered wire, outside.	Current (amp.).	$t - \theta$	Emissivity.

I may next refer to experiments on a length of wire which was first tested in its ordinary state, then when highly polished, and afterwards with the surface covered with coatings of shellac varnish thickly put on and gradually increasing.

Here I had—

Length of copper wire	50 centims.
Diameter	0·97 millim.
Resistance with feeble current	·01268 B.A.U.
„ „ German silver wire	·020
Ratio.....................	·634

With current of 10 amperes I found—

Condition of surface.	Ratio of copper to G.S.
Bare unpolished....................................	·6635
Bare highly polished	·6534
One coating shellac	·6547
Two „ „	·6510
Three „ „	·6466
Three „ „ and a covering of cotton wool after three minutes	·6595
Ditto six minutes	·6668
Ditto nine „	·6325

Another wire was similarly treated with coatings of Brunswick black and thin tissue paper, and gave the following results :—

	Ratio of copper to G.S.
Bare wire	·9895
One coating Brunswick black	·9745
One B.B. 5-ply fine paper	·9833
One B.B. 5 paper 1 B.B.	·9844
One B.B. 5 paper 2 B.B.	·9853
Same with 20-ply paper added...................	·9982

The current was in every case 10 amperes. Increase in the numbers indicates increase in the resistance of the tested wire, and therefore increased temperature; while decrease in the numbers quoted shows decrease in the temperature. The change in the permanent temperature is not more than two degrees; and the result of these experiments may be briefly stated to be this, that there was exceedingly little effect in the way of keeping up the temperature of a No. 20 B.W.G. copper wire, about 1 millim. in diameter, by covering it up with paper and Brunswick black till it attains an external diameter of more than a centimetre and a half.

A large number of experiments were tried of a kind similar to the one just quoted, and all of them giving similar results for wires of similar dimensions. I propose with improved arrangements which I have now at command, to obtain numbers which shall be more accurate than those which I have yet obtained; and to extend the experiments to the case of wires of larger diameters.

(TO BE CONTINUED.)

SUBMARINE CABLES IN WAR TIME.

Sir James Anderson writes as follows to the *Pall Mall Gazette* of Oct. 22 :—

"In the *Pall Mall Gazette* of October 17, 'One Who Knows' says, in paragraph 1, after the heading 'What should be Done'—

"'A telegraphic cable should be laid down connecting West Africa and the Cape direct with England. All our telegraphic communication with South Africa passes through Suez, and would be intercepted in case of war. From the Cape cable communication should be established with India and Australia. A cable should also be laid to Bermuda. The telegraph stations where the cable touches ground should be placed within fortifications, and this of course applies equally to the English end of the cable.'

I am at one with him as to the necessity of arming our coaling stations and increasing our cruisers, but I consider his reasoning about telegraphic communication very wide of the mark. I have not a word to say against cables being laid anywhere if Governments care to subsidise them, but it is altogether misleading to assume that cables laid where proposed, or the fortification of the landing places, will give us any security whatever for uninterrupted telegraphic communication.

"There are only two ways of looking at this feature.

"There should be as many alternative lines of communication as possible, so as to make it not worth while for any enemy to cut cables. All cables can be cut at all depths out of sight of guns or land, but they cannot so easily be repaired, and those suggested would be more difficult to repair than any yet laid.

"Cables in time of war should be landed at certain well-defined points, and, where convenient, landed at certain harbours—these points and harbours, as far as possible, to be known only to the Government for their own use. Then, if at any port or point telegraphic communication is interrupted, a despatch vessel must go from one point to another until she finds communication uninjured.

"In my opinion there can be no other plan of making use of the telegraph at distant points where alternate land lines do not exist. Government should therefore favour telegraph cables being laid where possible, so as to touch at as many points as can be made convenient. Despatch vessels should have the means of lifting cables at any of the points arranged, and telegraphing on their own account. The cables suggested by 'One who Knows' favour this arrangement less than any others, unless the line proposed to be laid along the West Coast of Africa be made to touch at all the ports, and at other points to be agreed upon, by the nation giving the indispensable subsidy.

"But if English commerce is to be defended by the Cape route, in my opinion the telegraph will do little for it, and the commerce will be limited to fast steamers, defended by fast cruisers stationed or cruising between certain latitudes and longitudes. Our slow steamers and sailing ships must sail under another national flag or lay up in docks idle. It will be very strange if this should come about. It can only continue if Great Britain ceases to be a European Power; and before that takes place there has to be a great war and a supreme struggle. This will not depend upon any Government. The nation will demand the struggle at any cost and any sacrifice. This is not Jingoism.

"One cannot fail to observe that no matter who makes the shortest road, by canal or otherwise, and no matter who opens up a trade route, our countrymen go for it and use it. The Mediterranean is the shoutest route to India, China, and Australia, and we are not going to give it up until we are thrashed out of it—that is, until we can no longer call ourselves a European Power.

"Then there exist so many alternate European routes, so that if all the main cables were cut it is only a few hours to two days' sail for a despatch vessel to reach telegraphic communication through some neutral territory. In this case it would answer no useful purpose to cut cables, and if cut they could be repaired under the protection of our cruisers. To my judgment we shall have to fight for the right of way along this route, no matter what it costs, or cease to be a great Power, and so long as we cannot command that right of way we must depend mainly upon vessels sailing under a foreign flag for our food supplies.

"Cables laid in short sections, despatch vessels specially fitted, and ships with cable, to connect such points as may be desirable in the vicinity where war is imminent or in progress, are the only methods of providing for telegraph communication in time of war, where there exist no alternate lines in the hands of neutral powers.

"I cannot understand the hesitation in arming our coaling stations for defence. This has to my mind been always unaccountable, but I have a strong conviction that when danger really becomes evident to our public we will pull ourselves together, and give our neighbours a good deal of trouble before they push us off the European track to the Mediterranean, India, Australia, &c. It will be a poor day for our country and our commerce when we are driven on to the Atlantic for all our supplies and trade."

ELWELL AND PARKER'S PATENT ENGINE.

This engine, although of the ordinary single acting type, presents some features of novelty, and its performances are said to be excellent.

The particular engine which is the subject of our illustrations has a 10in. cylinder, 9in. stroke, and is arranged to run at 500 revolutions per minute. This is by no means the highest speed at which they will run, but the company, wisely, do not recommend excessive velocities, as the difference in the power given on the brake and that shown on the diagram becomes so great, owing to the rapid increase of friction, as to seriously detract from the efficiency and economy of the engine.

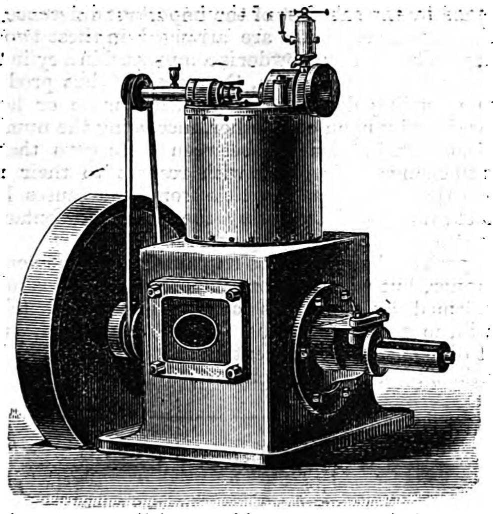

Fig. 1.

It will be seen on reference to the illustration that the engine differs from many of the same class, by the fact of its having only one cylinder, an arrangement which, without sacrificing the steady running, very greatly lessens the number of working parts, reducing the wear and tear to a minimum, and simplifying the whole machine. The cylinder is mounted on a base of box form, which encloses the working parts, and into which the exhaust steam passes. It is provided with circular facings on each side for the two side covers forming the main bearings, a square cover for access

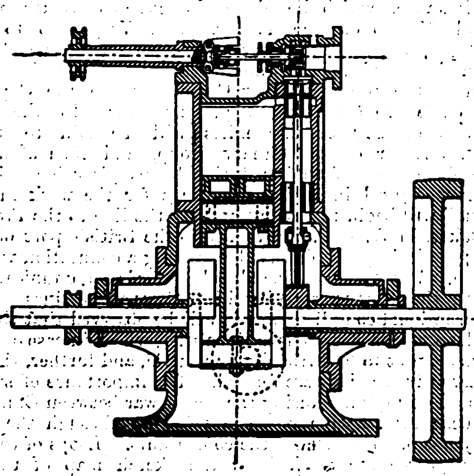

Fig. 2.

to the interior and the exhaust outlet. The position of the latter plays an important part in the working of the engine, as upon this the efficient lubrication depends. The exhaust steam condenses slightly as it passes through the base, and the water, with the oil floating on the top of it, accumulates and rises up to the level of the outlet. Before, however, it quite reaches this height the connecting rod end is arranged to dip into it at each stroke, which splashes the oil and water over the whole of the moving parts. The main bearings are of very ample length, and fitted with phosphor bronze bushes. A passage is cast in the cover above the bush, which catches the oil and water, and conducts it to the outer end of the bearing, from where it circulates back along the usual oil grooves into the base again. A small stuffing box and half round gland serve to prevent any leakage to the outside. The crank shaft is of forged steel, and the balance weights are dovetailed on and securely bolted.

The slide valve is of the piston type, of novel construction. It consists of three rings united to each other and to a central boss by webs, the central ring forming a diaphragm to divide the steam and exhaust ports, the other two forming guides which prevent the cutting of the edges of the ports. A valve of this character is found to work quite tight without any spring rings, and remain so after a large amount of usage. The passages are designed to allow a maximum speed of 5,000ft. per minute for the steam, the exhaust being enlarged as much as possible, and an auxiliary port formed at the lower end of the cylinder, to be uncovered by the piston in its travel. We have now before us diagrams taken from this engine at various speeds, showing a very good distribution of steam, which should go far to overcome the objection often raised against this class of engine on the score of economy. The governor is placed horizon-

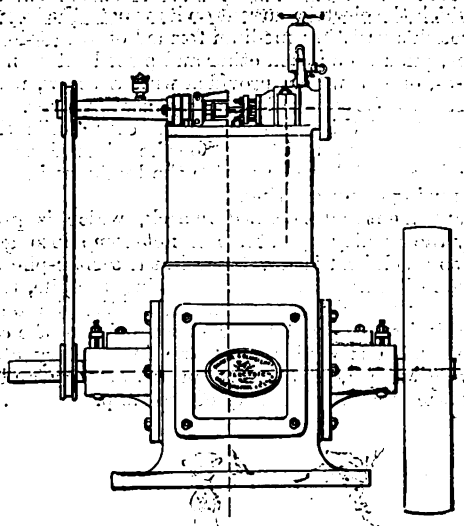

Fig. 3.

tally across the cylinder cover, operating an equilibrium valve in the steam-pipe, and is made extremely sensitive in its action by a very neat device, adjustable to any required speed. The driving shaft is carried by a phosphor bronze bush, bolted to the cover, at the outer end of which is the driving pulley. The lubricator which supplies oil to the whole of engine, with the exception of the governor spindle, stands on the steam-pipe.

Speaking generally of the engine we may say that the whole of the flanges and phosphor bronze bushes are bright, and fitted with

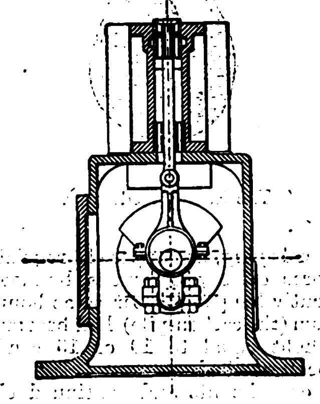

Fig. 4.

bright nuts, the flywheel is turned and polished, and the cylinder lagged with sheet steel, forming a very handsome and compact piece of workmanship. The castings are of the exceptionally clean and perfect character for which the company are so justly celebrated, and the workmanship is no less creditable.

These engines have up to the present been principally supplied to the inventors, Messrs. Elwell and Parker, of Wolverhampton, for use in conjunction with their well-known dynamos and accumulators, where they have been a great success, but we feel sure they only require to be known to engineers to ensure their being extensively applied not only for electrical purposes, but for all situations where a high and uniform velocity is required. We may mention, in conclusion, that the Coalbrookdale Company are now engaged in rearranging and adding to their engineering department, in which, when finished, they will be able to deal with work of the heaviest and highest class.

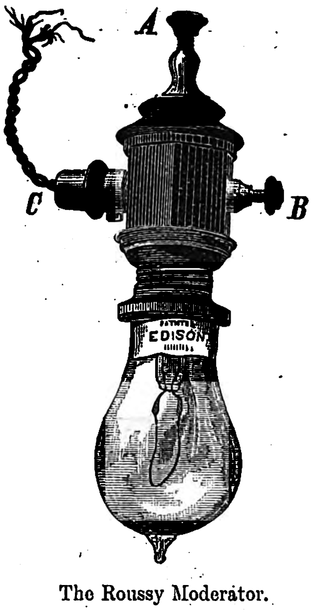
THE ROUSSY ELECTRIC LIGHT MODERATOR.

Since the application of incandescent electric lighting, many attempts have been made to invent an apparatus, simple and at the same time working with precision and safety, so as to regulate, according to requirements, the intensity of each individual lamp within the same circuit. It has not yet been found possible to practically apply the results of these trials, because the contrivances for that purpose, more or less satisfactory, are all very complicated, and cannot be easily inserted into the lamp-holders without causing inconvenience.

The apparatus most nearly fulfilling the desired object before the invention of the "Roussy" moderator was the "Stanley" regulator, by which the electric current on its way to the lamp was made to pass through a resisting medium formed of a certain number of carbon discs, piled up on each other and placed between two steady metallic discs, one of which, provided with a screw, permitted the carbon discs to be pressed one against another. According to the intensity of this compression the carbon-pile thus formed opposed more or less resistance to the electric current; and it was therefore possible to guarantee the luminous intensity of the lamp by screwing or unscrewing.

This arrangement had a great drawback, which is probably the reason why the Stanley regulator has not come into general use. In its use, so much heat is developed in the carbon-pile as to cause an expansion of each of the discs forming the pile, the height of which is thus increased; but, as the ends of the pile touch the two fixed metallic discs, an automatic compression of the carbon discs takes place, which is equivalent to an involuntary effect of the screw above described, and causes an involuntary and automatic increase of the luminous intensity of the lamp.



The Roussy Moderator.

For instance, after having, as supposed, regulated the intensity of a lamp to a force of, say, 8 candles, by means of the Stanley regulator, it frequently happened after some hours' lighting, when the resisting medium (the carbon-pile) had become heated, that the lamp produced a light equal to 10 or 16 candles without the regulator having been touched.

After numerous experiments and continued observations upon the circuit of Edison lamps at the Gilamont Mills, their owner, M. E. L. Roussy, who introduced incandescent electric lighting into Switzerland, succeeded, independently of Stanley's invention, in constructing a regulator, or, as he calls it, a *moderator*, also composed of a resisting carbon medium, but not open to the great objection described above.

The accompanying illustration shows a lampholder with the Roussy moderator, carrying an Edison lamp. A is the turn button of the moderator; B the interrupter; and C the aperture for introducing the wires. M. Roussy places inside the lampholder a small hollow cylinder made of glass or some other insulating substance, and filled with carbon powder. This powder is put in contact with one of the lamp poles in order that the electric current may pass through the carbon powder before reaching the lamp. Moreover a screw permits of the powder being more or less compressed in its cavity. If a strong compression be exerted upon the carbon powder it will form a compact conductor, allowing the current to pass to the lamp without hindrance. But if the compressing button be unscrewed, the electric current causes an automatic disaggregation of the compressed powder, and the more this becomes loosened the greater will be the resistance to the current, and the less brilliant will be the light of the lamp. What happens on such a resisting medium becoming heated? Numerous and protracted experiments have been made to clear up this question; and they have shown that the heated state of the powder in this regulator does not alter the intensity of the resisting property of the latter, while the mechanical compression of this same carbon powder will to a certain extent reduce the resistance it exerts against the current passing through it.

This result, although practically attained, seems contradictory, as it must be conceded that in the Roussy moderator, as well as in the Stanley regulator, the heating must necessarily be followed by an expansion of its elements. However, the difference in the results may be explained by the sole fact of the important difference in the form and in the manner elements are arranged in these two systems of regulating. When carbon powder is compressed in a cylindrical cavity by a screw acting like a piston, the pressure thus produced causes little or no settling down. The particles, more or less reduced, press more heavily upon each other, increasing the number of their points of contact, but leaving between them gaps that allow the particles to change their places with respect to their neighbours, when the expansion of each particle from heat causes lateral pressure, which, instead of increasing the points of contact, only produces a natural settling of the powder.

It will perhaps be possible to explain this phenomenon in some other manner, but what is most important is the result, obtained and confirmed by numerous carefully-conducted trials. These results will, moreover, soon be publicly confirmed, as M. Roussy intends to demonstrate his invention at the International Exhibition of Inventions to be held in London next year.

WEST AFRICAN CABLE.

The largest of the great steamships specially constructed for the purpose of laying ocean cables, the "Silvertown," a vessel of nearly 5,000 tons burden, sailed on Wednesday from the Thames with the second section of the telegraph cable by which it is proposed to connect the English settlements on the West Coast of Africa with this country and the Cape of Good Hope. In three capacious tanks, 55ft. in diameter and 30ft. deep, she bears, coiled in convenient lengths, about 1,200 miles of cable manufactured by her owners, the India Rubber, Gutta Percha, and Telegraph Works Company (Limited). Although this may seem a very long piece of one of these lines for telegraphic communication with which the earth is now girdled, the section on board the "Silvertown" forms barely more than half the load the ship is constructed to carry. In laying the cables, for instance, which lie along the coasts of South and Central America and Mexico on the Pacific, from Valparaiso to the Gulf of Tehuantepec, she took for one section of that line 2,370 miles of cable in her tanks. She now steams to Teneriffe, where the first section of the proposed West Coast route to the Cape Colony, the direct cable from Cadiz, at present ends. In the first place a short cable of 200 or 300 miles will be laid to the island of Lanzarot, another of the Canary group, and then after receiving information from the staff on board the Company's cable ship "International," now engaged in taking soundings for the work in hand, the "Silvertown" will begin to pay out and lay the line to the French settlement of Dakar, in Senegal, and thence to the British port of Bathurst. From this port it is probable that before long a connection will be made with St. Jago, whence a short line already affords communication at St. Vincent with the Eastern and Brazilian Companies' lines. In view of possible international complications, it will be observed that the projected route includes stations of various nationalities, which in case of a European war we might expect to find friendly or neutral, and further, that as far as possible, alternative sections are formed. The importance of such precautions has been exemplified during the recent war between Chili and Peru by the frequent interruption of communication through the cutting of the cable by one or the other of the combatants. Loops of the projected West African cable are marked on the sketch map of the route to join Bathurst with Bissao and Bulama, and independently to link Bathurst with Freetown (Sierra Leone) and Freetown with Accra. Whether the several forts and stations of the Gold Coast Colony shall be provided with telegraphic means of inter-communication or not the Government do not appear to have yet decided. The selection of the port or ports at which the cable shall touch in order to supply the wants of the Congo region also remains to be made. A guarantee of traffic has already been obtained from the Portuguese Government, and landing rights have been granted by the Government of the Cape, and the company is now in negotiation with the Home Government, with a view to obtain a subvention for stations at Sierra Leone, and on the Gold Coast. Among a party of visitors who were invited to inspect the works of the company at Silvertown, and were afterwards entertained at luncheon on the cable ship, were the Chargé d'Affaires at the Portuguese Embassy, Sir T. Scanlen, Mr. J. X. Merriman, M.L.A. of the Cape Colony; Sir Samuel Rowe, Governor of the Gold Coast; Sir Charles Tupper, Captain D'Almeida, Royal Portuguese Navy; Mr. Juland Danvers, Mr. Alfred Giles, M.P.; Count d'Oksza, and M. Laporte and M. L. Couzy, French Government engineers.—*The Times.*

COMPANIES' MEETINGS & REPORTS.

West India and Panama Telegraph Company (Limited).

The fifteenth ordinary general meeting of this Company was held at the City Terminus Hotel, Cannon-street, on the 22nd inst., under the presidency of Mr. C. W. Earle.

The SECRETARY (Mr. R. T. Brown) having read the notice convening the meeting and the minutes of the last meeting, which were confirmed by the present meeting and signed by the Chairman as correct, the report of the Directors was taken as read.

The CHAIRMAN: The accounts for the half year show a falling off in the total gross receipts of £1,964. There is a reduction in the expenditure of £1,477, and the balance is smaller than it was in the corresponding period of last year by £487. But it must be remembered that we are comparing with a very prosperous time. Our receipts in the corresponding period of last year were £6,000 better than in the preceding corresponding half year, and they again were the best we had ever had. Therefore I do not think that on the present occasion we show any very great reduction in the traffic, notwithstanding the depression through which the West Indies are passing. It is also to be noted that there was a small item of £800 in the last year's accounts which was interest, and which does not appear this year, because the interest upon the reserves now being invested in interest-bearing stocks has been carried to the credit of reserves and figures in the balance sheet. If that amount had appeared where the similar credit appeared last year, it would convert the comparison into a small profit, not into a small loss. As to the expenditure side of the accounts, the reduction in the expenditure is attributable entirely to some exceptional charges which appeared in the corresponding accounts last year. There was an item of the expense of the missions to the West Indies, and some exceptional expenses were incurred on this side. This accounts for the comparison being in this half year's favour, because I do not think there is anything to be hoped in the way of reducing the expenditure of the Company. Every item is watched with the greatest care, and I do not see myself where any further saving is possible to be made. During the half year we have had as many as twelve interruptions to cables. Fortunately our system is almost entirely duplicated, so that most of those interruptions occasioned no loss to traffic. But there was a serious interruption to the British Guiana (Demerara) cable, which is not duplicated, and that affected our traffic for a time. There was also an interruption to the Barbadoes cable, which affected our cable for a very short time, and then the connecting cables between Florida and Havanna were simultaneously broken with the cables belonging to the International Ocean Company. That company employed our two ships to repair those two cables. It was very promptly done, but still for a time there was a certain delay—a delay, perhaps, of 20 hours in communicating with the West Indies. The progress we have made in repairing the original San Juan (Porto Rico) cable has been satisfactory. We have completed it up from Porto Rico to within 30 miles of Jamaica. The ship is now engaged in grappling for the end near Jamaica. While she was at work there the other day an intertuption occurred on the other Porto Rico cable. She therefore left the work she was on, and repaired this last mentioned interruption very promptly, and it was only five days interrupted. But at the same time a cyclone swept over the island of Jamaica, and blew away or washed away a great portion of the land line which connects the northern landing place to the town of Kingston, and consequently the Colon cable. The result of that was shown in the serious falling off in the last returns published in the papers —a falling off of 30 per cent. I am glad to say, however, that the traffic revenue of this half year is a little in excess of what it was in the corresponding half year, notwithstanding the serious falling off in the last fortnight. It is a great matter of satisfaction to us that we have been able to persuade the colonies of St. Lucia and Grenada to make the increase alluded to in the report in their subsidies to us. At a time like this, when every one is very much disheartened about the commercial affairs of the country, it is very generous of these two colonies to have given us this small increase. Just look back on what we found the state of this subsidy grant when we took office in 1874. The total nominal subsidies then were £1,680. They were very irregularly paid, however, because the lines were in a very unsatisfactory condition, and, in fact, I may say, so far as I know, that we did not get very much more than a few hundred pounds out of all these subsidies before 1874. Since then, however, the lines have been put in order, and the subsidies have been paid almost entirely. But we have been able to obtain from the colonies a total increase of those subsidies, amounting to £7,800, bringing up the nominal subsidy account payable to £24,600 instead of £16,800, which we found it. It is not a very easy thing to induce people to pay more than they have contracted to pay. There is a saying somewhere of Lord Salisbury, when he was called upon to make some foreign negotiations, to the effect that he did not like to go into the market without money in his pocket. We have always had to do that. I do not mean actual cash, but we have had nothing to offer the foreign colonies. We have been merely able to say "your subsidies are not anything like sufficient to give a fair return on the capital invested, and we beg you to increase them." Well, gentlemen, we have so far succeeded to the extent of obtaining an increase of £7,800 in that way. There are still the colonies of Barbadoes, and the group of the Leeward Islands, with the Island of St. Vincent, which adhere to their pound of flesh, and have not granted us any increase as yet. As to the foreign colonies I do not expect to receive very much consideration from them. In the first place, St. Thomas is in a very low financial condition, and perhaps it is as much as they can do to pay the £1,000 they pay us now. The subsidy expires at the end of this year, and we have applied for its renewal. The French colonies are in the same condition as to the expiration of their subsidies, and we have applied to them for their renewal, and we must wait to see what comes of the application. Unfortunately there is not a very favourable feeling between France and England now, and I should be deceiving you if I expressed myself in a very sanguine manner of getting very much more out of them than we have hitherto done. No doubt every one has noticed the amount of attention which the West India Colonies have received since last we met in this room. The commercial depression has been very striking. The price of sugar has fallen 50 per cent. Sugar we were importing two years ago at about £1 per cwt. has been down as low as 10s. 9d. on the 3rd of this month. You can easily see what a deplorable change that heavy fall must make in the great industry of the colonies which we serve, and although we have not as yet apparently suffered very much from it, we must expect that the want of prosperity on the part of those whose business we carry on must affect us more or less. I will only say that we feel very great sympathy with them at this extraordinary depression from which they are suffering. There have been many suggestions made as to remedying it. Countervailing duties, amalgamation with the United States of America, incorporation with Canada, and various other schemes have been suggested. But it is, of course, for the statesmen of this country to see whether there is any way out of the difficulty which threatens so seriously our West India possessions. There has also been a little stir about the defence of our colonies. There are two important ports in our West India region, the ports of Kingston, Jamaica, and also St. Lucia, both of which are important coaling stations, and may be more important when the Panama Canal is completed. Whether the attention of the Government will be turned to strengthening the defences of these places I do not know, but if it is one cannot conceive that telegraphic communication with those countries will not form a very large portion of the elements for consideration. We must wait and see what turns out, and all that we have to do is to try by the formation of sufficient though not extravagant reserves to keep up such a position that we can act in association with the Government in the best way to strengthen the colonies, and also if possible to improve the position of the long suffering shareholders of this Company. I now beg to move, "That the Directors' report and accounts to the 30th June, 1884, submitted to this meeting be and the same are hereby received and adopted, and that as recommended by the Board a payment of 6s. a share on account of arrears of dividend on the First Preference shares be and is hereby declared."

Mr. WILLIAM FORD seconded the motion.

Mr. CHAPLIN asked whether the Board considered it discreet to mention the amount to which they proposed to build up the reserve fund. Speaking as a debenture holder, he himself would be perfectly satisfied if it reached £100,000.

Mr. GRIFFITH said that the Chairman had stated that the land line to Kingston, Jamaica, had been interrupted, and that that interruption had caused a serious falling off in the income of the Company. He (Mr. Griffith) wished, therefore, to know whether the land line had been renewed.

The CHAIRMAN replied in the affirmative, adding that it was renewed in five days, and that they were now working at every station.

Mr. MORTON said he was a second preference holder, and he wished to know how long they were to wait for a dividend. The Company was now earning the full interest on the first and second preference shares, putting £20,000 to the reserve fund, and spending a large amount on the cables. There was a reserve fund of £80,000, and they had also a reserve of £9,000 for depreciation of ships. The total arrears of dividend now on the first and second preference shares was £64,000, so that there was really in hand not only the whole of the money to pay off all the arrears of the preference dividend, but also a considerable reserve, which might be built up every year. He would not object to forego his dividend for another year, but he could not gather from the remarks of the Chairman any hope that the second preference shareholders would be paid at all. He did not say that the Directors did not earn their fees, but he certainly objected to their receiving £2,000 a year when he received nothing. There was really £100,000 in hand which belonged to the shareholders, and he maintained that the Directors had no right to add to the reserve fund and so keep the shareholders out of their dividend. He would not move any amendment to the report on the present occasion, but next half year, if they were not treated with proper fairness, he would move an amendment with the view of their obtaining fair treatment.

The CHAIRMAN: It is just a year since that Mr. Morton brought up this same subject—the subject of the reserve fund—and Mr. Chaplin asked a question as to what extent the reserve fund was to be built up. I am not prepared to say when we shall cease adding to the reserve fund. There must always be a gradual contribution towards it. You must remember that our reserve fund is a very small one—very much smaller than that of any other submarine telegraph company in existence. When you recollect that the cables and the establishment of the Company cost £1,272,000, it is not very much to have in hand £90,000 or £100,000 to replace this wasting plant, which is depreciating every year at a certain unknown rate. I should be sorry to encourage any hope that this reserve fund is to be divided among the preference shareholders, for we depend upon it for our security, and it is that on which the ordinary shareholders rely for the reversion of their property. To divide it, therefore, would be most improper. The question of Directors' fees has been threshed out so often in this room that one would have thought that it would not be brought up again. The Directors were invited to come and manage your affairs. You never had one shilling of dividend before we came. We have done our best for you. You can dismiss us, but as long as we are here you must expect to pay us for our work. You might just as well expect to have your offices for nothing or to get the services of the staff for nothing as to expect the Directors to work for you without re-

Digitized by Google

muneration. Nothing would give us greater pleasure than to be able to pay off all those arrears, and all we can do is done by us. We found this a most deplorable undertaking, not earning a halfpenny, and a bad field chosen, with which we had nothing to do, and it has been a work of extreme labour to bring about the comparatively small success which we have been able to obtain. I do not see that there is any argument or reason for taking the small reserve fund that we have and paying it away. The whole property might collapse, and no one would have a shilling by it if we found a necessity to use that reserve fund and we had not got it.

Mr. Morton: You have £9,000 reserve for the ships.

The Chairman: The ships are depreciated. They are eight or nine years old. They were not as good on the 1st of January this year as they were on the 1st of January last year. There is a certain depreciation going on which every business man must know has to be provided for. The cables are thirteen years old, and we have £100,000 to replace what cost us one and a quarter millions.

Mr. Morton maintained that justice ought to be done to the shareholders.

The Chairman: Justice is only what you can justly get. You cannot get blood out of a stone.

Mr. Morton: But the money is there.

The Chairman: Yes, but for the repairing of the plant which is depreciated.

Mr. Morton: Well, I have given you notice of what I shall do.

Mr. Robinson Kendal though that the speech which Mr. Morton had delivered showed what a dangerous thing a little knowledge was. Mr. Morton would lay his fingers on the £90,000 reserve fund and divide it among the preference shareholders, but if they looked at the balance-sheet they would see that there was no such sum as £90,000 to divide. The Company had a debenture debt of £50,000, and surely that debenture debt was a first claim on the Company. If they deducted that amount from the reserve fund there would be only £40,000 left, which was little enough. He would not enter into a discussion with Mr. Morton as to whether the Directors deserved their fees, but he would say that the accounts showed that the Directors had given the most valuable attention to the affairs of the Company, and whether the shareholders thought of the increase in the subsidies which the Directors obtained, or of the general management of the Company, or the manner in which the reserve fund had been created and invested, it was his opinion that the Board were entitled to the best thanks of the shareholders. As the Chairman had said the Company had very poor ground to work on. Moreover, trade had been restricted and almost paralysed by reason of the great depreciation in the sugar market. When they took into account the commercial position of the islands served by the Company, and the almost destitute condition that some of them were in, the Directors were not to be blamed for the want of increase in the revenue of the Company. He believed that the Board had done their best, and that, if there was any fault to be found, they could not be held responsible. The Directors were, on the contrary, to be praised for the manner in which they had conducted the Company and built up the reserve fund, without which the undertaking would have been in a very weak condition.

Mr. Morton maintained that it was absurd to contend, as the last speaker had done, that the arrears should not be paid off.

The Chairman put the motion and declared it carried unanimously, which concluded the business before the meeting.

The Telephone Company of Ireland.

The fourth ordinary meeting of this Company was held at Dublin on Friday, 17th inst., Mr. James Winstanley, one of the Directors, occupying the chair. A letter was read from Mr. Dwyer Gray, Chairman of the Company, regretting absence through ill-health, but congratulating the shareholders on their prospects, original shareholders receiving interest at the rate of 8 per cent., with reasonable prospect of increase. He added that no real points of difference remained between the Company and the Post Office Department, and he was assured the new license would be granted in a few days. The Chairman of the meeting, in moving the adoption of the report, said that the Company had, at considerable expense, erected poles and wires to Kingstown in anticipation of obtaining a considerable number of customers there. At that moment the circuit to Kingstown was complete; and gentlemen wishing to speak round that circuit, which was 15 miles in extent, could do so after the meeting was over. It was not yet fixed where the exchange was to be; but at present anyone in Kingstown requiring a private wire could have it. They were not prepared, however, to deal with exchange customers until they had their license. As soon as that was obtained, a scale of prices would be fixed which he was sure would prove satisfactory to customers in Kingstown. The report declared the dividends of 5 and 6 per cent. to the preference shareholders, a few of the 6 per cent. shares remaining unconverted.

Mr. Joseph Bond Morgan, representative of the United Telephone Company, London, said he had great pleasure in seconding the motion. He regretted that Mr. Gray, who had worked indefatigably for the development of the Telephone Company in Ireland, and also for the promotion of telephone interests in Great Britain, had not been there to say what he had so tersely written. Under the new license he did not see why they should not be able to talk to all the towns of England, while the English towns would be in communication with each other. The other day he spoke by telephone from Liverpool to London. Experiments had taken place between Liverpool, Manchester, and Bolton, round circuits of from 300 to 500 miles; and in the North the trunk lines between Glasgow and Edinburgh were being developed and extended. A line to Brighton was also under consideration, and it was even said that with sufficient insulation they would eventually be able to talk round the world, which was no doubt scientifically true. He was sure the future of the telephone was so vast that each year they would be more and more surprised by the progress made. That Company had never been in a better position than it was at present. With regard to patent rights, they had fought and won. They held patents of all the telephones that would be of practical use, which was a source of great encouragement to them and would also be a source of immense profit.

The report was adopted unanimously, as was a vote of thanks to the Chairman, who, in acknowledging it, said that the Company had plenty of scope and plenty of money, so that they had nothing to do but to work in order to ensure success.

The Brazilian Submarine Telegraph Company.

The report and accounts of the Directors for the half year ended June 30, 1884, to be presented to the twenty-second ordinary general meeting, October 31, 1884:—The revenue for this period amounted to £76,794 17s. 6d., and the working expenses to £12,868 17s. 8d. After providing £838 14s. 9d. for income tax, there remains a balance of £63,087 5s. 1d.; to this is added £243 17s. 3d., brought forward from 31st December last, making a total of £63,331 2s. 4d. A quarterly interim dividend amounting to £19,500 has been paid, and £24,000 transferred to the reserve fund, leaving a balance of £19,831 2s. 4d. The Directors now recommend the declaration of a final dividend of 3s. per share, making a total payment of 6 per cent. for the year ended 30th June, 1884, and that the balance £331 2s. 4d. be carried forward to the next account. The duplication of the Company's entire system of cables between Lisbon and Pernambuco has been successfully completed at a total cost of £650,922 18s. 6d., of which £500,922 18s. 6d. has been taken from the reserve fund; and the balance, £150,000, has been provided by the issue of the Company's Five per Cent. Debentures for that sum. Since the last meeting, the 1874 cable between Madeira and St. Vincent has been interrupted at two points, one near the Canary Islands, and the other close to St. Vincent. The cable was repaired thirty-two days afterwards, but the interruption resulted in no inconvenience, as the second cable was laid and working, thus preventing a serious loss of revenue to the Company. The cable, which has been submerged ten years, was found in excellent condition both as regards the iron sheathing and the core. All the Company's cables are now in good working order. Two of the Directors, Sir Thomas Fairbairn and Mr. Henry Daniel Gooch, retire by rotation at this meeting, and, being eligible for re-election, offer themselves accordingly. The two auditors, Mr. Henry Dever and Mr. John Gane, also offer themselves for re-election.

NOTES.

BOOK RECEIVED—"Die Elektrische Beleuchtung," by Dr. Ernest Hagen.

TELEPHONY.—The trunk line between London and Brighton is, we understand, almost completed.

ELECTRIC LIGHT AT EASTBOURNE.—The Swan incandescent electric light has been introduced in to the library of the Grand Hotel at Eastbourne.

LECTURES ON ELECTRICITY.—Professor Tyndall's "Lectures on Electricity," translated by Joseph von Rosthom, have been published at Vienna.

BRAZILIAN SUBMARINE TELEGRAPH COMPANY.—The traffic receipts of this company for the week ending 24th October amounted to £3,454.

ELECTRIC LIGHT IN MEXICO.—It is reported that the darkness which now prevails at the town of Chihuahua, in Mexico, is about to be dispelled by some form of the electric light.

ROCHESTER, N.Y.—The Citizens' Committee have reported in favour of lighting by electricity, and the Brush Company has offered to furnish 800 lamps at 90 dollars per light per annum.

THE CHINESE TORPEDO SERVICE.—In reference to the note in our last issue, a letter has appeared in the *Morning Post* stating that Mr. Betts was not in the employ of the Silvertown Company.

ELECTRIC LIGHT ON STEAMSHIPS.—A paper on this subject, by Prof. A. Jamieson, Principal of the Glasgow Science College, is to be read at the Institute of Civil Engineers on November 11.

EASTERN TELEGRAPH COMPANY.—The Eastern Telegraph Company announce the payment this day (Saturday) of interest for the half year ending 31st ult., on their 4 per cent. mortgage debenture stock.

ELECTRIC LIGHT AT HARROGATE.—The six arc lights, fixed in the Market Hall, Station-square, James-street and Parliament-street, were started last week, and are reported to give a very steady light.

ELECTRIC LIGHT AT LINLITHGOW.—A proposal has been made to light this town by electricity; and negotiations are going on with the electric lighting companies, with a view to ascertain the first cost and expense of maintenance.

ELECTRIC LIGHT AT VIENNA.—It is said that the Vienna Municipality wishes to adopt the electric light at the new Rath-haus, but that the conditions are so hard that they prevent any electrician from going in for the installation.

LECTURES.—Mr. E. J. Bruce is announced to give a popular lecture on Electric Light and Energy at the Kensington Assembly Rooms on Tuesday, 11th November. This lecture forms one of a series to be given in the metropolis during the winter months.

WESTERN AND BRAZILIAN TELEGRAPH COMPANY.—The traffic receipts of this company for the week ending 24th October, were £2,724, after deducting the "fifth" of the gross receipts payable to the London Platino-Brazilian Telegraph Company.

SOUTH SHIELDS.—Mr. Eltringham, boiler maker, has just lighted his works by means of 12 Brush arc lamps, driving the dynamo from his shop engine. The work has been carried out by the Hammond Company, and the installation gives complete satisfaction.

WEST INDIA AND PANAMA COMPANY.—The repairs to this company's original cable between Jamaica and Porto Rico were completed on the 24th inst. By the re-establishment of this cable the duplicated telegraphic system of the West Indies is now in working order from Jamaica to Trinidad.

THE TELEPHONE IN BELGIUM.—While inaugurating the long-distance telephony on the Van Rysselberghe system between Brussels and Antwerp, the Belgian Government and the Bell Telephone Company agreed to take every precaution for maintaining the privacy of telephonic messages.

NATIONAL TELEPHONE COMPANY.—We have received the tenth issue of the list of subscribers to the Aberdeen district exchange of this company, corrected to October, and capitally got up. Besides the numerical list, there is an alphabetical and also a classified list, which greatly facilitate reference.

SIXPENNY TELEGRAMS.—On Friday, in reply to Mr. Ruston, the Postmaster-General said there was no intention to alter the decision announced by the Chancellor of the Exchequer when introducing his Budget, that the reduced rate for inland telegrams would be brought into operation on the 1st of August next.

ELECTRIC LIGHT AT HAVANA.—We hear that a few sugar houses and plantations in the island of Cuba are lighted electrically by means of Edison dynamos and Armington and Sims engines, for the ordinary motive power of sugar boileries cannot be relied upon for driving electric machines with sufficient regularity.

GAULARD AND GIBBS.—These inventors have written a long letter to the *Bulletin des Téléphones*, maintaining the correctness of the statement that, in the recent experiments between Turin and Lanzo, their secondary batteries yielded 89 per cent., and stating that this was verified by the International Jury of the Turin Exhibition.

ELECTRIC LIGHT AT CREIL.—The works of MM. Essaude Frères, at Nogent-les-Vierges, near Creil, are now lighted by six Jablochkoff candles, maintained by a self-exciting alternate-current Gramme dynamo. This has nothing to do with the plant being put down at Creil for generating current to be transmitted to Paris.

"ELECTRIC LIGHTING."—Under this title, Messrs. A. R. Sennett and Co., of Hatton-garden, E.C., have issued a pamphlet with some practical observations on electro-lighting, energy and power, the arc and incandescent systems, generators and accumulators, followed by approximate estimates for incandescent lighting and prices of their specialities.

THE POST OFFICE AND THE TELEPHONE COMPANIES.—In the House of Commons, on Thursday evening, Mr. Kenny asked the Postmaster-General if it was a fact that a proposition had been made to Government to buy up the interests of the United Telephone Company and its affiliated companies, at the sum of £2,000,000.—Mr. Fawcett said no such suggestion had been made.

CHELSEA.—We have frequently referred to the work of Mr. J. H. Stayton, in Chelsea, and regret to have to notice that he has been compelled to resign his position as engineer and surveyor to the vestry, owing to ill health. A number of Mr. Stayton's friends have presented him with a testimonial, to

Digitized by Google

show their appreciation of his labours at Chelsea during the nine and a half years he was in office.

BLACKPOOL AND ELECTRIC TRAMWAYS.—The General Purposes Committee of the Blackpool Town Council, resolved on Thursday, October 25, to recommend electricity as the motive power for the new tramways about to be laid the full length of the Blackpool promenade. These electric tramcars are intended to surpass anything yet attempted in that direction, and may be expected to begin running early next season.

TELEGRAPH CHARGES IN SOUTH AUSTRALIA.—The Superintendent of Telegraphs states that "in future cipher rate is only to be charged in the case of artificially constructed words or groups of figures, a group of five letters or figures counting as one word, but one such group making the whole message chargeable with cipher rate. Proper names or plain dictionary words, whether they have a connective meaning or not, are to be accepted at ordinary rates."

ELECTRIC LIGHT IN THE CITY.—At a meeting of the commissioners of sewers, held recently in the Guildhall, Mr. Altman, the chairman of the streets committee, replying to Mr. Deputy F. Cox stated that that committee had before them an application for electric lighting, which, with modifications, they were likely to accept. He saw no reason why the greater part of London should not be illuminated by the electric light, an announcement which was received with marks of manifest approbation.

NEW THERMO-ELECTRIC BATTERY.—Professor Riatti has devised a new battery, based on the production of electric current through the difference of temperature of two states of one and the same substance. Two copper pipes, fixed a slight distance apart, pass through the wooden or porcelain cell, containing a solution of sulphate of copper, and are traversed, the upper one by steam and the lower one by cold water. When the circuit is closed, the copper of one pipe becomes dissolved and deposited on the other.

ELECTRIC LIGHT AT THE LAW COURTS.—Of course the *Journal of Gas Lighting* chuckles over the absence of the electric light at the Law Courts on the first day of term; but our contemporary ignores the fact that the delay is totally unconnected with the electric plant, as explained in our note last week. Several of our contemporaries complain of the insufficiency of the temporary means adopted for illumination; but the electric light will only be the more highly appreciated when the erection of the motors enable it to shine forth.

THE JOHN PENDER GOLD MEDAL.—This medal, which was offered by Mr. Pender, M.P., for competition to the electrical engineering students of the Glasgow College of Science and Arts last session, has been gained by Mr. D. S. Sinclair, originally from Caithness-shire. The medal, which was designed by the Principal, and executed by Messrs. Smith and Son, jewellers, Queen-street, Glasgow, is so far novel in shape. It consists of a watch guard pendant, containing a delicate compass card, while the frame, side, and back are of solid gold.

MAGNETIC HAMMERS.—Hammers, the heads of which are magnetised so as to attract nails, for facilitating the making of rough boxes for packing fruit, are now used on the Continent. We remember using magnetised tack hammers, so long as twenty-five years ago; but, although the heads were protected by a piece of india-rubber tube, they soon lost their magnetism. Certainly, we omitted to place them at night due north and south, parallel with the main direction of the earth's magnetism, which is perhaps the reason of their failure.

INSULATION OF CONDUCTORS.—Herr Justin Malisz, chief of the telegraph department on the Galician Railway, remedies the induction from telegraph wires passing through walls, due to the condensation of vapour in the ordinary porcelain tubes, in the following manner:—He forms the insulating covering of three porcelain tubes, slightly inclined outwards, surrounded by cement, and jointed with Jew's pitch dissolved in pure turpentine, the last tube terminating in a bell on which the water of condensation drips both inside and outside.

ELECTRIC LIGHT AT GENEVA.—A central station for electric lighting has been opened at Geneva, with an Edison dynamo, driven by an Escher-Wyes turbine, and capable of maintaining about seventy 16-candle lamps. The main cables are hung on posts for a certain distance and then fixed to the walls of houses. The illumination is at present confined to the Grand Quai and a few shops and cafés; but fresh applications are constantly being made, which will necessitate the laying down of additional plant, for which municipal authorisation is required.

ELECTRIC LIGHTING OF THE BONN STATION.—This station, which is to be opened on 1st April next, will be mainly illuminated by electric light, so arranged as to avoid simultaneous extinction. Three Siemens dynamos will generate current for as many separate circuits; while a fourth dynamo, driven by a special motor, will be held in reserve to guard against unforeseen breakdowns. The exterior, entrance hall, and waiting rooms will be lighted each with a Siemens differential arc light; and the offices, &c., by 80 Edison incandescent lamps. Provision for gas will only be made in the subsidiary departments.

ELECTRICITY AT THE ANTWERP EXHIBITION.—Independently of the question of electrically lighting the interior, referred to in another note, we learn that there is to be a special committee for electric experiments at the exhibition, and that the international committee on electricity will be divided into four sub-committees with the following functions: 1. Dynamical experiments; 2. apparatus producing or requiring intense currents, including dynamos, primary batteries and accumulators; 3. conductors and means for carrying them; and 4. apparatus for producing or requiring weak currents, such as those for telegraphs and telephones.

THE TELEPHONE IN ITALY.—On 1st October the General Telephone Company of Italy absorbed its last competitor in Rome, the Roman Telephone Company; and the new Società Romana dei Telefoni ed Electricità now works the Eternal City with 1,700 subscribers. With the increased accommodation, the subscriptions have been raised to 180 *lire* (£7 4s.) for the city proper, and 300 *lire* (£12) for the suburbs within three kilometres (nearly two miles); while, beyond this distance, an extra charge of 50 *lire* (£2) is made for every kilometre, or 1,093 yards. Subscribers who use a second receiving instrument pay an additional 6 *lire* (5s.) yearly.

STENOGRAPHIC TELEGRAPHY.—We learn from *Kosmos* that an Italian inventor has constructed an appliance for telegraphing stenographic signs. The transmitter consists of two series of ten keys, each of which corresponds with a special sound, and each sending a current to the receiver, as in the Morse instrument. The receiving apparatus consists of a combination of 20 Morse receivers, provided with a style, which traces its special mark on the paper, and thus reproduces the stenographic sign. It is stated that this new instrument is capable of transmitting 10,000 words in an hour, as against 500 by the Morse instrument, 1,200 by the Hughes, and 1,800 by the Wheatstone.

Digitized by Google

ANOTHER POINT SCORED BY ELECTRICITY.—We learn from the *Mouvement Industriel Belge* that the insurance companies refused to take the buildings of the Antwerp Exhibition of next year if gas were used in the interior; and so the buildings, or at any rate the main portions, are to be illuminated exclusively by the electric light. Independently of the motive power, about 350 h.-p., it is estimated that the expense will amount to about 80,000f., or £3,200, unless the electric light companies switch on some current gratuitously. We further learn that the committee of the electrical section is actively deliberating the matter, but that the details are not yet decided, on account of the expense.

ELECTRIC LIGHT IN CARRIAGES.—We have certainly seen lately, at an exhibition in London, incandescent lamps placed on either side of a carriage instead of candles. Such lamps have also been used in one or two instances in connection with accumulators. We now learn, from our contemporary, *Les Modes*, that similar lamps are used for carriages in the Paris boulevards. They are also arranged so as to illuminate the interior of the vehicle, and in some cases a head light, with powerful reflector, is provided for the horse. The arrangement is due to M. Abailard, manufacturer of incandescent lamps, who maintains them for six hours by means of accumulators placed under the seats and charged by a Daniel battery.

PLATINUM IN RUSSIA.—The platinum mines of Russia, discovered in 1824, are near Bogoslowsk, Miask, Newjansk, and Nischnei Tagilsk, in the Ural Mountains. At six places in 1868, 1869, and 1870, from 494,000, 367,000, and 263,000 tons of sand, 6,675, 7,770, and 6,455 pounds of raw platinum were obtained respectively. The metal always contains some other substances; thus Le Play found, in a sample from Nischnei Tagilsk, 75·1 platinum, 1·1 palladium, 3·5 rhodium, 2·6 iridium, 0·6 osmiridium, 2·3 osmium, 0·4 gold, 1 copper, and 8·1 iron. The raw metal is almost entirely sold, at about £14 per pound of pure metal, to England and Paris, where it is refined before it can be worked up into manufactured articles.

TELEPHONE DIFFICULTIES AT PLYMOUTH.—The Joint Committee of the Plymouth Chamber of Commerce and the Plymouth and Devonport Mercantile Association appointed to consider the present position of the Telephone Exchange at Plymouth, Stonehouse, and Devonport, which, with their suburbs, practically form one town, has arrived at conclusions which will be embodied in separate but similar memorials from the two bodies to the Postmaster-General. The memorialists are gratified at the intention of cancelling the onerous restrictions, and that opportunities are now afforded to individual companies to apply for licenses for the formation of exchanges, but deprecate the multiplication of separate systems.

THE CREIL EXPERIMENTS.—We learn from the *Bulletin* of the Cie Internationale des Téléphones that these experiments (for which a sum of £20,000 has been set apart) for the transmission of 100 horse-power through an electric conductor have been deferred, in order to permit of every possible precaution being taken to ensure success. Those concerned in the installation have, most laudably, consented to accept only the bare reimbursement for their outlay. Only that portion undertaken by the Northern Company is complete, and this is not a matter for surprise, seeing that the machines, which are of unusual size, are being studied and executed with the greatest care, while the various accessory instruments are subjected to the most stringent tests.

ELECTRO-PETROLEO-MOTOR. — Herr Siegfried Marcus, of Vienna, has invented a petroleum motor, in which the explosive mixture is ignited by an extra-current spark produced by the interruption of the circuit of an induction coil, at the moment of its de-magnetisation or the change of polarity of the soft iron core. The ends of the coil wires, between which the spark is produced, are so arranged as to approach one another, inside the chamber where the explosion is to occur, to slide one over the other and then to separate quickly. This action is regulated, with reference to the rotation of the magneto-electric apparatus, so that the ends of the wires be in contact while they are magnetised, and separate at the moment of de-magnetisation or change of polarity.

THE ELECTRIC TRAIN AT THE FORESTRY EXHIBITION.—On Monday last, at the London Bankruptcy Court, a meeting was held for the public examination of H. B. Binko, described as of Bunhill-row, London, chemical manufacturer, trading as Binko and Co., but who ran the electric train at the recent International Forestry Exhibition at Edinburgh. At the first meeting it transpired that the train had been taken possession of by Messrs. Dyson and Co., who had seized it in respect of a judgment which they had recovered against the debtor, and who had afterwards let it to him upon a hiring agreement, under which they now claimed the train in question. It was further alleged that the debtor had taken upwards of £20 a day during the time the train was on exhibition.

CHOLERA AND THE TELEPHONE.—The Syndics of Rome and Naples have addressed letters to the President of the Italian General Telephone Company, warmly thanking him for gratuitously establishing telephonic communication between the various hospitals and cholera refuges, by means of which, in a great measure, the spread of the disorder was considerably circumscribed. The president, Commendatore D. Gallotti, in replying, pays a high tribute to Signor Ernesto di Maria, technical director of the central office, who was urged to use the utmost dispatch in placing a telephone instrument at Pendino for the Relief Committee. He succeeded in effecting communication, but could not himself reply to a message, having fallen a victim to the cholera in the discharge of his duty. Of a truth, Peace hath its victims and its heroes no less than War!

THE ELECTRIC RAILWAY AT FRANKFORT.—The towns of Frankfort and Offenbach are now connected by an electric railway, about 4½ miles long, of 39in. gauge. It leads from the old Romerbrucke, Frankfort, through Sachsenhausen, Oberrad, and through the entire town of Offenbach, the trains running over the entire route in about 25 minutes. Two steam engines, of 125 horse-power each, drive four dynamo-electric machines, by means of suitable cables, from which machines the current is conducted through suitable cables and conductors over the entire line. A switch is provided, regulating, governing, and directing the currents, as may be necessary. The conductors consist of tubes slit along their entire length at the bottom, insulated and securely fastened on poles. In the tube a small cylinder slides, from which a conductor extends down to the car and to the dynamo in the car in the usual manner. The railway was built by Messrs. Siemens and Halske, of Berlin.

THE WESTON MAMMOTH LAMP.—The *Electrical World* gives the following description of these lamps:—"The carbon filament is made by carbonising 'tamadine,' Mr. Weston's preparation from cellulose, and is made to have a resistance of from 68 to 70 ohms while hot. The lamps are run in 'multiple series,' that is to say, there are five parallel series con-

Digitized by Google

taining four lamps each. The source of the electricity supplied to each 20 lamps is a 20 arc lamp dynamo of Mr. Weston's pattern, having an electromotive force sufficient to sustain a difference of potential of 160 volts between the binding-posts of each lamp. These data, mathematically arranged, give the following equations: $\frac{160 \text{ volts}}{70 \text{ ohms}} = 2{\cdot}3$ amperes strength of current, and 2·3 amperes × by 160 volts = 368 watts = 0·49 horse-power energy of each light. It is said that the actual commercial efficiency of these lamps is 125 candle-power to each lamp, or 250 candle-power to each horse-power.

Speed of Balloons.—At a recent meeting of the Paris Society of Civil Engineers, M. de Bruignac gave the following figures of the speed per second attained by cigar-shaped balloons:—Giffard (1852), 3 metres; Giffard (1855), 4 metres; Dupuy de Lôme (1871), 2·8 metres; Tissandier (1883), 3 metres; Renard and Krebs (1884), 5½ metres; Tissandier (1884), 4 metres. The only propeller hitherto employed was the screw, which might be placed fore and aft, on the car or at the centre of resistance. It had hitherto invariably been placed in the rear of the car, until Messrs. Renard and Krebs placed it in front; but it increased the resistance when in this position. An elongated car with smooth surface appeared the best, while the net should be replaced by a smooth covering, as recommended by Giffard. The helm should be of sufficient size, not detached from the car, and placed aft. In conclusion, M. de Bruignac considered that a speed of 10 metres (33ft.) a second might be attained in the actual state of science.

Electrolysis in Preparing Indigo Vats.—F. Goppelsroeder in continuance of his researches on the use of electrolysis in dyeing and printing, gives a description of the method adopted by him for the preparation of the alkaline indigo vat. He mixes finely divided indigo with a concentrated solution of caustic potash, and fills a copper vessel half full with mixture, as also a porous cell, which is then placed into the copper vessel. The latter communicates with the negative pole of a galvanic battery or dynamo machine, whilst into the solution contained in the porous cell a large platinum plate is placed which forms the positive pole. The apparatus is then warmed gently, and the current passed through during three or four hours. At the negative pole, *i.e.*, in the copper vessel, hydrogen is liberated with the formation of much froth and the characteristic odour of the indigo vat. The indigo blue is converted into indigo white, which dissolves in the alkaline solution. The resulting yellowish-green vat is then used for dyeing cotton fabrics indigo blue.

Chrysanthemums and Electricity.—The usual Chrysanthemum Shows are now being held in the Temple; and the new varieties, distinguished by pink cards, are creating much interest among those who are able to snatch a moment during the day to visit them. But the show is limited by the fast-decreasing days. How many toilers, whether by hand or brain, would gladly inspect these choice flowers if they could do so, as at the Healtheries, after business hours. We should think some of our manufacturing friends—amateur horticulturists, perhaps—would only be too glad to send a storage battery with a few incandescent lamps to light up the show for a few hours at night. If not, the coppers dropped into a box by an appreciative public would more than pay for the temporary installation. During Mr. Bolckow's *conversazione* given to the Iron and Steel Institute at Middlesborough last year, the conservatories and ferneries were lighted up by secondary batteries sent down from London the previous day, and the novel effect was much admired.

Formation by Electrolysis of Oxy-cellulose and Chloro-cellulose.—Herr F. Goppelsröder contributes the following remarks on this subject to our *confrère*, *L'Electricien*:—"I communicate the first results which I have obtained, while seeking to modify cellulose into oxy-cellulose or chloro-cellulose by electrolysis. For instance, on immersing a cotton tissue in a solution of saltpetre, chloride of sodium, or chlorate of potassium, neutral, acid or rendered alkaline, there occurs, on placing on the top a platinum sheet as positive electrode, and causing the current to pass for a certain time, a change more or less intense, more or less deep of the cellulose, so that, after this operation, it has an affinity for certain colouring substances, methylene blue, for instance, just as if it had been treated with a mordant. On dyeing in a bath of methylene blue or aniline or fuschine green, &c., and on well washing with boiling water, all the places which had been touched by the positive pole appear of a darker blue than the other parts of the stuff, which are but slightly coloured, according to the degree of purity of the cellulose employed."

Electric Current at Berlin.—We learn from *L'Electricien* that the German Edison Company has opened its first great central station in the basement of a house in the Friedrichstrasse, for the production and house-to-house supply of current. There are four large dynamos for maintaining two thousand 16-candle incandescent lamps and three others for 18 arc lamps, each dynamo being driven direct by a 65 horse-power steam engine, making 275 revolutions a minute, steam being generated by three tubular boilers, each of 100 square meters (1,076 square feet), heating surface placed in the court-yard. The current generated by the four incandescent-lamp dynamos is transmitted by copper conductors to a central switch, which distributes it over the cables and wires of the system. Each of the latter is provided with an Edison counter for checking the quantity of current supplied to the various customers, and also with special instruments which the electrician has at his command for ascertaining if the conductors work well, if his lamps burn satisfactorily, and how many there are alight, and also regulators which permit of proportioning the current to the requirements of subscribers. Special arrangements have been made to deaden the sound of the street and from the machines.

Telephono-Thermometer.—In the *Bulletin* of the St. Petersburg Academy of Science, Dr. Lenz describes a new application of the telephone to measuring temperatures at a distance. Let two stations, A and B, be connected by two wires, one iron and the other silver, soldered at both ends. If the solder joint of A be at a different degree of temperature to that of B, a thermo-electric current will circulate through the wires. Given an interruptor and a telephone introduced into the circuit, and the telephone will speak until the observer, placed at B, raise or lower the temperature of his solder joint so as to make it identical with that of A, and in this case there will no longer be a current. The correctness of this method depends upon the precision with which the moment can be determined when the telephone ceases to speak, for a certain resonance continues after the equalisation of the temperatures at the two ends of the instrument. In the first series of experiments, the stations A and B being only distant one metre, Dr. Lenz determined the temperatures with great precision, the errors only varying between 0·01° and 0·17°. He concluded therefrom that, by the use of iron and silver wires 2 mm. thick, the observations might be extended to 5 kilometres (three miles), or even five times that distance, if bismuth and antimony wires were employed.

ELECTRIC LIGHT IN FRANCE.—The French Edison Company has lately put down plant for lighting the Cosmydor Soap Works, at Levallois-Perret, a suburb of Paris, with 50 A lamps; the works of the French Linoleum Company, at Olry, with 100 A lamps; the Hyat and Ward celluloid factory at Monville, near Rouen, with 100 lamps; the Grande Chartreuse Distillery; the Montgolfier Paper Mills; the Lemaire-Dellis Spinning Mills; and the Bucharest Theatre, with 1,500 Edison incandescent lamps. This last-named installation (we learn from the *Bulletin* of the Compagnie Internationale des Téléphones) has actually been ordered by the Bucharest Gas Company, to which the work was entrusted; while the Lemaire-Dellis Spinning Mills, which were totally destroyed by fire due to gas, have been re-erected without any provision for that dangerous and deleterious illuminant. Besides their own installation, the proprietors have put down plant for maintaining 500 incandescent lamps for their neighbours. The Edison Company is now making small dynamos for running twenty 6-candle lamps. In the installation lately put down by this company for Hatchette's publishing house in Paris, the three dynamos (one for 200 lamps and two for 60 lamps each) are arranged so that they can supply current to each other's circuit in case of breakdown in one of them.

THE INSTITUTION OF CIVIL ENGINEERS.—The council of the Institution of Civil Engineers invite original communications on any of the subjects included in a list, which may be obtained from the secretary, or on analogous questions. For these, if approved, they will award premiums, arising out of special funds bequeathed for the purpose, viz.:—1. The Telford fund, which produces £250 annually. 2. The Manby donation, of the value of about £10 a year. 3. The Miller fund, which realises £160 per annum. 4. The Howard bequest, the annual income of which amounts to rather more than £16. The council will not make any award unless a communication of adequate merit is received, but will give more than one premium if there are several deserving memoirs on the same subject. In the adjudication of the premiums no distinction will be made between essays received from any one connected with the institution (except in the cases of the Miller and the Howard bequests, which are limited by the donors), or from any other person, whether a native or a foreigner. Among the subjects included in the list we notice the following as coming more especially within our readers' knowledge and practice:—Machines and measuring apparatus for testing metals, and the equipment generally of mechanical laboratories; the thermic properties of metals commonly used in the arts, especially with respect to conductivity and diathermancy at high temperatures; mechanical power on tramways, including steam, compressed air, electricity, cables, &c.; electro-motors, their theory, practical construction, efficiency and power; on gearing for dynamo machine motors and other high-speed machines; the transmission and distribution of electricity over large areas for lighting and for motive power, including electric railways, hoists, &c.; electrical measuring instruments; submarine telegraph cables, their manufacture, laying and repair, including deep sea sounding; telpherage, or the automatic electrical transport of goods and passengers; the measurement of work by dynamometers, with descriptions of the apparatus. Instructions for preparing communications and regulations as to proprietorship accompany the list. Among the premiums awarded for the session 1883-84 we notice that the Miller scholarship was granted to Alfred Richard Sennett, Stud. I. C. E., subsequently elected Assoc. M. I. C., for his paper on "The Electric Light."

STORAGE BATTERIES.—An excellent article over the well-known initials "O. J. L." appeared in a recent number of *Nature*. The author of the article pointed to the great desirability of storage, and examined the causes of partial failure. While mentioning one of the main objections to be the loss of energy, he pointed out that where the whole energy would otherwise be wasted, the storage of even 50 per cent. is a clear gain. We benefit also by storage when a fitful and irregular supply of energy is changed to a regular and continuous supply, and again a weak supply may perhaps be stored to give for a short time a storage supply. The various forms of storage battery are considered and their weak points discussed; such are, in the positive plates, the scaling of the plates, the non-circulation of the acid, the buckling of the plates, defective contacts, &c. The author goes on to say:—"The age of plates is a point of vital interest, though but little is known as to the possibilities in this direction at present. A year may be regarded as a fair average age at the present time; but this a low rather than a high estimate. Thick plates are found to last far longer than thin, which is only natural when it is remembered that the wearing out is due to corrosion, that corrosion proceeds mainly from the surface inwards, and that the internal portions of a thick plate are to a great extent protected by the mass of superincumbent material. If it can be shown, as we understand it can, (1) that the cost of materials is far more than the cost of manufacture; (2) that the worn-out material has a market value not incomparably less than the original; and (3) that the frequency with which plates have to be renewed is not such as to cause much inconvenience; then we hold that the first stage of the durability difficulty has been overcome. Much more may be hoped for in this direction as experience increases, and it is not extravagant to hope that a well-ribbed, properly clamped, and fairly-treated thick plate may last as long as five years before it becomes disintegrated." Another point of great interest, and one too often overlooked, is thus stated:—"It is not to be supposed that one type of cell will answer every possible demand. A dynamo to be highly efficient must have a large and massive field magnet, but in some places bulk and weight are fatal objections, and in these places smaller and more compact dynamos may be more suitable; something, however, must be given up to secure the required lightness and compactness, some sort of compromise must be effected. Just so with cells. We can point out what is theoretically the best form, and this form may, for large stationary electric light or power installation, be actually the most suitable; but we may also see that for boats, for tramcars, and for fish torpedoes, some very different and far more compact form may be quite essential." After a similar but short discussion of the negative plate the article concludes:—"The subject of the electrical storage of energy is really one of national importance; it is comparatively a small matter whether this or that form of storage, or this or that company of manufacturers, succeeds in bringing out the permanent form. It sometimes unfortunately happens that enterprising pioneers only clear the way, and retire just in time for other men to come in and reap the fruits of their labours. So much capital and so much labour have been already expended in the effort to bring storage batteries to perfection, so great progress has been made, and so apparently small are the steps which yet remain to be accomplished, that we may surely fairly hope that some of the original believers in their great, and as it seems to us inevitable, future may yet live to see their faith justified and their patience rewarded, and may even taste some of that so-called 'substantial' reward without the hope of which great commercial enterprises would never be undertaken, and modern civilisation would have scarcely yet begun."

NEW UNIPOLAR DYNAMOS.

BY JNO. M. M. MUNRO.

So-called unipolar dynamos occupy a position in the electrical world similar to that of rotary engines in the world of steam. Theoretically they are very perfect, but practically they are very difficult to construct. At least, the E.M.F. of all the forms hitherto tried has been so low as to make the machines useless for nearly all every-day purposes. I am not aware that any one has tried the device of running two armatures in contrary directions.

Some three or four years ago I began some experiments in this direction, but had to lay them aside for others of more immediate practical use. My chief aim at that time, however, was to construct a dynamo in which the mutual action of two armatures, either with or without iron, and running in opposite directions (or one stationary the other moving), would

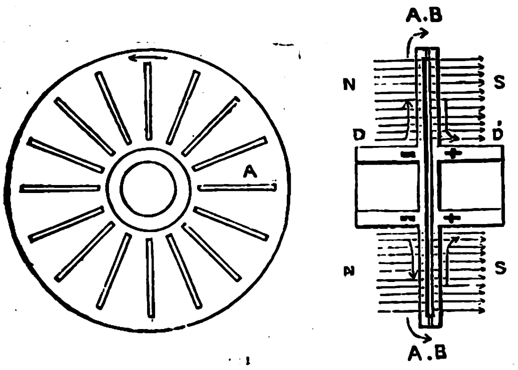

Fig. 1.

supersede the usual armature and field magnet. Each armature was to act as field magnet for the other, residual magnetism being represented by the earth's field or a small current from a cell. I became convinced, however, that although such machines might be interesting, the slight gain in efficiency would not compensate for the various disadvantages. Probably the same remark applies to the proposed unipolar dynamos, which I will now describe.

The field is produced by two long massive E magnets. The pole pieces consist of a great number of soft iron rods screwed into the poles of these magnets. In some forms of these dynamos

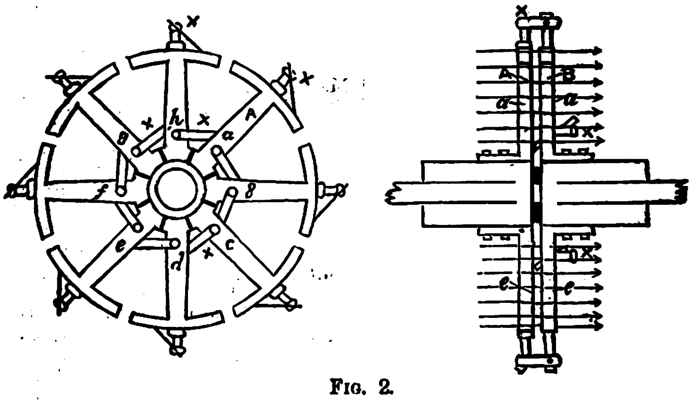

Fig. 2.

the armature is cylindrical, but the radial forms will be the more easily described. The rods forming the E magnet pole pieces take in the mass the form of circles corresponding to the armature, and this circular bundle of rods has a few turns of wire wound round and within it to reinforce its magnetism. The faces of these circles approach each other north against south, producing a very intense uni-directional field in which the armature may revolve. In Fig. 1 consider armature as two copper discs slit radially to avoid eddy currents, but continuous round inner and outer edge. These are suitably mounted and rotated in opposite directions. As in all armatures, the currents react on each other, in this instance favourably and unfavourably alternately, but the E magnets abundantly overpower all such action. Projections P P′ from the inner edges of armatures form the terminal poles from which the current is drawn, as well as drums by which they are driven. The outer edges run against each other. In this way the E.M.F. is double that of a single plate, for the current flows from the negative pole outwards in one armature, A, passes into the other B at its outer edge, and thence inwards to the positive pole. It would be possible by more complicated arrangements to increase the number of these discs, and therefore the E.M.F., but I will describe more simple ways of attaining this end. Thus the armature in Fig. 2 has its discs built up of separate insulated radiating bars. Contact is made by brushes X and other appliances between the outer end of each bar of A armature and the outer end of the nearest bar of B armature. The inner ends are similarly united, but the connection is made not to the nearest bar of A, but the one next it. In this way there is a continuous circuit right round the two rings; outwardly in *a* bar of A,

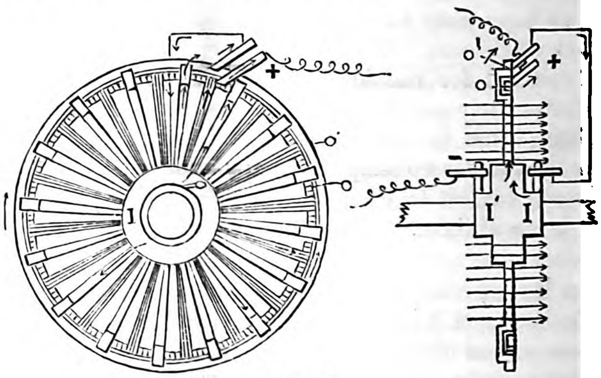

Fig. 3.

inwardly in *a* bar of B, across to and then outwards in *b* bar of A, then at outer end into *b* bar of B, and thence downwards, then into *c* bar of A, and so on. Of course the the necessity of having so many sliding contacts neutralises one of the chief benefits of a unipolar dynamo. At a certain point in the circumference the continuity of this circuit is broken, and the two ends are connected to two rings not shown, one running with each armature, and these rings form the two poles of the combined armature.

In Fig. 3 we see only one disc, two outer rings, O O′, and two inner rings or bosses, I I′. The radial bars are connected to

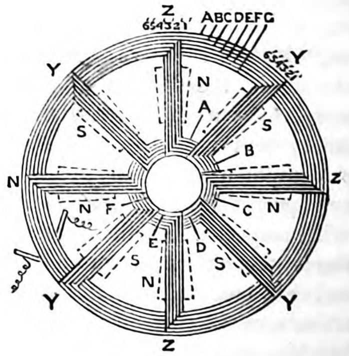

Fig. 4.

the one or other of these alternately. The current enters by I′, passes outwards along every second bar into ring O′, thence by brushes (which may be numerous to reduce resistance) and wire to I, and then outwards in the remaining bars to ring O, and thence to external circuit. If higher E.M.F. is required more rings may be added. The two machines next described hardly fall within the scope of the title of this article, yet they are in many points closely related.

In machine Fig. 4 we no longer use "unipolar" currents, but two crowns of *b* magnets similarly arranged to those of Siemens's alternate current machine or the Thomson-Ferranti. The armature consists of groups of radial bars equal in number to the E magnets on each side. There must be as many inner rings as there are bars in the group, and of the outer

Digitized by Google

rings there must be one more. Each group is always cutting through a field of opposite direction to that through which the contiguous groups are passing, and the currents in any two neighbouring groups, therefore, are always flowing in opposite directions. Let it flow inwards from ring A in No. 1 bar of groups marked Y; it will then flow from these round the outermost of the inner rings, marked A′, and thence outwards in No. 1′ bars of groups Z. But these bars do not reach to A but only to B. This puts them in series with No. 2 bars of Y, which descend to B′. From B′ spring bars No. 2′ of Z, and these end in C ring and so on. Rings A and G form the terminals of machine. The currents are alternate. The arrangement for continuous currents is not so easily shown by a diagram. There are more rings and more bars and fewer magnets. The inner rings are furnished with projecting pieces so disposed that they form an ordinary sectional commutator with a gradual

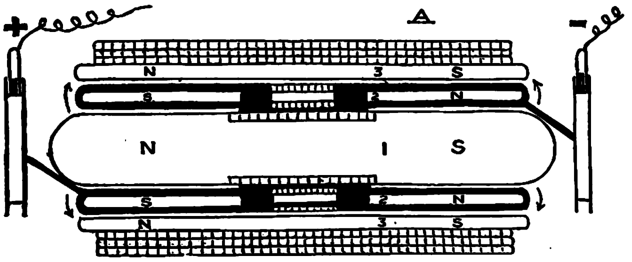

Fig. 5.—Longitudinal Section.

fall of potential in the contact plates both ways from the positive to the negative sides. Only one pair of brushes are necessary, as parts that are at the same potential are always connected together by the same rings. Figs. 5 and 6 show a unipolar dynamo. 1 is a round E magnet with a depression in the central third of its length in which is wound a layer of wire (wire being always of rectangular section). When the other arrangements of the machine permit, a second layer of wire is wound upon this in the more central part. Around this is constructed a cylinder composed of long straight bars of softest iron 3.3. These bars are magnetised by layers of wire wound across them individually, but around the cylinder, and concentrically with the surface of the round magnet 1. In the space between the cylinder 3 and the round magnet 1 the armature, also cylindrical, revolves. The core 2 of the armature consists of iron rods similar to 3 except that

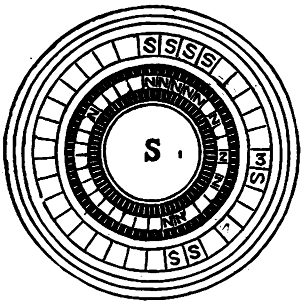

Fig. 6.—Transverse Section at A.

at two points, situate fully two-thirds of the way from the ends to the middle, they have slots cut in their sides so as to allow the conductors to pass from their inner to their outer surface. These slots are not deep, but are of considerable breadth, the conductor at this point taking the form of very thin broad plates, suitably insulated with mica and paper. The conductors on either end of these magnets are arranged so that they form a continuous spiral, just like two Gramme rings. The broad black lines are the conductors. The one end of the left hand spiral is attached to a ring which forms the positive terminal. The other end is connected through the right hand spiral to the negative ring. The magnets of armature may have wire wound round their middle parts. This cylinder, 2, of E magnets forming the core may be fixed, but that construction is most difficult, and I do not think that their motion will be injurious to the working of the dynamo. Of course there is no changing of its magnetism as it rotates. The armature is rotated by means of drums, to which are affixed bars which pass along the armature, or, if preferred, clasp the armature by its ends suitably insulated. With a different form of outer magnets the armature can be driven by its middle part.

ELECTRIC TRANSMISSION OF POWER IN MINES.*

BY PROFESSOR W. S. SCHULZ.

The author deduces from the executed electrical transmissions of power tabulated below that the maximum electrical efficiency of the receiving dynamo practically attainable is 50 per cent. of the transmitting motor:—

Name of Pit.	Power of Motor.	Machine Driven.	Length of Lead.	Efficiency.		
				Electrical.	Mechanical.	Total.
	h.-p.		Metres.	P.c.	P.c.	P.c.
La Peronnière, near Rive-de-Gier ...	37·1	Hauling-Machine	1,500	50·0	37·0	30
Thibaut, near St. Etienne	5·0	"	250	45·0	38·0	25
Blanzy	17·0	"	634	...	51·0?	30

"	5·0	Fan	780	50·0	26·0?	...
St. Claude, near Blanzy	8-10	"	900	...	...	...

On this basis he compares the cost of electrical transmission of power with the actual cost of transmission by compressed air and water applied to rock-drills and coal-getting machines, locomotives, cable and rope-hauling machines, and ventilators, and finds the former more costly than other methods, except where air is compressed by steam power without being cooled, and in the case of locomotives for haulage on levels. The comparative cost of such haulage in actual operation is given in the table:—

Underground Haulage by Locomotives.

For the separate ventilation of a lateral drift of the Zaukeroda mine† a 40in. Schiele fan is used, driven by a Siemens dynamo actuated by a Dolgorouki steam engine; the cost per 1,000 cubic metres is 0·27d., which is cheaper than transmission by compressed air only where a special compressing plant for the small fan has to be put down. The author concludes that there is no field for electrical transmission in mining, special cases excepted, except for hauling on levels by locomotives, which could advantageously replace rope or cable-haulage.

ELECTRICITY AS A MOTIVE POWER ON RAILWAYS.*

BY BARON GOSTKOWSKI.

The author first inquires into the use of primary batteries (instancing Page's locomotive, 1850), and then into the use of accumulators, and showing that they cannot at present be used for ordinary railways on inclines on account of their weight. He then passes to the cases in which the current goes direct to the electro-motor on the locomotive first introduced by Siemens (Berlin, 1879). In this case the current passes from the two rails through the wheels. In the case of the electric locomotive at the Paris Exhibition (1881), and the recently-opened line between Mödling and Brühl, the current passes to the electro-motor through a copper tube the whole length of the line, in which slides a piston which the car draws along with it. On the Portrush Railway there is a third rail, on which runs a contact wheel forming the positive lead, the two running rails forming the negative. Which of these three systems is best yet remains to be seen. The following applies to all. The mechanical work necessary to supply a current of C amperes and E volts is—

$$\frac{C.E}{g} \text{ kilogrammetres,}$$

where g is the acceleration = 9·81 metres. The available work of the motor will be

$$\frac{C.e}{g} \text{ kilogrammetres,}$$

where e is the electromotive force at the motor. The loss of work is $\frac{C}{g}(E - e)$ or R being the total resistance,

$$\frac{C^2.R}{g} \text{ kilogrammetres.}$$

The object is to minimise this loss. This is to be done, supposing R constant, by making C as small as possible. This entails a high electromotive force, which involves better insulation, and so increases cost. It is thus seen that the values of C and e must be so chosen as to make the cost as small as possible.

It is found that about 30 per cent. of the work is lost. This, taken in connection with the result of experiments made in the Paris workshops of the Northern Railway of France, gives

$$\frac{e}{E} = a = 0{\cdot}83.$$

If, then, p is the work furnished by the motor in kilograms per second

$$\frac{C^2.R}{g} = 0{\cdot}3p,$$

but $$C = \frac{E - e}{R} \text{ and } \frac{e}{E} = 0{\cdot}83,$$

therefore $$E = 10\sqrt{p.R} \quad \ldots\ldots \quad (1)$$

Further, according to Uppenborn, it is best to have the internal resistance $\frac{3}{7}$ of the external resistance.

And if r_1 = resistance of generator,
r_2 = " motor,
r_3 = " conductor,

$$r_1 = \frac{3}{7}(r_2 + r_3).$$

If similar machines are used for generator and motor

$$r_1 = r_2,$$

in which case $$R = r_1 + r_2 + r_3 = \frac{5}{2} r_3.$$

If 1 kilogram of conductor has a resistance of $\frac{1}{5}$ ohm, and the distance between generator and motor is l kilometres, then (allowing for two conductors),

$$r_3 = \frac{1}{5} \cdot 2\,l = \frac{2}{5}\,l,$$

in which case $$R = \frac{5}{2} \cdot \frac{2}{5}\,l = l \text{ ohms,}$$

substituting in (1) $$E = 10\sqrt{p\,.\,l} \quad \ldots\ldots \quad (2).$$

From this the electromotive force can be calculated for a line l kilometres in length, where p kilogrammetres per second must be supplied.

For an electric railway, where the motor is required to do as much work as a 300-cheval-vapeur (295·89 H.P.) steam engine on an ordinary railway,

$$p = 300 \times 75 = 15^2 \times 10^2 \text{ kilogrammetres,}$$

and from (2) $E = 1{,}500\sqrt{l}$ volts.

On a line 4 kilometres long, therefore, an electromotive force of $1{,}500\sqrt{4} = 3{,}000$ volts would be required, a tension which could scarcely be permitted. Assuming the practical maximum at 500 volts, there would be required in a line 4 kilometres long at least $\frac{3{,}000}{500}$ = six generators and as many motors, which would be far from economical. It is for this reason that the lines at present made are only short.

In the case of an engine worked by accumulators, the weight of the accumulator was found to prevent their advantageous use on ordinary railways; in this latter case, however, the limit is the difficulty of insulation.

* *Proceedings* Institute Civil Engineers.

THE PHILADELPHIA EXHIBITION.—V.

(FROM OUR SPECIAL CORRESPONDENT.)

PHILADELPHIA, OCT. 10.

The Electrical Exhibition is to be closed to-morrow evening. It has been very successful, and has already more than paid all expenses, including the erection of the building at a cost of $35,000. It is probable that there will be a cash profit of $20,000, and the Institute will hold the building for a few years for the purpose of giving other specialty exhibitions. It is not a permanent structure, but may outlast two or three exhibitions, giving a chance to make larger profits. The Institute has also gained by the display of a library on electricity comprising about 2,000 books and pamphlets, and quite a large museum of electrical inventions and models.

The examiners are much behind time with their work, and the engines will be kept at work for two or three weeks after the close of the Exhibition to enable them to make their tests. There are already signs of trouble. Some of the reports are being made up, without tests, on the judgment of the examiners, based upon statements of exhibitors. These are likely to be rejected by the full Board. There is a strong feeling now amongst the engineers who have spent time in making careful tests to call a special meeting of the full Board, and have a resolution adopted refusing to make or publish any reports except such as are based upon actual trial by the sub-committees of the Board of Examiners. If this is done it will add a great deal to the value of the reports. The exhibitors are getting very nervous over the matter, some because of faults in their machines, which they recognise, and others because they have not full faith in the ability or methods of the examiners. This, however, is an old story of exhibitions where competitive trials are made. The Board of Examiners, it may be said, is constituted of fair-minded men, and a large majority are fully competent to make the tests.

Of the Exhibition itself it is to be said that it has been very well managed throughout. A distinguished English electrician says that though it cannot be compared with the Exhibitions

Digitized by Google

of Paris or Vienna with respect to size or expensiveness of exhibits, and is not, properly speaking, an international exhibition, it is nevertheless of greater scientific interest than any previous electrical exhibition, and a finer display with respect to variety of inventions than any nation of Europe could organise.

Some weeks ago I wrote to you about a mysterious lamp in the Edison exhibit, which was supposed to show conductivity in a vacuum. It had, your readers will remember, a third electrode (a platinum strip) within the loop of carbon, but separated therefrom. A current being passed through the lamp, and connection made between the positive pole and the platinum through a galvanometer, strong indications were given of the passage of a current, the space between the carbon and the platinum becoming in some way a part of the conductor. When connection was made in the reverse way the deflection of the galvanometer was scarcely appreciable. It is now supposed that the phenomena is due to a Crooke's bombardment, and that atoms of carbon bombard the platinum and furnish the conducting medium. To account for the smallness of the deflection when the reverse connections are made, it is pointed out that the platinum offers greater resistance to the action of the current than the carbon. Edison has prepared another set of lamps. One of these has a horizontal tube leading out from the side of the bulb opposite the filament. The platinum electrode is placed at the end of the tube. The bombardment (assumed) is direct, and the galvanometer shows the passage of a current. Another lamp is precisely similar, except that the tube is bent at right angles, and the platinum electrode is thus removed from the direct line of bombardment. The galvanometer shows no current between the carbon and the platinum.

A great variety of underground systems for electrical conductors is shown. Nine-tenths of them are mere mechanical contrivances to provide a hole in the ground through which insulated wires may be laid. Some of them are very ridiculous. One that I call to mind has great plates of hammered glass separating a copper trough into compartments. The glass slabs, placed 4ft. to 6ft. apart, are pierced with holes, through which the wires are to be strung. It is needless to say the inventor presents no estimate of cost. Another contrivance is an arrangement of iron curbs and gutters which form covers to a subway. The only system electrically complete in itself is that of David Brooks of this city, who has, I believe, four miles of his pipe laid in London on trial. In this system cotton covered wires in cable form are drawn through small iron pipes, which are then filled with paraffin oil, which is kept under pressure by being connected with reservoirs placed at the high points of the system. Mr. Brooks has eight miles of this conduit laid down in this city, through which telegraph and telephone wires have been worked for several months. Since the Exhibition opened he has made a contract with the Western Union Telegraph Company to put all its main lines in this city underground.

One of the deficiencies of the Exhibition has been the want of an electric railway. A miniature line was laid down, but of an untried system. Another railway of full size has been laid on Thirty-second Street within a few days, and is to be opened to-morrow—the last day of the Exhibition. It is to be run by a Griscom motor of 15 horse-power. This motor differs from his small sewing machine motor in having a Gramme ring in place of a Siemens armature. The magnet is of the ring form, It is an entirely new machine, and is to be put in operation at this late day only to secure tests. Connection is made with one outside or running rail, and a central rail used only as a conductor, not through the wheels, but by means of brushes.

Drawbaugh's exhibit of telephones attracts a great deal of attention, and is rather amusing than otherwise. All the telephones owned by the Bell company are duplicated in this collection, and are alleged to have been invented prior to 1876, the carbon transmitter as early as 1864. The queer part of it is that Drawbaugh apparently abandoned perfect instruments to experiment with others, and has finally patented twenty-two carbon transmitters, no one of which is as good as his original device, which he did not patent.

ELECTRICITY AT THE BREWERS' EXHIBITION.

We were pleased to find that electric lighting was carried out to a larger extent at the Sixth Annual Brewers' Exhibition, held last week at the Agricultural Hall, than it had been at the Dairy Show, held a fortnight previously. What is wanted, however, is a comprehensive installation for thoroughly illuminating the whole premises, where one show or exhibition follows another in quick succession. In view of the rapidly approaching Cattle Show, the Agricultural Hall Company should invite a few leading electricians to send in a project and estimate for thoroughly illuminating the building. And now that so much plant is set free by the close of the Health Exhibition, and this great means of keeping the various systems before the public is at an end, the offers should be very low, if not absolutely gratuitous, as, during the Cattle Show, there will be motive power in abundance. It is well known that some of the abnormally fat beasts have before now succumbed to the London fog; and it seems no more than humane to adopt any means for preventing unnecessary vitiation of the atmosphere.

But, to return to the Brewers' Exhibition. The Electric Lighting Supply and Fitting Company, of York-street, Westminster, whose arrangements to afford light in darkness at the Dairy Show had been to a considerable extent frustrated by disappointment in their motive power, had this time provided themselves with one of Marshall's portable engines of 12 horse-power nom., which drove three Franklin dynamos and an exciter; but even on this occasion we noticed that some of the incandescent lamps were not giving out their full quantum of light. One 1C Franklin dynamo, making 1,800 revolutions a minute, gave out 300 volts at 20 amperes, and fed five Brockie 2,000-candle arc lights, of which two illuminated the stand of Sir Joseph Causton, Sons, and Co., printers. Two C2 Franklin dynamos at 1,800 revolutions, giving 140 volts at 35 amperes, maintained sixty 20-candle 100-volt Swan incandescent lamps. The field-magnets of the three machines above named were excited by a 1B Franklin dynamo giving, with 1,800 revolutions, 200 volts at 20 amperes. The incandescent lamps, distributed about the stands of several exhibitors, were provided with porcelain reflectors. In addition to the current produced by the dynamos, two Holmes-Burke primary batteries of 7 cells, giving 25 volts at 20 amperes, maintained twelve 10-candle 20-volt Swan incandescent lamps, fitted to the gas pendants of Messrs. Borroughes and Watts' billiard tables, supplied for the tournament. Moreover, two Holmes-Burke primary batteries of 5 cells, giving 18 volts at 20 amperes, supplied the current for lighting the stand of Messrs. Haselgrave and Co., of Leeds, by four 10-candle incandescent lamps, and also for working their patent registering meter for wine, spirits, &c. In this ingenious appliance for preventing the surreptitious abstraction of liquors, a gauged and graduated reservoir is fitted between the cask and the tap. The action of opening the latter closes the circuit, which, however, is interrupted by the ebonite portion of the scale on the reservoir, the metallic divisions only causing the counter to register. Closing the tap interrupts the circuit to the counter, but sends a current through the electromagnet which attracts its armature attached to the float, and so draws it up ready for the next flow and registration. The proprietor switches off the current at night, and thus prevents the possibility of liquor being drawn off; and any tampering with the apparatus also stops the flow.

The British Gas Engine and Engineering Company, Albion Works, London, ran one of their 3½ horse-power horizontal compression gas engines, at 80 revolutions a minute, driving a Gramme dynamo, which maintained twenty-one 20-candle incandescent lamps on their own and the adjoining stands. The light was remarkably bright and steady; and it is claimed that this gas engine (Atkinson's patent), with circular revolving slide-valve, giving an ignition at each revolution, is the only one that will drive a dynamo with sufficient regularity for direct electric lighting, unless there be a heavy fly-wheel on the dynamo, which necessitates working with a slack belt, thus sacrificing one-third of the power.

IMPERIAL DEFENCES AND THE TELEGRAPH.

We have shared with the rest of the English public the anxiety created by the revelations of the *Pall Mall Gazette*, and we share, too, the general desire that steps may be speedily taken to remove all ground for apprehension with respect to the preponderance of our fleet or the security of our coaling and naval stations. But when the author of those startling articles came to his concluding remarks, we were somewhat amazed at the recommendation placed first on his list, though we could take no exception to the rest. We had, in fact, felt some alarm on our own account, so to speak, and had wondered that among the unprotected objects of national possessions and commerce referred to by the writer he had made no serious mention of telegraph cables. We had thought that they were a subject of great solicitude, demanding some of that protection which the commerce of the nation would certainly obtain in time of war. But the writer has apparently regarded them simply as aids to warlike defence, and only incidentally as things requiring to be protected. Here are his exact words, copied from the *Pall Mall* of 17th October:—"I will therefore summarise what ought to be done: a telegraphic cable should be laid down connecting West Africa and the Cape direct with England. All our telegraphic communication with South Africa passes through Suez, and would be intercepted in case of war. From the Cape, cable communication should be established with India and Australia. A cable should also be laid to Bermuda. The telegraph stations where the cable touches ground should be placed within fortifications; and this of course applies equally to the English end of the cable. At present a single boat's crew landed at Port Darwin could sever Australia from communication with England, and keep all our commanders in the southern seas in total ignorance, until the mails arrived, whether we were at war or peace."

We wish we could share the *Pall Mall* writer's apparent confidence in the utility of these measures for the purposes of defensive warfare. They strike us, on the contrary, as multiplying the causes of anxiety; and although we by no means deny their usefulness, we do say that they add to the necessity for increasing our naval strength for their protection, just as it is admitted, except by political partisans, that every increase of our maritime commerce demands a proportionate augmentation of our fleet. The notion, fostered by niggardly administrations, that the navy is intended only for our defence against invasion has been happily blown to the winds by the discussion arising out of the *Pall Mall's* revelations; but it ought not to be lost sight of that submarine cables, regarded either as an indispensable medium of trade or as valuable British property, are entitled to the protection which our shipping and colonies would receive as a matter of course. That these cables would be safe in deep sea or be rendered so by landing them under fortified places we cannot admit for a moment. Where this may be practicable it ought to be done, and such an incident as that pictured as happening at Port Darwin should be put out of the range of possibility. But, as has been pointed out by Sir James Anderson, a fortification could afford no sort of protection beyond the range of its guns, and to rely on such an expedient would be as foolish as to fasten your orchard gate in order to keep out the birds.

In respect, however, to the advisability of duplicating our cable systems, or rather increasing the number of alternative routes and their points of landing, there can be but one opinion, especially if secrecy could be maintained with regard to routes of some of them at least, and their points of landing. This brings us to the question of Government responsibilities in respect to submarine telegraphy. It is certain that cables ought to be laid to every naval and military station of importance, irrespective of the traffic that is likely to pass over them. Unless the Government undertake this on their own account they must, in such cases, subsidise the private undertakers. When, however, we see on our own shores places, which on military grounds ought to have a telegraph, still left in a worse position than they were in the days of semaphore and beacon, simply because the Postmaster-General does not consider that the traffic would be remunerative, the prospect of seeing the *Pall Mall's* programme carried out is, we fear, somewhat remote. But Sir James Anderson does the *Pall Mall* writer perhaps less than justice in respect to West African and Cape cable suggestions. Evidently they are intended as alternative routes to South Africa and India, on the assumption that the Suez route would be instantly interrupted on the outbreak of war. Sir James declares, with a vigour that is quite refreshing in one who disclaims being a Jingo, that "we are not going to give it (the Suez route) up until we are thrashed out of it." We think so too, notwithstanding Mr. Gladstone's declarations to the contrary not more than five years ago. But the *Pall Mall* distinctly asserts that the cables, if not the commerce, would be intercepted; and if this be the case it only strengthens the need for further defensive appliances in that part of the route to our Eastern Empire.

This indeed is a matter of first importance, more so even than the laying of a cable, or a series of cables, along the West African coast, especially if that scheme is to take the shape set forth in *The Times*, and reprinted in our last week's issue. *The Times'* view of "international complications," when

Digitized by Google

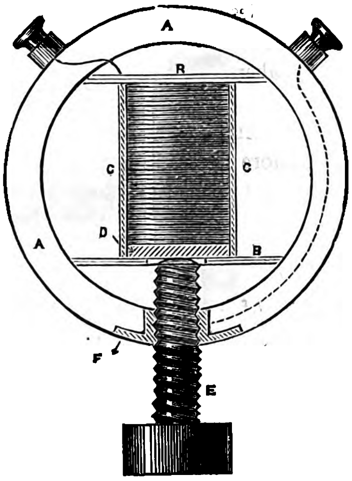
it has a scheme to back up, is highly original. Warned by what happened during the war between Chili and Peru, says *The Times*, the projectors of the West African cable are going to start it from Spain, then touch at various French ports and Portuguese islands or colonies before it is finally planted on British possessions. As we have recently been quarrelling with Portugal about the Congo, and may any day have a fight with France, the avoidance of international complications by this arrangement is not apparent to anybody outside Printing House-square. It seems to us exactly the way how not to do it; and if it be true, as was announced in the *Daily News* last Thursday week that "proposals have been made to the Government for the establishment of telegraphic communication with the West African colonies," we hope that some better arrangement than the one described in *The Times* will be adopted. We are greatly deficient in governmental responsibility as it is. It would be the height of folly to accept responsibility for the benefit of our possible enemies. We should prefer to learn that the proposal referred to by the *Daily News* is the one which has long been submitted to the Government for putting British possessions directly in communication with existing British cables in proximity to the western shores of Africa, and which would be free from most of the objections of the other scheme. What we are in want of just now, however, is a frank recognition that British submarine cables are part and parcel of the British Empire, and require to be guarded and defended like all other vulnerable points of our imperial possessions.

CORRESPONDENCE.

THE ROUSSY ELECTRIC LIGHT MODERATOR.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: In the autumn of 1882 I constructed a carbon resistance switch for incandescent lamps. The switch was roughly made, as in the enclosed sketch, in which A was a turned



wooden box of about 2in. diameter by 1in. in depth, having two brass shelves, B B, between which was placed a short length of gauge glass, C, filled with carbon resting on a circular plate of brass, D. Through a hole in the bottom shelf B passed a screw, E, working in a nut, F, inside of box and having a milled head for adjustment, the terminal attachments being to top plate B and nut F. The switch was designed with the double object of enforcing a very gradual switching out of any incandescent lamp with which it might be in circuit, and, within certain limits, of regulating the amount of light given off by the lamp. I first tried thin carbon plates, afterwards finely-broken pieces of carbon, which arrangements I now see are styled respectively the "Stanley" regulator and "Roussy" moderator. For my own part I copied it from the well known Brush regulator, and found both arrangements of carbon to fail in their action as regulators, owing to the cause mentioned in your description of 25th October. It will be interesting to learn the exact means by which M. Roussy has overcome this difficulty.—Yours, &c., R. E. DUNSTON.

27, Gaisford-street, Kentish Town, October 26.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: With reference to your article in *The Electrician* of the 25th inst. on the Roussy electric light moderator, I beg to inform you that I designed the same apparatus about three years ago, and it was used by the Duplex Electric Light Company. As regards permability of resistance its performance was perfectly satisfactory, but, owing to improvements in generator, its services were dispensed with.

I found by experimenting that carbon in a granulated form (granules about the size of hemp seed) was the most suitable. I first tried discs and experienced same difficulty as in the Stanley moderator. I discarded powdered carbon on account of the difficulty in adjusting it, the smallest alteration of tension considerably affecting its resistance.—Yours, &c.,

ST. GEO. W. DAVEY.

Sheffield, October 29th, 1884.

THE ELECTRIC ENGINE.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: With reference to the electric engine illustrated in *The Electrician* last week, may I be allowed to point out that these engines may be obtained in several ways other than by purchases from the Coalbrookdale Company? The following recipes for their production may be useful:—(1) Take an improved Brotherhood engine; remove two of the pistons and piston valves, and drive the governor by a belt. (2) Take a Westinghouse engine, and admit exhaust steam into the crank chamber, having previovsly disconnected one of the working pistons. (3) Take a Willans two-cylinder compound engine, and work it always as a simple engine; a connection must also in this case be made between the crank chamber and exhaust pipe, so that the escaping steam may have free access to the bearings.

Any of the above arrangements will apparently make an electric engine, and the parts removed will always be useful as spare gear.—Yours, &c., J. W. WILLANS.

Thames Ditton, Surrey, October 27.

THE EARTH AND ITS RELATION TO TELEGRAPHY AS A *RETURN* WIRE.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: There appears to be a considerable diversity of opinion as to the action of the earth in a telegraph circuit.

Mr. Culley quotes Gavarret's explanation, which in effect treats the earth as a huge reservoir, &c.

In Mr. Sprague's valuable work, "Electricity: its Theory, Sources, and Applications," the theory laid down seems to me to be far more feasible. He concludes that the earth really acts as a conductor without any appreciable resistance, and in thinking this out an idea struck me—that, suppose a long wire giving no appreciable resistance were carried all over the telegraph world, and all the earth wires instead of being joined to earth were joined to this wire of no appreciable resistance, what would be the result?

On the face of it, it looks as if the circuits would be in a state of confusion; but a little thought, I believe, will lead to the conclusion that though all the circuits were joined to this wire they would work perfectly independently of each other, because at the points of junction of the different circuits there would be *no resistance*, and therefore no divided current, and we should have a system *entirely insulated* from the earth but acting (to my mind) precisely in the same capacity.—Yours, &c.,

HEALTH EXHIBITION.—XI.

The PILSEN ELECTRIC LIGHT COMPANY have had a very important part assigned to them in the lighting of the Health Exhibition. The success with which they have executed their work, and the satisfactory manner in which they have maintained their large installation, render the latter worthy of notice. It offers many points of interest to the engineer and the electrician. As an example of progress it claims attention, inasmuch as it includes several novelties, the outcome of experience, and exhibits, partly in consequence, that degree of completeness for which the Bethnal Green installation of the same company is remarkable. The distinctive features of this exhibit will be best understood by setting them out in order.

The dynamos are of the Schuckert type, but the design and construction have been materially modified by the electricians

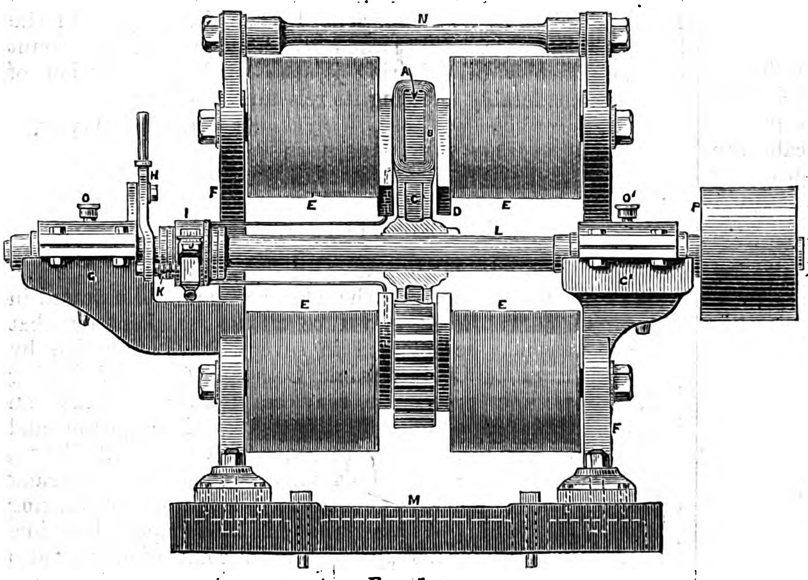

FIG. 1.

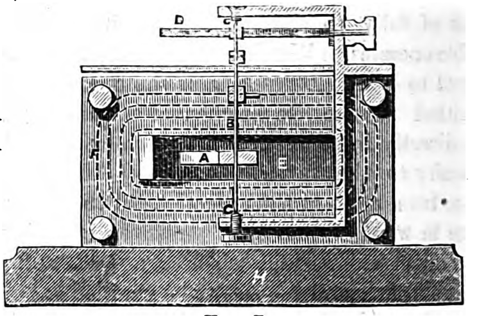

FIG. 3.

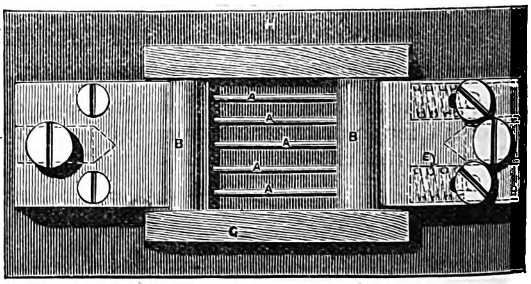
FIG. 4.



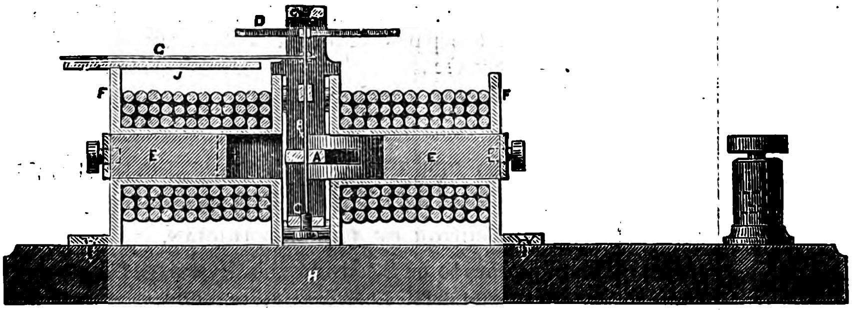


FIG. 2.

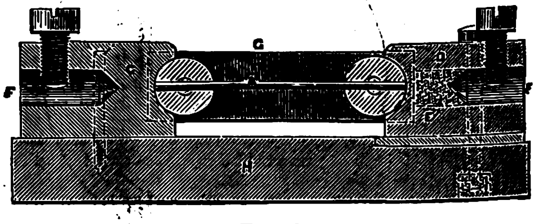

FIG. 5.

of the Pilsen Company. The exhibits are arranged to show clearly the nature of these modifications and the advantages to which they have led. Of the four machines used to maintain the arc lamps, two, those nearest the eastern end, are of the original form devised by Herr Schuckert. The armature in this design consists of flat wrought-iron rings, separated one from another by air spaces, but held together at small intervals by brass rivets and distance washers. Upon the iron core thus built up the wire sections are wound, and the completed ring is mounted upon a metal hub, and secured in position by the friction of metal flanges on either side. The other two machines are of the modified construction of armature introduced by the Pilsen Company, and distinguished as the "Pilsen-Schuckert type." The core of the armature is of soft hoop iron, wound up tightly in volute form. The layers of iron are separated one from another by strips of calico or longcloth wound in with the iron; a sufficient number of turns is given to form the broad flat ring characteristic of the Schuchert type. The sections of wire are wound upon this ring, and the finished armature is fixed upon the hub in the usual manner. Other machines exhibited are of more recent construction, and these have been further improved in the method of mounting the armature. In these machines the central boss carries a number of radiating arms, terminating in a kind of fork, into which the hoop iron is wound directly. This method of mounting the armature allows the latter to be built up of large diameter. The sections of wire on this ring are separated one from another at the periphery by soft iron shoes or wedges insulated from the rest of the iron in the core. These separate pieces increase in a notable degree the efficiency of the machine. The improvements here indicated, besides affording obvious mechanical advantages, have reduced the internal resistance in the proportion of 12 to 7, while the sectional area of the wire has been increased 40 per cent. The increase of efficiency allows for equal external work a reduction of the speed by about 21 per cent. At the Exhibition each of the original type machines maintains 14 arc lamps through about 400 yards of wire leads at a speed of 775 revolutions a minute. Each of those of the later type maintains 14 arc lamps through about 400 yards of leads at a speed of 614 revolutions. Fig. 1 represents one of the latter machines.

The conductors from each machine are led to a common switch-board, constructed to allow any one of the machines to be in a moment put into connection with any one of the circuits. The advantages of such an arrangement are obvious. Besides this circular switch there are :—1, an ordinary two-way switch for throwing the current, without breaking circuit, into the ammeter for measurement; 2, a solid and cheap form of copper "test plug," by the withdrawal of which an accidental or premature closing of the circuit is avoided; and 3, a water-switch, designed to break or close the circuit gradually when the machine is running at a high speed This gradual

Digitized by Google

action relieves the insulation from the strain to which it would otherwise be subjected by the extra current.

The current meter, which is common to the circuits, is of an altogether novel construction. The form is that of an ordinary flat coil galvanometer, the directive action of whose coils is intensified by the introduction into them of soft-iron cores. Between the poles of this electro-magnet rotates a soft-iron armature against the tension of a spiral spring. This armature carries an indicator needle, which moves over a graduated dial. The shape given to the poles of the electro-magnet produces equal deflections for equal increments of current. The readings, unlike those of instruments depending upon the action of a permanent magnet, are constant, and the armature is sensitive to extremely small variations of current. As constructed for arc circuits these meters indicate distinctly variations of one-tenth of an ampere. The iron cores are made to slide in

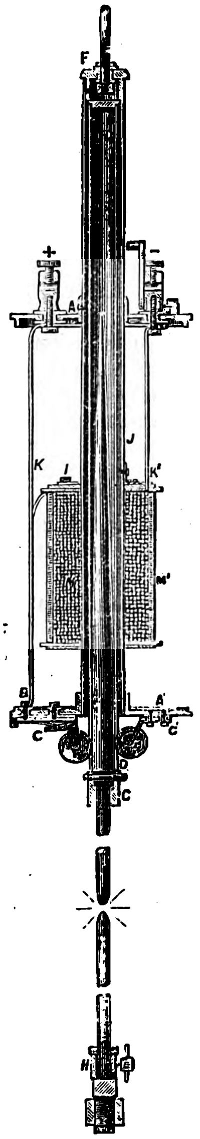

Fig. 6.

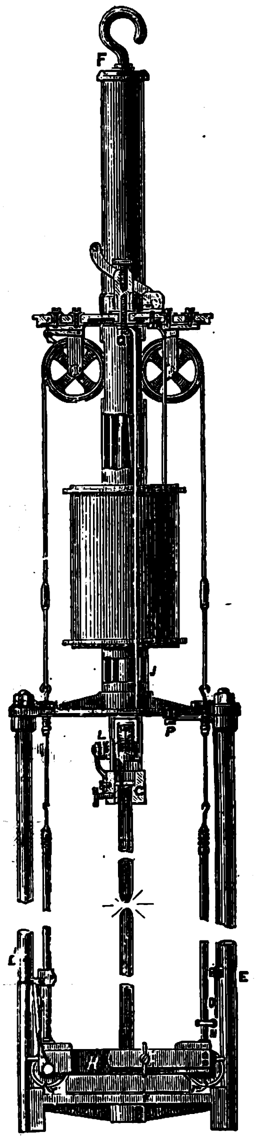

Fig. 7.

the coils, and they are adjustable with respect to their distance from the armature. The needle is dead-beat. The company's voltmeter differs from this instrument only in the winding. A "touch" is added to give security in ignorant hands. Figs. 2 and 3 represent the current meter.

Safety cut-outs or fuses are now a necessary part of an electric lighting circuit. Those of the Pilsen Company possess features which render them both convenient and certain in action. They consist essentially of a group of lead rods held in place by the pressure of a spring against the brass socket into which their ends are set. This snap action not only insures good contact, but allows the fusible rods to be removed or replaced by others when destroyed by the current in a few seconds and with the greatest ease. The arrangement permits also the use of a varied combination of fuses, of different areas, through which it is easy to arrive at the exact sectional area of lead required. A large number of these cut-outs are used at the Bethnal Green Museum lighting installation of this company, one in each main circuit, secondary circuit, and branch, in conformity with the stringent requirements of Mr. Musgrave Heaphy, on behalf of the fire insurance offices. Figs. 4 and 5 represent this safety fuse.

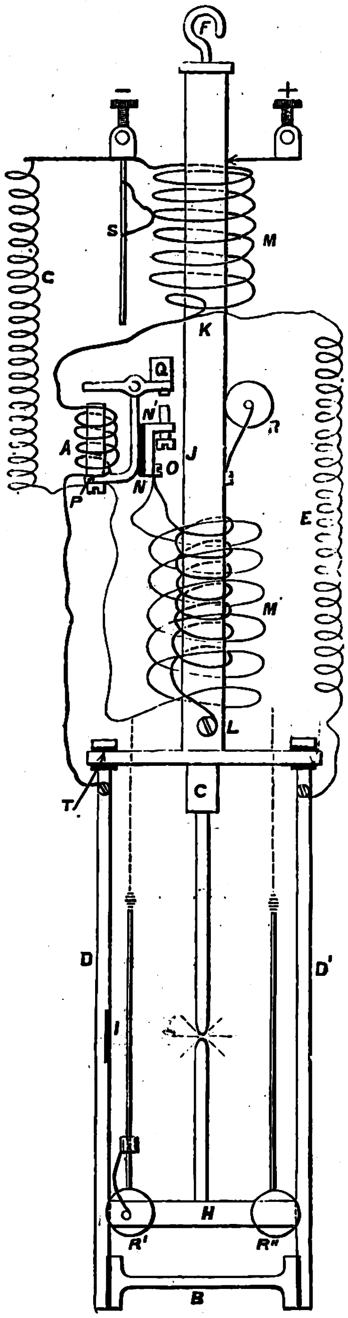

Fig. 8.

The west gallery, in which are the principal exhibits of machinery in motion, is lighted by 28 Pilsen arc lamps of 2,000 candle-power nominal, hung in two parallel rows, one on each side of the gallery. The effect is striking. This arrangement shows to advantage the steadiness of the Pilsen lamp, for an observer stationed at one end of the gallery has the whole installation in view, and the slightest flickering in any one of these numerous foci of light would become apparent. These lamps are of the common type known as P^1, the characteristic features of which are the biconical solenoid core and "tandem" coils. Near the machines is exhibited, for inspection of the working parts, another type known as P^3, having two conical cores and parallel coils. A third type, P^2, is also here

Digitized by Google

exhibited. In this lamp there is but one spool, on which are wound both the main and the shunt coils, within which moves a single tapered core. It is claimed for this lamp that it possesses the steadiness of feed distinctive of the other types of Pilsen lamps, while its moving parts are so few that derangement is, with reasonable care, hardly possible. Figs. 6 and 7 show a lamp of the P^2 type. Fig. 8 shows the details of the lamp connections and coils.

The east central courts are lighted by 350 improved incandescent lamps of 20 candle-power actual. These take a current of 1·08 ampere, with an electromotive force of 44 volts. "This," says a contemporary, "is a very remarkable result, inasmuch as it indicates the highest efficiency yet reached in incandescent lamps." The lamps are distributed singly over the French and the Swiss courts, whereby a better diffusion of the light is obtained than by the method of grouping commonly adopted. This is another instance of care, knowledge, and sound judgment—everywhere visible in this installation—brought to bear on the difficulties encountered by this system of illumination. The Pilsen Company have here equalled, if they have not surpassed, their achievement at the Bethnal Green Museum.

THE THEORY OF THE DYNAMO-ELECTRIC MACHINE.*

BY PROFESSOR J. FITZGERALD.†

The point which I was led to call attention to frequently some years ago, and which has been investigated and experi mented upon by several, is this: Taking a coil in which the current is being started from there to there (*a* to *b*, Fig. 13); the current is going in this direction (small arrow) and the

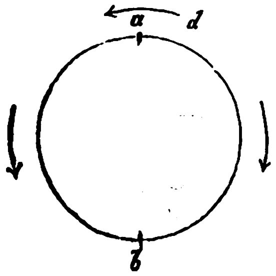

Fig. 13.

ring is turned in that direction (large arrow). When the coil was at that side (*d*) the current was running down through it in that direction (arrow); as soon as the current passes across the brush at *b* it is reversed, the current passing off. Consequently the current, which was at one time running in one direction, is reversed so as to cause the current to be running in the opposite direction. That in itself necessitates no loss of energy. The work that is to be done in stopping the current and turning it in an opposite direction does not in itself involve any loss of energy, if energy in stopping the current could be utilised in starting it again. If you could use the energy which is necessary to stop the current to start a fresh current in the opposite direction, there would not be necessarily any loss of energy in your arrangement; but what I want to call attention to is this, that in general a coil is short-circuited when it is passing from one of these positions to the other across the brushes, and consequently the energy in stopping is used in sending sudden and short currents through itself. There is in general a circuit through the coil, which is in short a short circuit in itself, and the energy of the coil which goes out in stopping is not used in starting the current in the opposite direction. Therefore you have lost the energy of the coil due to its own induction through a short circuit.

The loss of energy due to this cause for this coil will be proportional to the induction and the square of the current passing through it. If M is the induction of each coil, and C the current passing through it, M C 2 is the loss of energy due to the self-induction of the coil being wasted on the local current. This will be on each coil; hence, if N were the number of coils that were passed per second, M N C 2 would be the loss per second owing to this fact. This can be put into another form by substituting for M N the terms of the self-induction of the unit of length of the ring. If V is the velocity of the edge of the ring, and L is the self-induction per unit of length on the ring, then necessarily V L = M N; and V L C 2 will represent the loss of power owing to the self-induction of the coils. For a given ring it varies directly as the linear velocity of the ring. It was a very difficult thing to make experiment upon this effect as to whether there was any loss of power due to the self-induction of the ring. The term V L is in the nature of a small resistance which we may call R, so that the loss may be written R C 2. This is a resistance of the machine due to its velocity, and is proportional to the linear velocity and the self-induction per unit of length. The resistance of the ring is easy to obtain by rotating the ring under the action of the earth's magnetic force. One great difficulty was to get an arrangement in which there should be no reaction between the magnetic field and the ring itself. Field magnets were therefore used instead of the magnetic force of the earth, and consequently there could be no reaction from induced magnetism in the earth owing to the magnetisation of the ring. It was therefore assumed that the initial magnetic field was constant. That is the difficulty—to determine the reaction between the magnetism of the ring, and the induction which would be occasioned on the field magnets. A number of experiments were tried, and it was found that as far as the experiments went there was an increase of resistance owing to an increase of velocities, and that it was approximately proportional to the increase of velocity, and that it was approximately equal to what it was calculated it should be. It was found that the increase of resistance was a little larger than this amount; but it is almost impossible when turning a Gramme ring rapidly to prevent the jumping of the brush upon the commutator. The result of the experiments, however, led to the conclusion that the increase of resistance was to be calculated upon, and that there was a reason for not running dynamos any faster than a certain amount; that there was a certain velocity which it was well to not drive them at, because this internal resistance varied as the linear velocity of the ring. You can get over this resistance due to self-induction by constructing what are called unipolar dynamos.

First of all I may say something of the effect which Professor Rowland called your attention to—the effect of size upon this apparatus. In the first place the angular velocity is inversely as the square of the linear dimensions. Therefore the linear velocity will vary inversely as the linear dimensions. Consequently the effect due to this linear velocity would be less in the larger machines, not more than half that of a machine of half the size.

The effect of the self-induction per unit of length of the ring will be independent of the size of the machine. For the coefficient of self-induction is in general proportional to the linear dimensions of the system. The coefficient of self-induction is in general of the dimensions of a line, and therefore the self-induction of a unit per length will be independent of the dimensions of the system. Consequently you will get this: the increase of resistance is inversely proportional to the linear dimensions. Inasmuch as the increase of resistance will be inversely proportional to the linear dimensions, and inasmuch as the current varies as the linear dimensions, you have that the loss of power will be directly proportional to the linear dimensions.

The whole power is directly proportional to the linear dimensions, so that the proportion of the power lost to the whole power will be constant and independent of the size of the machine.

It is possible by constructing what are called unipolar dynamos to get over this loss owing to the self-induction. For instance, take the simplest case of Faraday's experiment with a magnet rotating. In that case there is evidently no sudden change in the current. The current is gradually diminished. There is no sudden alteration in the current; it is a uniform action, and consequently there will be no loss in this case so

* A Paper read at the Congress of Electricians at Philadelphia.

† In continuation of Professor Rowland's Paper on this subject in our last issue.

Digitized by Google

far as I can see owing to the increased velocity at which it goes. You will have here the self-induction of the current diminishing, and helping to increase the current at some other point. Hence, there will be no loss due to the stopping and starting. Some people find difficulty in understanding how there can be no loss in an opposing force. It is the case of a crank running upon a wheel, there is no loss owing to the reciprocation of the crank, the mechanical force that is required to start it at one end being given out at the other end. But in this case it is like a bad crank, which joggles upon its bearings; and in this case there is a loss by the reciprocation of the action.

In this case we have the loss due to short breaks, and in that case there would be a loss owing to the increased pressure of the crank on the bearings. In every check of the crank there will be a loss, and hence in this case there will be loss, owing to the fact that you have to change the current from one direction to the other. But in this case of the unipolar machine it is like a crank axle in which the motion goes on uniformly without any unnecessary joggle round and round. Therefore there is no loss due to self-induction.

It is possible, also, to arrange Gramme armatures in such a way that there would be no loss owing to this cause, by arranging them so that there shall be a number of different brushes and the current divided between these different brushes. The easiest way in which I can explain this is by taking the case of two Siemens armatures, the current being divided between them, part to one and part to another. Now, it is evident that it is possible to arrange the brushes in a certain position so that the brushes themselves shall make a contact in this armature at the time when the electromotive force is exactly the same as the electromotive force that is required to be sustained between those two wires, whereby the potential at the ends of the armature is the same as at the ends of the two brushes, the potential of the brushes being kept up while this contact is being made at the armature; so that you can make the contact with the brushes when the potential of the brushes is the same as the potential of the armature, and therefore there will be no tendency for the current to start or stop at that time through the armature, and therefore it must start gradually. On the other hand, it is evidently possible to arrange the electromotive force so that at the instant of turning it shall be able to stop the current in this direction, but not to drive the current in the opposite direction; thus driving the current in this direction during a part of the revolution and in this direction during another part. During the intervening time, it is evident that there will be some instant in which there is no current running in this armature. If that is the moment which is chosen for breaking the current there will be no spark owing to the self-induction at that time. So that by making the contact between the brushes and the corresponding commutator at the time when the potential of the brushes is the same as the end of the armature, and when there is no current running in that coil, you will necessarily have a machine in which there is no loss in this way owing to the sudden breaking and stopping of the current.

I would just like to say something in connection with the question that Professor Rowland mentioned upon another point, and that is, that in a large dynamo you have got an obvious advantage; that it is possible to make the clearance very much less in proportion than in the small dynamo.

You can make the angular distance between the armature and the poles very much smaller in proportion in the large dynamo than in the small one, owing to the possibility of making the clearance much less. Another advantage in the large dynamo, on account of the electromotive force being nearly the same in the two dynamos, you may make the proportion between the area involved in the insulation and the area of the conductor smaller in the large dynamo than in the smaller one. It would not be necessary to make the area of this armature proportional to the linear dimension, consequently you can have a much larger conductor in proportion in the large than in the small dynamo; so that that is an additional advantage you can have in the large dynamo.

With reference to the centrifugal force, while I was waiting I worked out a little point that I would like to draw attention to, and it was with reference to the Gramme ring. I have come to the conclusion that the tension of the material and the wires per unit of area will vary directly as the square of the linear velocity; and that therefore the velocity being inversely proportional to the linear dimensions, the tension per unit of area will vary inversely as the square of the linear dimensions; and that therefore you may drive the larger Gramme ring considerably faster than you could the smaller without any danger of its flying to pieces. I think the tension of the ring is exactly proportional to the square of the linear velocity. But I am not sure. I am sorry that this is all I can give you upon the subject.

ON THE PERMANENT TEMPERATURE OF CONDUCTORS.*

(CONCLUDED FROM PAGE 540.)

I have also made some preliminary experiments on copper wires of various diameters without solid covering, cooling in air and in vacuum. In commencing these experiments I used as a formula for controlling my results an expression derived as follows:—

A current passing through a given wire produces heat of which the amount, according to the well-known formula of Joule, is given by—

$$H = C^2 R/J \quad . \; . \; . \; . \; . \; . \quad (1)$$

where C is the current, R the resistance, J Joule's equivalent, and H the quantity of heat produced per second, each being reckoned in C.-G.-S. units. Lel l be the length of the wire experimented on, and d its diameter; and let σ_t be the specific resistance of the substance at the temperature $t°$. Then—

$$R = \frac{\sigma_t \times l}{\frac{1}{4}\pi d^2} = \frac{4\sigma_t l}{\pi\, d^2}$$

Hence from (1)

$$H = \frac{C^2}{J} \times \frac{4\,\sigma_t\, l}{\pi\, d^2} \quad . \; . \; . \; . \; . \; . \quad (2)$$

Now let H′ be the quantity of heat lost by the wire by emission from the surface; let e be the emissivity; and let θ be the temperature of the surroundings within which the wire is cooling.

Then

$$H' = \pi\, d\, l \, . \, e\,(t - \theta) \quad . \; . \; . \; . \; . \quad (3)$$

But when a permanent temperature is attained H must equal H′, and hence we have from (2) and (3),

$$e = \frac{4\, C^2\, \sigma_t}{J\pi^2 d^3 (t - \theta)} \quad . \; . \; . \; . \; . \; . \quad (4)$$

Experiments have been made by Mr. D. Macfarlane (*Proc.* Roy. Soc., 1872, p. 93) for the purpose of determining the emissivity of surfaces in absolute measure. Mr. J. P. Nichol has also obtained results, which were communicated to the Royal Society of Edinburgh by Professor Tait, 1869-70, and which have been reduced to absolute measure by Professor Everett, "Units and Physical Constants," Chap. IX., Sec. 137.

On calculating the value of the emissivity for small copper wires by means of the formula (4) given above, I have found in every case a much greater emissivity than was obtained by these experimenters; and so far as I have been able to go up to the present the emissivity seems to increase as the diameters of the wires experimented on are diminished. Macfarlane's determinations of emissivity were made for a copper globe of 4 centims. diameter, and found to be about $\frac{1}{4000}$ of the thermal unit C.-G.-S. per square centim. per second per degree of difference of temperature for a polished surface with a little over 60° of excess of temperature, and for a blackened surface with excess of 5° or under. For round wires of small diameter I have found very much larger emissi-

Digitized by Google

vity than $\frac{1}{4000}$. I have obtained different values of e for wires of different sizes, varying from $\frac{1}{2000}$ with a polished wire diameter 0·83 millim., and excess of temperature 27·5° C., down to $\frac{1}{400}$ with a wire of 0·40 millim., and excess of temperature 24° C.

In order to examine the question more thoroughly, I have commenced experiments in which I am endeavouring to do away with the part of the emissivity which is due to convection and carriage of the heat by air. I have experimented to a certain extent on small wires in the nearly perfect vacuum obtainable with the mercurial pump, and I am preparing for a more complete series of experiments. It seems certain that this method of experimenting will give a very accurate way of determining the value of e in absolute measure for the surfaces of wires.

During the writing of this paper Professor Stokes has kindly reminded me of the experiments made by Mr. Crookes (*Proc.*, Roy. Soc., Vol. 31, p. 239). I find that my results, so far as they go, agree perfectly with those of Mr. Crookes, showing a decrease in the emissivity due to lowering the air pressure, this decrease being very small for a reduction down to one-half or one-third of the ordinary atmospheric pressure, but becoming very great with the almost perfect vacuum obtained with the mercurial pump.

The following table shows the emissivity of a copper wire with bright surface half a metre long, 0·40 millim. in diameter, and sealed into a glass tube, about 1·5 centim. internal diameter :—

Current Amperes.	Pressure, 760 millims.		Pressure, 380 millims.		Pressure, 180 millims.		Very high vacuum pump worked continuously.	
	$t-\theta$	e	$t-\theta$	e	$t-\theta$	e	$t-\theta$	e
	deg.		deg.		deg.		deg.	
1	4·7	$\frac{1}{1822}$	4·5	$\frac{1}{1784}$	5·5	$\frac{1}{2170}$	17	$\frac{1}{6443}$
2	22·5	$\frac{1}{2084}$	21·5	$\frac{1}{1996}$	23·5	$\frac{1}{2174}$	68	$\frac{1}{5620}$
3	56	$\frac{1}{2114}$	58	$\frac{1}{2180}$	55	$\frac{1}{2082}$	140 ?	$\frac{1}{4606}$ *

* Temperature probably much too low. The wire, sagging down, touched the glass tube in several points.

In the somewhat crude state of my preliminary experiments I have not considered it necessary in calculating to make any allowance for heat lost at the ends of my wires by conduction to the masses of metal to which they were soldered. The following appended note, however, contains an investigation of the correction which, in future experiments, it will be necessary to apply.

Note by Sir W. Thomson.

To estimate effect of conduction of heat from the tested wire through its ends, suppose the ends to be kept at the atmospheric temperature. This supposition corresponds to the greatest possible degree of the effect in question. (Adopting Fourier's notation, in the first four symbols), let v be the excess of temperature in the wire, at distance x from one end :

a, the length of the wire ;
k, its thermal conductivity ;
h, the thermal emissivity of its surface ;
g, the girth of its cross section ;
A, the area of its cross section ;
s, the specific electric resistance of its substance (C.-G.-S.);
$\frac{1}{10}$ Ac, the strength of the current (C.-G.-S.) ;
(or c, the current in amperes per square centimetre of cross section) ;
and J, Joule's equivalent multiplied by the force of gravity at Manchester (42344 × 981·34 = 41·55 centimetre-dynes), the dynamical equivalent of the thermal unit (C.-G.-S.),

we have by Fourier and Joule :

$$\frac{d}{dx}\left(k\mathrm{A}\frac{dv}{dx}\right) - g\,h\,v + \frac{c^2 s}{100\,\mathrm{J}} = 0 \quad . \quad . \quad . \quad (5)$$

Neglect now the variations of k and s with temperature, and suppose the conductor of uniform material and area and girth of cross-section throughout its length from $x=0$ to $x=a$. Equation (1) becomes—

$$\frac{d^2 v}{d\,x^2} - \frac{g\,h}{k\,\mathrm{A}}v + \frac{c^2 s}{100\,\mathrm{J}\,k\,\mathrm{A}} = 0 \quad . \quad . \quad . \quad (6)$$

and its integral, fulfilling the end conditions, is—

$$v = \frac{c^2 s}{100\,\mathrm{J}\,g\,h}\left[1 - \frac{\epsilon^{-m\,x} + \epsilon^{-m\,(a-x)}}{1+\epsilon^{-m\,a}}\right] \quad . \quad . \quad (7)$$

where $$m = \sqrt{\frac{gh}{k\mathrm{A}}}. \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (8)$$

For round wire or rod of diameter D, we have—

$$g = \pi\mathrm{D}, \text{ and } \mathrm{A} = \tfrac{1}{4}\pi\mathrm{D}^2 \quad . \quad . \quad . \quad . \quad (9)$$

whence $$m = \sqrt{\frac{4h}{k\mathrm{D}}}. \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (10)$$

For copper we have $k = {\cdot}91$ (Angström).

Now put $$h = \frac{1}{n \times 1000}$$

where n might be about 4 for the ranges of temperature in Mr. Bottomley's experiments, if we could judge from Macfarlane's experiments on the cooling of a globe of copper of 4 centims. diameter; and in the wires experimented on by Mr. Bottomley, D = 0·08. Hence for these wires—

$$m = \sqrt{\frac{4/n}{{\cdot}91 \,.\, 80}} = \frac{1}{8{\cdot}5}\sqrt{4/n} \quad . \quad . \quad . \quad . \quad (11)$$

Hence if $n=4$, $m = \frac{1}{8{\cdot}5}$. But Mr. Bottomley's experiments show n to be more nearly $=1$, and to be actually <1 for wires of somewhat less diameter than ·08. Hence we have, as a practical rough approximation, $m = \frac{1}{4}$; and (7) becomes

$$v = \frac{c^2 s}{100\pi\,\mathrm{D}h\,\mathrm{J}}\left[1 - \frac{\epsilon^{-\frac{x}{4}} + \epsilon^{-\frac{a-x}{4}}}{1+\epsilon^{-\frac{a}{4}}}\right] \quad . \quad . \quad . \quad (12)$$

In Mr. Bottomley's experiments $a = 50$, and therefore

$$\epsilon^{-\frac{a}{4}} = 1/\epsilon^{-12{\cdot}5} = 1/268000,$$

which may be neglected ; and we have

$$v = \frac{c^2 s}{100\,\pi\,\mathrm{D}\,h\,\mathrm{J}}\left[1 - \epsilon^{-\frac{x}{4}} - \epsilon^{-\frac{50-x}{4}}\right] \quad . \quad . \quad (13)$$

which shows that at a distance of 4 centims. from either end the temperature is less than in the middle by ϵ^{-1}, that is 1/2·7 of the middle temperature ; at 8 centims. it is less by 1/7·4 ; and at 12 centims. it is less by 1/20. Thus we see that the cooling by the ends is very sensible through a quarter of the length from either end ; and must be carefully allowed for by aid of (7), unless lengths of considerably more than half a metre are taken. But we also see that the results stated in this preliminary paper are not sensibly affected, or hardly sensibly affected, by cooling from the ends.

LONG-DISTANCE TELEPHONING IN BELGIUM.

As stated in a note, bearing the above title, in our last week's number, the Van Rysselberghe system has now been applied to the telegraph wires between Brussels and Antwerp, thus permitting of oral communications being made between the subscribers to the exchanges in both cities, as well as by the general public, without interfering with telegraphic messages. We have been favoured with extracts from the *Moniteur Belge*, the official journal of the Belgian kingdom, containing the report on the subject to the King, his Majesty's decree on the subject, and the regulations issued by the Postal and Telegraphic Department of the Ministry of Railways, Posts, and Telegraphs, translations of which we give below :—

REPORT TO THE KING.

SIRE,—Art. 1 of the law of 11th June, 1883, authorises the Government to undertake itself, or to concede to others, the laying and working of telephone lines. As a first application of this law, the new service of intercommunication has been conceded in Brussels, Antwerp, Ghent, Liége, Verviers, Charleroi, Mons, La Louvière, Louvain, and the sur-

rounding communes for a distance of 10 kilometres (6 miles). Most of these local systems are now in regular operation, and have already been considerably extended. Circumscribed by the limits of the concessions, the telephone does not yield all the advantages which can be derived from it by the public and the various branches of national industry. Telephonic communication should be rendered possible, within the kingdom, between important centres, and by and by with neighbouring countries. Placing the systems conceded in intercommunication is one step in this direction. The Government should retain the working of long distance telephoning, which might to a certain extent affect the revenue derived from telegraphic messages. It was, therefore, especially incumbent on the Government to establish conducting wires for connecting local enterprises. But the laying down of special telephone conductors would have entailed such expense and delay as to defer the realisation of this improvement. Thanks to the remarkable inventions of a young Belgium *savan*, M. Van Rysselberghe, existing telegraph lines may be utilised, at slight expense, for transmitting oral communications without any interruption of telegraphic messages. In presence of this result, my department may legitimately take credit for having considerably aided the investigations and preliminary trials of the inventor. The carrying out of the transformation, undertaken by the Administration at the beginning of the present year, being now completed, and the main lines of the State connected with the central stations of the concessions, it only remains to fix, for regular working, the tariffs and regulations for telephonic messages exchanged between any two points of Belgian territory over the State lines. Such is the object of the decree which I have the honour of submitting to your Majesty.

The Minister of Railways, Posts, and Telegraphs,

J. VANDENPEERENBOOM.

ROYAL DECREE.

Leopold II., King of the Belgians,

To all present and to come, greeting.

In presence of the law of 11th June, 1883, with reference to the laying and working of telephone lines, and especially Article II., which extends to telephonic messages the provisions of the law of 1st March, 1851 ;

In presence of the law of 26th December, 1883, proroguing the law of 1st March, 1851 ;

Considering that it is advisable to regulate the tariffs and regulations as to long-distance telephonic communications between the systems established and worked by virtue of Article I. of the law of 11th June, 1883, aforesaid ;

On the proposition of Our Minister of Railways, Posts, and Telegraphs,

We have decreed and decree:—

Art. 1. Telephonic messages exchanged between any two points of Belgian territory by means of local systems and the State lines are subjected to the following fees:—

During the day:

One franc (10d.) for an integral period of five minutes' actual conversation ; 1fr. 50c. (1s. 3d.) for an integral period of more than five and not more than ten minutes' actual conversation.

The fees during the night (from 9 p.m. to 7 a.m.) are double those during the day.

This tariff is applicable from the moment direct communication is established between the public or private stations that are called.

The duration of actual conversation may not exceed ten minutes.

Art. 2. The fees are payable by the person who has applied for communication to be established.

The subscribers to telephone exchanges are responsible for the payment of the fees for all messages transmitted by their respective wires.

In offices open to the public, fees are always payable in advance.

Art. 3. The messages of telegraph officials, the *concessionnaires* of telephone exchanges in communication and the agents of *concessionnaires* specially authorised are exempt from the payment of fees, when the messages are connected with the service of long-distance telephoning.

But *concessionnaires* and their agents can only correspond with one another gratuitously from one central station to another.

Art. 4. Our Minister of Railways, Posts, and Telegraphs is charged with the execution of the present decree; and he will fix the date of the commencement of the service.

Given at Brussels, 10th October, 1884,

LEOPOLD.

By the King,
The Minister of Railways, Posts, and Telegraphs,
J. Vandenpeerenboom.

REGULATIONS.

The Royal decree of the 10th October fixes the rates for telephonic communications, transmitted at long distances between the telephone exchanges established in the principal towns and centres of the country. The service will commence on the 20th October between the conceded systems of Brussels and Antwerp. Conversations may be carried on, either between subscribers' stations, or between public telephone offices and subscribers' stations, or, again, between public telephone offices. The rates are applicable, without distinction, to the communications exchanged by means of local exchange subscribers' instruments, and those of persons who make application to send communications in public offices. These rates are:— During the day, from seven o'clock in the morning till nine at night, 1 franc (10d.) for five minutes' conversation or less ; and 1 franc 50 cents. (1s. 3d.) for a conversation of more than five minutes and not exceeding ten minutes. During the night, from nine o'clock in the evening to seven in the morning, the fees are raised respectively to two and three francs (1s. 8d. and 2s. 6d.). No additional charge can be made to non-subscribers. The communications are made in the order of application. The duration of calling subscribers' stations or public offices is limited to one minute by day and five minutes by night. The time is counted from the moment communication is established between the public or private stations called. Consequently, calls not followed up by conversation will not be charged. The duration of actual conversation may not exceed 10 minutes. At the expiration of this period communication will be interrupted, as a matter of course. Those who have not finished their conversation can only obtain renewed communication if there are no other applications. In this latter case, the application for renewed communication will take its turn with others. In either case the conversation will be subject to the application of the tariff given above, just as if there were a distinct application. The fee is due by the person who *applies* for the communication, and is collected, for the Administration, by the *concessionnaire* of the local exchange. The subscribers of telephone exchanges are responsible to the *concessionnaire* for the payment of fees for *all* the conversations applied for by means of the instruments at their command. They may, however, free themselves from this responsibility by giving notice in writing of renouncing the use of these instruments for calling for long-distance telephonic communication ; and the *concessionnaire* will acknowledge by letter the receipt of this declaration. Subscribers are bound to pay the amount of the fees within three days following the despatch of the account prepared by the *concessionnaire*, after which period this functionary may claim payment through the post at the subscriber's expense. In the event of absolute refusal to pay the fees, the affording of future long-distance telephonic communication may be made dependent on the previous payment of the back fees due, without prejudice to recovery thereof at law by the *concessionnaire*. In the telephone offices open to the public, the previous payment of the maximum fees (1fr. 50c. or 2fr., as the case may be) is always required. They are, however, returned wholly or partially, according as the communication applied for shall not have been established, or only for five minutes at the outside. The central offices of the *concessionnaires* are open day and night for long-distance telephoning. The offices accessible to the public are constantly open, including Sundays and holidays:—

At Brussels:—1. At the Bourse (entrance in the Rue de la Bourse) from 9 a.m. to 7 p.m.; 2. Place des Palais (Kiosque at the entrance to the Parc) from 9 a.m. to 7 p.m.

At Antwerp:—1. At the Eastern Station (Salle des Pas Perdus), from 8 a.m. to 8.30 p.m.; 2. Chaussée de Malines, near the "Harmonie" (Tramway Station), from 9 a.m. to 7 p.m.; 3. Place de la Commune (Tramway Station), from 9 a.m. to 7 p.m.; 4. Avenue de l'Industrie, near the National Bank (Tramway Station), from 9 a.m. to 7 p.m.; 5. At the Bourse (ground floor), from noon to 3 o'clock, provisionally.

A general list of the subscribers to the local exchanges in communication lies at the disposal of the public in these offices.

Communications applied for to be sent *to* a public office are only made if, by previous arrangement between the parties desiring to hold conversation, the *telephonee* be present at that office. This understanding may be arrived at by the ordinary means, such as a letter, telegram, &c.

It is expressly recommended, in the interest of those holding conversation:—

A. To place themselves opposite and only at a few centimetres' distance from the vibrating plate of the microphonic transmitting instrument.

B. To speak slowly without forcing the voice, and to articulate clearly.

As the words have to be transmitted to a much greater distance than the limits of the local exchange, speaking to one side of the transmitting instrument, turning the back to it, or standing at any considerable distance therefrom, must be carefully avoided.

The Government and the *concessionnaires* of the local exchanges are exempt from all responsibility connected with the service of long-distance telephoning.

ANCIENT TELEGRAPHS.

At the Wigan Free Library, on 17th October, Mr. Alderman Bailey delivered the first of the present winter lectures, the subject being "Ancient Telegraphs, from the Fall of Troy to the Battle of Waterloo." The lecturer said:—

Talking by means of signs and without the tongue being used is called telegraphing. The word "telegraph" is derived from two Greek words, which signify "to write" and "at a distance." We are told by Lubbock and other writers of the history of civilisation that many savage tribes, by reason of their poverty of word language, are compelled to carry on a conversation by signs. Some have thought that certain of these tribes are entirely without language, but this seems extremely improbable. The statement may have arisen from the fact that in all countries inhabited by savages the number of languages is very great, and hence there is a great advantage in being able to communicate by signs. James, the American traveller in the Rocky Mountains, mentions that several tribes under the influence of one great chieftain were totally ignorant of each other's vocal language, insomuch as it was no uncommon occurrence to see two men of different nations sitting upon the ground and conversing freely by means of the language of signs. Fisher, another traveller among the American Indians, mentions a language of signs, however, by which all nations and traders can understand one another, and they always make these signs when communicating among themselves. The men, when thus talking together, sit cross-legged like Turks and communicate with each other at a speed and with a

Digitized by Google

definiteness which would even be understood by a deaf man. For instance, Fisher says, "I meet an Indian, and wish to ask him if he has seen six waggons, drawn by horned cattle, with three Mexican and three American teamsters and a man mounted on horseback. I make these signs:—I point 'you;' then to his eyes, 'see.' Then hold up all all my fingers on the right hand and the forefinger on the left, meaning 'six.' Then I make two circles by bringing the ends of thumbs and forefingers together, and holding my two hands out, move my wrist in such a way as to indicate waggon wheels revolving, meaning 'waggons.' Then, by making an upward motion with each hand from both sides of my head, I indicate horns, signifying 'horned cattle.' Then, by first holding up three fingers and extending my right hand below my lower lip and moving it downwards, stopping it midway down the chest, I indicate 'beard,' signifying 'Mexican.' And by this way and by other similar signs and motions I ask the Indian, 'You see six waggons, horned cattle, three Mexicans, three Americans, and one man on horseback.' If he holds up his forefinger and lowers it quickly, as if he was pointing it at some object on the ground, he means 'yes.' If he moves it from side to side —on the principle that people sometimes move their head from side to side—he means 'no.'" Fisher says it takes about the same time to make these signs that it would take if you asked the question verbally. The bushmen of South Africa, we are informed by another traveller, intersperse their language with so many signs that they are perfectly unintelligible in the dark; and when they want to converse at night they are compelled to gather round their camp fires. The celebrated traveller, Burton, says of a tribe of North American Indians, who possess so scanty a vocabulary that they cannot talk in the dark, that to make a stranger understand them they must always repair to the camp fire for a "pow-wow." For purposes of war, methods of communicating from distant places have been used in all historic times, varying very little in character, and distinguished by more or less ingenuity. Bells, torches, flags, and symbols have been used for telegraphing from the earliest known periods. Probably the earliest record of such in the Old Testament is in the 6th chapter of Jeremiah: "O, ye children of Benjamin, gather to flee out of the midst of Jerusalem, and blow the trumpet in Tekoa, and set up a sign of fire in Bethacarem, for evil appeareth out of the north and great destruction." The Egyptians had signals to indicate the rank of important officers of State, many of which signals have been discovered in the excavations among the ruins of their great temples and monuments, and in the carving upon their sculptures. We are told that the banner of Benjamin, in the time of Moses, had on it a wolf, whilst the other tribes also had their emblems. The Lord, it is said, spoke to Moses and Aaron, and ordered that "every man of the children of Israel shall pitch by his own standard, with the ensign of their father's house." Among the Greeks, the Athenians had an owl, and the Thebans a sphinx upon their banners and standards, and we are told that by using these emblems and signs in a manner understood by the various companies of soldiers in war, the standard bearers were enabled to telegraph such orders as "advance" and "retreat," and to control other important military manœuvres. The use of these emblems in indicating the position of companies and regiments, in guiding friends and in warning foes, was of as much advantage to the soldiers in the old days as the numbering of the doors of the houses in our streets is to us in these later times. Indeed, this use of emblems, not only among the ancient Greeks and Romans, and even the Egyptians, but down to our own days, has given rise to the art or science of heraldry. In this way were the barons and knights of old as well as the commanders of famous legions enabled to emblazon various devices on their coats of arms, many of which we still see displayed by those who are proud of their family blood, and of what stock they claim to belong. On some occasions the device would be carefully prepared and thought out; in other cases the symbol would be something at hand which had been seized in an emergency and lifted up as a rallying point for the people, and afterwards adopted from the attachment which would cling to it as an object identified with patriotic deeds. One of this sort must have been the Persian blacksmith's apron, which for many years, until the Mahommedan conquest, was the standard around which the people rallied to resist the invader. Some person may remember how Longfellow, in his poem, "The Norman Baron," describes in fine sentences the freeing of his serfs:—

> "Every vassal of his banner,
> Every serf born to his manor,
> All those wronged and wretched creatures
> By his hand were freed again."

Beacon fires and torches by night and pillars of smoke by day seem to have been used both by most civilised and savage peoples in all ages for transmitting messages. Homer, describing "the lambent flame" which shone round the head of Achilles and spread its lustre all about, speaks by way of comparison of the signals made in the besieged cities, "the clouds of smoke by day and the bright fires by night, which call on neighbouring cities for assistance." Various Roman writers mention different methods of communicating by means of torches. Julius Africanus says "substances were made use of in making the torch fires," and some writers have thought that these fires and torches may have been of different colours, thus enabling the Roman general to ring the changes in spelling words and in sending messages. Probably one of the most ingenious telegraphs of ancient times was one used by the Greeks. The Greeks had a very good method of indicating the time of day by a clepsydra, or water clock, the indicating process being effected by means of a float in a vessel containing water which slowly subsided through a small hole in the bottom. The height of the float in the water told the time of day. Instead of winding up the clock, as we do, all that was necessary to start it again was to fill the vessel up with water, and let it resume running. Indeed, the idea was the same as in the old-fashioned hour glass; only instead of sand being used, observations were made by the fluctuations of the water. I will now endeavour to describe one of these clocks, a model of which we have on the table here. You will be kind enough to imagine two of these water clocks, which have been regulated for the floats to descend at exactly the same speed. They have been made—to use a scientific term—isochronous; that is, made to keep equal time. We will imagine one of these instruments placed at night, with the sender of a message, on the top of a mountain, and another on a distant hill, say two miles away. There we have them, sender and receiver. When a message had to be sent the sender would hold his torch up. That was the signal for the receiver to prepare his instrument and set it to zero by filling up with water. The sender would hold up his torch twice. This was a signal that he had permitted his clock to start running down; that is to say, for the water to escape by means of a faucit at the bottom. The receiver, seeing this signal, would at once allow his water clock to begin running down, and so both clocks would go on doing this at the same speed. Then, when the sender held up his torch again, it was a signal to stop. The receiver would stop his instrument and look on the stem for the letter of the alphabet which the sender meant to indicate, and thus, by repeating the operation the needful number of times, a message could spelled out with great facility. It is very remarkable that this ingenious water clock telegraph of the ancients, with a slight modification which I will explain later on, was similar to one of the first alphabetical telegraphs in this country, introduced by Mr. (afterwards Sir) Francis Ronalds about the time of the battle of Waterloo. Instead of using water clocks, Mr. Ronalds permitted two clocks with weights and wheels to run down; having, indeed, in his mind exactly the idea which the old Greeks had over 2,000 years ago. A celebrated Greek writer of tragedies, Æschylus, who lived over 500 years before Christ, wrote a tragedy in which he gave an account of the fall of Troy, an event which occurred—if it really did occur at all—from one to two thousand years before his time. In this work he describes the famous city as having been besieged, according to the accepted version, for ten long years. He tells of the watchman who had been stationed by Queen Clytemnestra to watch the signal station to which had to be sent the news of the fall of the doomed city. The watchman grumbles, bewailing his fate that through the long years the gods give him no deliverance from his vigil. He laments that he has had to crouch with his elbows on the roof like a dog, contemplating the hosts of nightly stars and the bright potentates that bear winter and summer to mortals, conspicuous in the heavens. He dreams, and says that even when he is at rest he starts with fright and fear, because of his monotonous occupation. He cannot even sing or whistle, he is in such a sad way; not only because of his melancholy work, but because his queen bedecks her couch with tears for her lord who comes not. But at last he sees the torchlight on the far-off mountain top, and exclaims, "But now may there be a happy release from all my toils, as the fire of joyous tidings pierces through the gloom. Oh! hail, thou lamp of light—thou that displays the light like the day and the marshalling of many dances in Argos, on account of this joyful event. Oh, oh, I will give a signal distinctly to the wife of Agamemnon, that she having arisen with all speed from her couch may raise aloud a joyous shout in welcome to this beacon. If indeed, the city of Ilion is taken, as the beacon light proclaims, I myself will dance a prelude. May it then befall me to grasp with this hand of mine the friendly hand of my king on his arrival at this palace." Clytemnestra receives the intelligence with gladness, and in expressing her delight the chorus of the Greek tragedy tell her it is foolish for her to believe in soothsayers and witchcraft, and that it is just possible she may be the sport of visions and dreams. She retorts upon them:—"I would not take the opinion of my soul when sunk in slumber." She is no young girl, she says, to be mocked by foolish rumour, and adds that the messenger has given her true intelligence, because she had arranged her signals in a proper manner. The city, she tells the chorus, was sacked the day before. The chorus ask, "But what messenger could come with such speed!" The Queen replies, "Vulcan sent forth a brilliant gleam from Ida, and beacon despatched beacon of courier fire hitherward. Ida, first to the Hermæan promontory of Lemon, and third in order Athos, Mount of Jove, received the great torch from the Isle, and passing o'er, saw as to ridge the sea, the might of the flame as it joyously travelled, the pine-torch transmitting its gold-gleaming splendour, like a sun, to the watch towers of Macistria. And the watchman, ever ready to do his duty, sent the light of the beacon coming from afar to the streams of the Euripus, gives signal to the watchmen of Messapius, and they lighted a flame in turn and sent the tidings onward, having kindled with fire a pile of withered heath, and the flame in its strength not yet at all bedimmed bounding over the plain of Asopus, like the bright moon, to the crag of Cithæron, aroused another relay of the courier fire, and the watch refused not the fire that was sent thus from afar, lighting a still larger pile, which darted across the lake Gorgopis, and having reached the mount and lighting up in increasing strength, they sent on the mighty beard of flame so that it glared beyond the headland that looks down upon the Saronic frith, and hence it darted down to the Arachnæan height, and therefrom to this roof here darts the light, no new descendant of the fire of Ida. Such were my commands to the bearers of the torches, fulfilled by succession from one to another. Such proof and signal do I tell thee of my husband's victory at Troy." It is obvious that the news of an invasion, or of a victory, or any special intelligence that would be well known to all the people along the country side, could easily be sent by means of torches and bonfires from mountain top to mountain top. But the system of spelling and using words would indicate greater ingenuity, and would require a trained staff to send the messages. We find, according to Sir Walter Scott, in his "Lay of the Last Minstrel," that an Act of Parliament was passed at Edinburgh, in 1455, which directed that one bale or faggot burnt at a station should be the warning that the English were advancing; that if the English were come indeed two bales must be used; and that if the enemy existed in great force, four bales must blaze side by side of each other. Gen. Fremont, when fighting

Digitized by Google

the American Indians of California some few years ago, reported in an official despatch that whenever he appeared in the country he noticed at scattered intervals upon the mountain tops pillars of smoke in the day time, and these, he observed, were the signals of the Indians communicating to the various tribes the intelligence that the enemy was in the country. We find in the names of many places in our own country evidences of old signal stations. Taking into consideration the number of times England has been threatened with invasion by foreign foes, one may imagine that great pains would be taken to perfect a system of telegraphy that would enable our ancestors to resist the invaders. But whatever steps may have been taken, it has been with the greatest possible difficulty that I have obtained records of any particular system, except within comparatively modern times. I have made a careful examination of that portion of English history one hundred years before the battle of Bosworth Field, only to find that writers seem to have been very silent as to the method in which intelligence was conveyed. It appears that when Richard III. was making arrangements to defend the throne at which he had arrived by foul and unnatural murders, he stationed horsemen along the principal roads of the Midland Counties, and leading to the coast, at twenty miles apart. These couriers could carry information very rapidly, the system being such as to permit of a letter being taken a distance of two hundred miles in two days. For some reason which is not explained, this plan was evidently not in operation just before the battle of Bosworth Field, for we are told that, despite Richard's vigilance, the Earl of Richmond landed at Milford Haven and rapidly advanced through Wales, and the valiant Welshman, Rhys ap Thomas, who contributed so much to the success of Richmond's enterprise, ordered beacon fires to be lighted on the mountain tops, and summoned his Welsh retainers to the field. Richmond and the Welshmen and the men of Lancaster were at Shrewsbury before Richard knew of Richmond's arrival in the country. There is a poem written by a Welsh bard, who tells us of the part which Rhys ap Thomas played, and praises his heroic deeds under the standard of Richmond; and the bard tells us that not only did all the enemies of Rhys ap Thomas fear him, but that even wild Irishmen had been known to tremble in his presence. There is one bit of local history in connection with Bosworth Field that may prove of some interest to the people of Wigan. It seems that when in France, shortly before that eventful battle, Richmond had registered a vow that he would wed the Princess Elizabeth if he ever became king of England. The princess, as you will be aware, was sister to the two young princes who had been murdered by Richard in the Tower. Elizabeth was very anxious to obtain the aid of the Stanleys of Lathom—Lord Stanley and his brother, Sir John—and also the Stanleys of Manchester, all relatives. In an old ballad of the period the princess is described as giving instructions to a messenger to go through Manchester to Lathom Hall, and mind and turn at Salford Bridge. Stanley promises to come, and assures the princess through her trusty messenger that on reaching London he will stay at an inn which he does not often frequent, and her friends may know that a Stanley is there when they see an eagle's foot chalked on the door. In this connection it may be mentioned that Stanley's retainers were called "Eagle's feet men," as some others were styled "Bears and Ragged Staffs," after the devices on their masters' crests. The other day I met with a very interesting account in the "Palatine Note Book" of the origin of the names of places. It seems the town of "Ingleborough" really means the signal or fire borough, "ingle" meaning "fireplace." Then we have Inglewood, Beaconsfield, and other places, which have derived their names from the ancient use to which they were devoted as signal stations. In the north we have "Scout Star," a hill where the scouts or watchmen were stationed. A new departure in torchlight telegraphy was made in the Shetland Isles at the beginning of this century by the Rev. James Bremner, to whom the Scottish Society of Arts presented its medal for his invention. By the use of a single torch the rev. gentleman was enabled to send messages. This was done by alternately exhibiting and concealing one torch. Indeed, so far as I have been able to learn, Mr. Bremner may be considered to be the inventor of the flash light system, which, in the modified form, is now used on the vessels of the British navy, and also by our army in the field at night. It was used in the recent campaigns in Abyssinia, Afghanistan, and Egypt. This alternate exhibition and concealment of the light enables a word to be sent nearly as fast as man can write. On ships at night, instead of a torch being used, powerful lanterns are substituted. No doubt most of you are aware that the flash light telegraph is made by means of a piece of looking glass, and when the sun shines this is called the heliograph. Messages are sent by simply placing this looking glass at such an angle as to reflect the sun's rays. By means of a telescope messages have been received in this way from a station ten miles away. The Morse code of the dot and dash system is used for the flash light purposes, and by alternately exposing and concealing the looking glass by day, and the lantern by night, messages can be sent, as I have said, nearly as fast as a man can write. It seems that Mr. Bremner, the Shetland clergyman, put his plan into operation, and was enabled to communicate at night between one island and another; and he established two stations, one in Scotland and the other in Ireland, and was thus in a position to telegraph between points twenty miles apart. Probably the most exciting conditions—at any rate to the people of this country—under which the old system of telegraphing by means of torches, beacon fires, banners, and guns, occurred on that memorable night when the whole country was roused to resist the invasion of the cruel and arrogant Spaniard, now close upon 300 years ago. Spain, it must be borne in mind, was at the time of the Armada acknowledged to be the most powerful military nation in Europe, and she had earned a reputation for cruelty which placed the people of this country in real fear. The story of that eventful period is in the mind of every school boy. Then was it that every man who could bear gun or pike placed himself at the service of the Queen. Does not Macaulay tell, in brave words, of the patriotic manner in which the Lord Mayor of London answered Elizabeth's demand for 15 ships and 5,000 armed men? And has not our blood circulated all the faster as we have read the sturdy answer which the bold Englishman gave his Queen—how he begged her Majesty to accept, instead of 5,000 men, 10,000 men, and instead of 15 ships fully armed, manned, and equipped, 30 ships to defend their native land? You remember how Macaulay, in that spirit-stirring "Fragment" of his, tells how the news came to the south coast that the Armada was in sight, and how the whole afternoon and night were devoted to sending warning signals throughout the length and breadth of the country. News of "the great fleet invincible" came by "a gallant merchant ship, full sail to Plymouth Bay," and—

Forthwith a guard at every gun was placed along the wall,
The beacon blazed upon the roof of Edgcomb's lofty hall;
Many a light fishing bark put out to pry along the coast,
And with loose rein and bloody spur rode inland many a post.

* * * * * *

And swift to east, and swift to west, the warning radiance spread,
High on St. Michael's Mount it shone—it shone on Beechy Head;
Far on the deep the Spaniard saw, along each southern shire,
Cape beyond cape, in endless range, those twinkling points of fire;

* * * * * *

And broader still became the blaze, and louder still the din,
As fast, from every village round, the horse came spurring in;
And eastward straight, from wild Blackheath, the warlike errand bent,
And raised in many an ancient hall the gallant squires of Kent,
Southward from Surrey's pleasant hills flew those bright courses forth,
High on bleak Hampstead's swarthy moor they started for the north;
And on, and on, without a pause, untired they bounded still,
All night from tower to tower they sprang—they sprang from hill to hill,
Till the proud Peak unfurled the flag o'er Darwid's rocky dales;
Till like volcanoes flared and heaved the stormy hills of Wales;
Till twelve fair counties saw the blaze on Malvern's lonely height;
Till streamed in crimson on the wind the Wrekin's crest of light;
Till, broad and fierce, the star came forth on Ely's stately fane,
And tower and hamlet rose in arms o'er all the boundless plain;
Till Belvoir's lordly terraces the sign to Lincoln sent,
And Lincoln sped the message on o'er the wide Vale of Trent:
Till Skiddaw saw the fire that burned on Gaunt's embattled pile,
And the red glare on Skiddaw roused the burghers of Carlisle.

During the American revolutionary war, or War of Independence, as it is called, many different methods of signalling the approach of the enemy were used. Among the various plans was one of which this model on the table is an illustration. This telegraph consisted of a post or mast which was portable. A tub or barrel placed on the top; a movable flag on one side and a basket on a bracket near the top were used to signal with. By ringing the changes with the flag, the basket, and the barrel, and by moving the flag up and down, various signals could be sent. Altogether I believe that 50 different signals could be given by this means. We now come to the semaphore signals, which are used even to the present day, chiefly for railway purposes. Probably the most ingenious and among the first of this class of telegraphs was that invented by the brothers Chappe. It appears that this invention is due to the affection entertained by the two brothers for each other. They were placed as students at different schools, a mile and a half apart. They were inconsolable at being thus separated; and by means of pieces of wood, exposed from the back windows of each school, the brothers Chappe contrived to talk to each other. In their first system of telegraphy they arranged a code of signals which enabled them to send 192 different messages; this being done by means of instruments similar to the one I now have on the table. As the ingenious brothers became older the invention was placed before the Government and was tried just before the revolution in 1791. The people, however, looked upon the invention as only another means of increasing the power of the Government and the aristocracy. The introduction of the invention was opposed; the people destroyed the telegraph stations, and the inventors barely escaped with their lives. A second attempt shared the same fate. Again the various telegraph stations were burned to the ground. The brothers Chappe, however, continued their efforts, and in 1793 the Government adopted the system. Circumstances were favourable. The telegraph, having been adopted, was fortunate enough to communicate to Paris the news of a great French victory; and now the brothers Chappe were considered part and parcel of the glories of France. This message was transmitted from the frontier to Paris:—"Condé is taken from the enemy;" to which the Directory replied, "The army of the north deserves the gratitude of the country." These messages ran like an electric shock throughout the Convention and throughout Paris. The once-abused telegraph was now the pride of the nation, and its inventors were worshipped as public benefactors. The system invented by the brothers Chappe soon became universal on the Continent. A line was carried from Paris to Lille, and two minutes only were occupied in transmitting a word. In 1802 the system was adopted in Denmark. Shortly afterwards it was made use of by the Governments of Belgium, Sweden, and Germany. Mahomet Ali erected stations on this system from Alexandria to Cairo. The most expensive series of stations was constructed in Russia by the Emperor Nicholas. A line of towers was erected from the German frontier, through Warsaw, to St. Petersburg. This line embraced 220 stations, at each of which were six men, so that 1,320 men were employed on this route, besides those who had charge of the general administration. The erection of these towers cost the Russian Empire millions of pounds sterling. The system was only finished and got to work so comparatively recently as the year 1858; and after being in operation a very short period, it was completely superseded by the electric telegraph. The towers

Digitized by Google

are still standing—silent monuments to the ingenuity of the past. Scarcely any description is required of this Chappe semaphore telegraph. The method of manipulating the arms was by means of levers, similar to those now in daily use on our own railways. Occasionally the system was used at night, by placing lanterns on the ends of the vanes. Men were stationed along the line of communication with telescopes, and thus, by means of known changes, various codes could be worked at great speed. In France, along the route between Toulon and Paris, a distance of 475 miles, there were 120 stations; and it is said that so complete were the instruments made that over 82,000 different signals could be sent. The Prussian system of semaphore signals—a model of which we have on the table—was introduced in the year 1782. It will be seen that this is but a modification of the French system. Forty thousand signals could be sent by this means. The English semaphore shutters, or Lowre telegraphs, were invented by Lord Murray, in 1795. The instrument, as you see here, consists of six shutters working on pivots. Sixty-four distinct signals could be sent by this system from London to Dover in ten minutes. These were placed along the coast leading to stations inland, and were in general use in this country up to the invention of the electric telegraph. Messages could only be sent in the day time by this system. It is mentioned that after one of Wellington's victories over the the French, when the news was being sent to London, the sender at the coast end began the signal with the words "Wellington defeated ——." A dense fog prevented the rest of the signal being seen, and the result was great consternation in London and a panic on the Stock Exchange. When the fog cleared up the following day the rest of the message was received, and the message then read, "Wellington defeated the French." I remember when I was a boy this system being used between Holyhead and Liverpool for sending news of the arrival of the American mail. On the vessel being sighted at Holyhead the news was sent forward right across Anglesey to Puffin Island, thence to the Great Orme's Head, thence right along the Welsh coast to Parkgate, across the mouth of the River Dee, and thence to Liverpool. For many years the intelligence sent in this old-fashioned way from Holyhead to Liverpool was sent from Liverpool to Manchester by electric telegraph. Many of the old stations on the line of route between Holyhead and Liverpool are still in existence, though their occupation has gone. I have said very little of the various naval telegraphs. Among the rude Vikings of the northern seas, signals were made with banners and by blowing trumpets and horns. In an account of the invasion of William the Norman we are told that he signalled his ships by means of trumpets. The ship of the commander of a fleet could always be found in the old tapestries and old engravings by the illustration of a trumpeter at the prow of a vessel. In the "Tales of a Wayside Inn," we have a legend of one of "the dead kings of Norway," a king who went

> "Sailing, sailing,
> Listening to the wild winds wailing
> And the dashing of the foam.
>
> * * * * * * * *
>
> 'Sound the horns,' said Olaf the King;
> And suddenly through the drifting brume
> The blare of the horns began to ring."

The old system of telegraphing from one ship to another was carried on by placing flags in various parts of the vessel, at the stern and at the masthead. This was introduced in the time of James II. Sometimes terrible mistakes were made. The pendant is a well-known flag in ships of war. Its usual length is twenty yards, while it is only four inches broad at the masthead. Its history is generally understood to have been this:—After the defeat of the English under Blake by the Dutch fleet under Van Tromp, the Dutchman carried at his masthead a broom, in token that he had "swept the seas" of all her enemies. Afterwards Blake defeated the Dutchman, whereupon the English admiral in command hoisted a long streamer from his masthead, to represent the lash of a whip and as a token that he had "whipped" his enemies off the sea. There is not sufficient time for me to explain to you the various methods of spelling by means of flags. This branch of the subject would occupy a night of itself. In the year 1801 the clumsy system of signalling in the navy was somewhat simplified by the method introduced Sir Home Popham. Admiral Nelson was requested by the Admiralty to experiment with this system and to report upon it. As every Englishman knows, just as the English vessels were in line of battle in Trafalgar Bay, Nelson signalled to the captains of his fleet, "England expects that every man will do his duty." The flags here are exact copies of those used on that memorable occasion. I am indebted to the Lords of the Admiralty for kindly permitting Messrs. Thomson and Son, Admiralty flag makers, London, acting in my behalf, to search in the records for a description of these signals. The model on the table here is one of the system invented by Sir Francis Ronalds. There are many points of similarity between it and the Greek water clock telegraph. Sir Francis recommended the use of two clocks with wheels, one at the sending and the other at the receiving station. These clocks were made to drive dials at exactly the same speed, to work isochronously. The alphabet, as you see, is painted on the dials, which revolve behind a little hole, showing only one letter at a time. The sending and receiving instruments are coupled together by means of an electric wire. Pith ball electrometers are hung in front of each dial. On the balls being extended by means of an electric current this signal would cause the receiver to allow the clock to run down. Another signal causes the clock to be stopped. The sender and receiver, starting and stopping the clocks in this way, were enabled to send and receive messages in a remarkably quick manner. This, although not the first electric telegraph, is one of the first invented that was of a workable character. The inventor communicated his ideas to the War Office soon after the battle of Waterloo, and he received an intimation from the authorities there to this effect:—"Now that the war is over telegraphs will be no longer required." The telegraphs I have endeavoured to describe are chiefly those used for the purposes of war. Even in this country it was considered by official persons that the arts of peace would not be much benefited by these quick methods of communication. It is not within the scope of the lecture this evening, nor have we time, to consider modern telegraphy. For the present it may be permitted to say that, according to Mr. W. H. Preece, an eminent authority on telegraphy, 400 words per minute can now be telegraphed along one wire, as a result of the recent improvements of duplex and quadruplex circuits in connection with automatic instruments. When the telegraph service was taken over by the Government a few years ago, 126,000 messages were sent per week. Now the weekly number is 600,000. In press work the increase is most marked, the rate in this period having risen from 5,000 words per day to nearly one million—that is to say, 340 million words of press messages have been delivered during last year. England has not a monopoly of this useful agent. All prominent countries exhibit corresponding growth. The Japanese even despatch 200 million messages a year. The telephone is another wonderful advance in telegraphy. To enable people to speak in actual words, with the accent and tone, to their friends miles away, is a splendid scientific triumph. I have endeavoured to describe the ancient methods of telegraphing, and must leave the subject at the very threshold of the electric telegraph. Lightning is now the errand boy of man, whose speed is greater than flight and sound. The future development of this useful art is in the hands of the men of science who have succeeded the old astrologers and alchemists. These men are, to use the words of Ben Johnson, "the Divine instructors who can extract the souls of all things by their art; call all the miracles of the sun into a temperate furnace, and teach dull Nature what her forces are." The electric telegraph is powerful in promoting the uses of civil life; this wonderful invention is blessed in strengthening the arts of peace, it imparts vigour to man in fighting his ancient enemies, plague, pestilence, and famine. May I say that it sings psalms to the poor, for if in any corner of this wide world thousands of miles away the crops are good and the earth is blessed with abundant food, the glad tidings are quickly proclaimed by this "Swift messenger of the Gods," even before the autumn tints proclaim that they are ready for the gatherer. This obedient servant of mankind never sleeps, it has no night, sunrise, no sunset; for the sun is always shining upon it somewhere. The merry click of the instruments seem to me like Longfellow's birds—

> Remember this: It is always morning somewhere, and above
> The awaking Continent from shore to shore,
> Somewhere the birds are singing evermore!

NOTES.

West Coast of America Telegraph Company.—The gross earnings of this company for the month ending Oct. 31st were £4,065.

Brazilian Submarine Telegraph Company.—The traffic receipts of this company for the week ending 31st October amounted to £3,618.

Death.—Mr. Walter Cross, clerk in charge of the Brazilian Submarine Telegraph Company's Lisbon office, expired on the 6th of October from hœmorrhage.

Indian Postal and Telegraph Service.—The Postmaster-General of India has arrived at Berlin to study the German postal and telegraph service.

The Postmaster-General.—The public will learn with regret that Mr. Fawcett, who was attacked at Cambridge by pulmonary congestion, expired on Thursday afternoon.

Direct Spanish Telegraph Company.—The estimated traffic receipts of this company for the month of October were £1,794, against £2,115 in the corresponding period of last year.

Eastern Extension Telegraph Company.—The traffic receipts of this company, including subsidies, for the month of October amounted to £41,357, and to £39,174 in the corresponding period of 1883, showing an increase of £2,183.

Western and Brazilian Telegraph Company.—The traffic receipts of this company for the week ended 31st October were £2,934, after deducting the "fifth" of the gross receipts payable to the London Platino-Brazilian Telegraph Company.

Electric Light at Wycombe.—We read that on the occasion of the Prince and Princess of Wales passing through Wycombe, on their way to visit Lord and Lady Carrington at Wycombe Abbey, the streets were brilliantly illuminated with the electric light.

Change of Address.—Messrs. Marshall, Sons, and Co., the well-known engineers, have now completed their London premises at Marshall's Buildings, 79, Farringdon-road, E.C., where they have a large assortment of their productions for sale or letting out on hire.

West India and Panama Telegraph Company.—The estimated traffic receipts of this company for the half month ended the 31st ult. are £2,468, as compared with £2,290 in the corresponding period of 1883. The July receipts, estimated at £5,865, realised £5,932.

Private House Lighting.—The Hammond Electric Light Company have received instructions from Mr. W. C. Alexander to light with electricity his residence, Aubrey House, Campden-hill. The plant to be installed will be sufficient to run 90 incandescent lamps.

Electric Light at Harrogate.—The lamps used at Harrogate are the Weston arc lamps; besides the arc lamps, however, a number of the Maxim-Weston Company's new incandescent lamps are used, the current being supplied by a 240-light self-regulating Weston dynamo.

Business Notice.—We are informed that Messrs. Mayfield and Co. have taken over that part of Messrs. Paterson and Cooper's business relating to educational, philosophical, and experimental apparatus, Messrs. Paterson and Cooper confining their work more especially to electric lighting, telegraphy, and telephony.

Cuba Submarine Telegraph Company.—The number of messages passing over the lines of this company during the month of October was 2,588, estimated to produce £2,200, against 2,814 messages, producing £2,744, in the corresponding month of last year. The traffic receipts for the month of July, estimated at £3,200, realised £3,219.

Chrysanthemums and Electric Light.—With reference to our note on this subject last week, Mr. Frederick C. Phillips, of 2, Victoria Mansions, S.W., writes to us as follows:—"You may be interested to know that I am this week lighting the chrysanthemum show of Messrs. Cutbush and Son, at Highgate, by means of four of my new 10-ampere arc lamps."

Brewers' Exhibition.—With regard to our notice of this Exhibition, Messrs. Oppermann Brothers write:—"Seeing your notice in last week's *Electrician* on the electric light at the Brewers' Exhibition, we beg to draw your attention to the fact that the twenty-one lamps you mention as being used to light the British Gas Engine Company's stand were our new specialty lamps at 2s. 6d. each."

Oriental Telephone Company.—In a circular addressed to the shareholders of this company, the directors caution them against some misstatements which are in circulation, and against "blindly sacrificing their property," adding that the revenues of the company and of its affiliated companies have materially improved since the last report, while the expenses have been considerably diminished.

Society of Telegraph Engineers.—The next meeting is for Thursday, Nov. 13th, when the following papers will be read:—(1) "On the Theory of Alternating Currents, particularly in reference to two Alternate Current Machines connected to the same circuit," by J. Hopkinson, F.R.S.; (2) "An Account of Experiments with Alternate Current Machines," by Prof. W. Grylls Adams, F.R.S., president.

Electric Repeating Clock.—Sig. Bianchini has applied an electric contrivance to all the bells of a clock striking the hours and quarters, in such a way that, by simply making contact, the bells, which otherwise remain silent—say, during the night—indicate the time at the next quarter. A special arrangement also permits of making all the bells sound at pleasure, or only one independently of the others.

Gaulard and Gibbs' Generators.—As these secondary generators had no competitors at the Turin Exhibition, and the jurors had only to regard the scientific aspect of the question, without being troubled by considerations as to the cost of the current transmitted, they awarded to these exhibitors the 10,000f. (£400) prize offered for the best process exhibited for the distribution of electrical energy at a distance.

Awards at the Healtheries.—The list of awards is prefaced with the remark that it has been decided to defer the adjudication of awards to exhibitors of electric lighting apparatus in Class 26 until the exhibits included under this head in the Inventions Exhibition of next year are dealt with, in order that the necessary comparative tests (which must extend over a long period) may be thoroughly carried out. Anent this matter see our leader of 20th September last.

International Society of Electricians.—The ordinary monthly meetings of this society were resumed on the 5th inst. in the hall of the Société de Géographie, Paris. The papers

Digitized by Google

on the list were on the following subjects:—Definitions, Conventions, Notations, and Electric Symbols, by E. Hospitalier; Mechanical Corrector of the Deviations of Mariners' Compasses, by Captain Fournier; and Electric Signals in the French Navy, by A. de Meritens, with experiments.

Electricity for Nothing.—At the Manchester Police-court last week, an elderly man, named Harrison, was committed for trial on the charge of obtaining money under false pretences. He had received £180 from a Mr. Frith in order to bring his invention before the public, the said invention being a self-acting apparatus, which could be put in a box like a gas meter, and was to supply electric light by simply turning on a tap, and work tramcars or locomotives without coal or motive power.

Extension of the Electric Light.—We understand that the Stanners Close Steel Company has decided to extend its electric light plant by the addition of some ten Brush arc lamps, six of which are now being erected. As this firm has been employing the light for some time, the present extension speaks well for its success. The work is being carried out by the Hammond Electric Light Company, which also carried out the work at the Grand Hotel, Eastbourne, mentioned in our last issue.

Great Northern Telegraph Company.—This company notifies that the rate to Canton has been reduced to 8s. 9d. per word from the 1st instant; and that a telegraph station has been opened at Swatow, for which place messages can now be accepted for transmission by this company's lines at the rate of 10s. per word.—The traffic receipts of this company for October amounted to £26,000; from 1st January to 31st October, £234,680; against, in the corresponding months of 1883, £215,285, and of 1882, £203,575.

A New "ism."—Professor Lambroso, writing to the *Revue Scientifique*, has given a new name to an old state of things—say condition of the mind. He calls "*misonéisme*" (from μίσος, hatred, and νέος, new), that dislike to change, even for the better, which is distinctive of most animals, man in particular, and perhaps Englishmen in the highest degree. *L'Electricien* asks if an instance of "misoneism" is not afforded by the English sticking pertinaciously to their old system of weights and measures, which leads to everlasting complication.

Electric Light in the Distillery.—The Anglo-American Brush Electric Light Corporation has placed incandescent lamps throughout the premises of Messrs. Andrew Usher and Co., distillers, Sciennes, Edinburgh. Besides effecting a saving of 33 per cent. in the cost of illumination, the new light will render the outbreak of fire a matter of very remote contingency, even in what is known as the spirit safe at the worm end, where the greatest care had to be exercised in the use of gaslight, owing to the liability of the spirit fumes to ignite.

Eastern Telegraph Company.—This company notifies the opening of a new station on the island of Perim, at the mouth of the Red Sea. The rate to this place is the same as to Aden, viz., 3s. 9d. per word. The company also announces the opening of a new station in China (Swatow), the rate for telegrams to this place being 10s. per word. The charge for telegrams to Canton is reduced from 10s. to 8s. 9d. per word. —The traffic receipts of the company for the month of October amounted to £53,865, and to £47,624 in the corresponding period of 1883, showing an increase of £6,241.

Close of the Health Exhibition.—The doors of the Healtheries were finally closed on Thursday, 30th October, to the great regret of many, who would have at any rate liked the week lost before the opening to have been made up by an equal prolongation before the close. In less than six months, during which the Exhibition remained open, it was attended by 4,167,683 persons, or 1,464,632 more than the admissions to the Fisheries of last year. It is certain that the clear profit will be at least £30,000, and more likely £40,000, of this, the most successful exhibition that has ever been held.

The Catastrophe at Glasgow.—Without dwelling on the details of this terribly cruel fatality—cruel alike on account of its prime cause and the want of means for prevention—we will put on record here the suggestion made by M. Buls, the Burgomaster of Brussels, for preventing a similar calamity. He would provide ample and independent exit doors opening outwards, kept shut by the attraction of bolts forming the armatures of powerful electro-magnets. On any alarm being raised, he would, by a single switch, break contact in all the wires and allow the doors to be forced open by strong springs.

Electric Burglar and Fire Alarm.—An improved electric burglar and fire alarm, one of which, we are informed, is being fitted up at Scotland-yard, was shown in action at the recent Brewers' Exhibition by Mr. G. L. Pearson, of Holloway, N. When the current from a battery or accumulator is switched on at night, any tampering with the doors or windows interrupts the circuit, causes a bell to ring, gives an alarm at the nearest police station, and, by means of an arrangement like the new electric gas-lighters, lights a red lamp with three bull's-eyes shining in three different directions.

Brake Worked by Electricity.—The Walker brake, worked by current from a dynamo on the locomotive, has been tried on the Alta Italia Railway. In each waggon, one of the axles is surrounded by a loose metal sleeve. When the current passes, it causes some pieces of soft iron to enter recesses, thus engaging the sleeve with the axle so as to revolve with it. A steel chain, attached to the sleeve, acts on a system of levers which tighten the brake blocks on the wheels. On the line between Turin and Orbassano, a train running at about 15½ miles an hour was pulled up in six seconds and in a distance of 60ft.

Prospecting for Minerals by Electricity.—Our old friend Dousterswivel's divining rod must certainly give way before the electric arrangement which hails from the other side of the Atlantic. Two iron bars, connected at their upper extremities by a lead including electric bell, are driven into the earth where ore is supposed to exist. If the bars do not encounter a vein, the circuit is closed by the earth, and the bell coil is arranged so that the bell shall not ring. If, on the other hand, a metallic deposit occur between the bars the circuit becomes very feeble, and the bell gives forth no uncertain sound.

Electro-Musical Effects.—The Alhambra—not in Spain but in Leicester-square—has reverted to the only entertainment for which such a building is suitable—viz., a variety entertainment like that of the Paris Folies-Bergère and the Brussels Eden-Theatre. The Bozza troupe are repeating a buffo-musical performance that they have already given in several Continental cities. Sig. Carlo Bozza plays the "Ranz des Vaches" on a piano-harmonium, working from the keyboard, by the electric current, all sorts of *obbligato* effects, such as the beating of drums and the blowing of horns, disposed at various points about the auditorium.

The Insulite Company.—A special meeting of this company is called for the 17th inst. for the purpose of confirming

Digitized by Google

the following resolutions which were passed at a previous meeting:—"1. That this company hereby adopts the agreement dated October 22, 1884, made between this company of the one part and the British Insulite Company of the other part, being the agreement mentioned in the notice of this meeting (dated October 10) as providing for the transfer to the British Insulite Company for the assumption by the last-named company of this company's assets and liabilities. 2. That it is hereby required that this company be wound up voluntarily."

Gas and Electric Light.—Speaking at Huntingdon the other day, Lord R. Churchill is reported to have said:—"Well, now, let us take another subject, not perhaps of such great importance, but still of importance to our urban population. I mean the question of electric lighting. That is a matter which promises to be a source of the greatest possible comfort and economy to our urban population. But Mr. Chamberlain took it in hand, with the result that electric lighting has for a time been utterly knocked on the head, and all enterprise and all invention for the time has been crushed, while those monsters of exorbitant extortion, those most mischievous monopolies—the gas companies—have been given a new lease of life."

Electric Light at Eastbourne.—On the report of the Lighting Committee being brought before the Town Council the other day—which report was against continuing the electric light for financial considerations, notwithstanding a petition in its favour—Alderman Pearson said it was with feelings of regret that the committee could not comply with the request of the memorialists and continue the electric light in the streets, and Councillor Chambers thought the light should not be cut off without a chance of having it again; but Alderman Pearson explained that the columns were the property of the Electric Light Company, and accident might arise from their being allowed to remain. Ultimately the report was adopted, and Eastbourne will be left in semi-darkness during the winter months.

New Lightning Conductor.—The setting on fire by lightning of the church at Belleville (an industrial faubourg of Paris), which was fitted with three lightning conductors and a permanent controller, induced M. E. Grenet to notify to the Paris Academy of Science that for some years he had applied to several houses of the arrangement described in the old instructions of Gay-Lussac, and which permitted him to protect buildings absolutely. He uses a copper band, 3 centimetres (1½in.) wide and 2mm. thick, traversing all the ridges, and surmounted, if necessary, by small points, also of copper, placed on the salient angles, and reaching to the earth with a surface of a square metre, represented by 15 metres of the same band placed in a trench, or connected with the underground gas and water pipes.

Electric Light at Hell Gate.—With regard to the electric lights in the iron tower at Hell Gate, which were put in operation on 20th October, an eye-witness records his impressions as follows:—The night was somewhat hazy, and all the lights on shore, except those in the tower, showed dimly. The tower, a skeleton structure, was not visible, and the first impression received on catching sight of the light was that the moon had risen. The light was more diffused and less glaring than the electric lights at Madison and Union squares. Buildings on Flood Rock and on the Long Island side of the Gate could be seen distinctly, but all their angles cast shadows of the most intense blackness. The water, whirling and surging through the Gate as the flood-tide swept up, could be seen as on a bright moonlight night with all the eddies visible.

Electric Lighting Memoranda.—Under this head the *Journal of Gas Lighting* says that the action of the Dynamicable Society for upsetting the Electric Lighting Act will probably be justified by the contention that the demand is not so much for special legislative facilities as for the removal of legislative disabilities. This plausible argument, however, will only be accepted as valid when it can be shown that the Electric Lighting Act is really to blame for the condition of affairs complained of; in other words, that electric lighting progresses better in countries where our terrible Board of Trade has no existence. Until this is proved the Act will remain unrepealed; for it will keep the way open for that perfect system of electric lighting which has not yet been produced, notwithstanding the pretensions of the syndicate of 1882. The note concludes with the statement that, whatever be the cause, it is certainly a very dead time at present with all electricians, except those who are making the most of their opportunities in the way of lighting steamships.

Boycotting the Monday Pops.—An over-heated frequenter of St. James's Hall, who signs himself "A Regular Subscriber to the Monday Popular and Richter Concerts," writes to us pointing out the fact that St. James's Hall being less stifling than usual at the first Monday Popular Concert was probably only due to the 'cold, biting wind.' The following night it appears there was no ill wind to blow the concert-goers any good. The hall was as hot as ever, which our correspondent attributes to the fact that 'the hall is over the dining rooms, and these are over the kitchens, both of which places are lighted with gas.'" The suggested remedy is to substitute electric light throughout the building. To bring this about the following suggestion is made: "Let a number of the regular subscribers to the concerts given at St. James's Hall agree not to renew their subscriptions unless the whole building is lighted by electricity, and let them inform the directors of the hall of this agreement." Which indeed would not be a bad plan. But when did concert subscribers ever combine in an organised strike?—*Pall Mall Gazette.*

The Creil Experiments.—We learn from the *Bulletin* of the Cie Internationale des Téléphones that, though the syndicate founded by Baron Rothschild has the sum of 500,000fr. (£20,000) at its disposal, for conducting the trials in connection with M. Marcel Deprez' system of transmitting electric current, the committee, which holds its sittings at the Paris Northern Terminus, considers the expense will not exceed 400,000fr. (£16,000). The programme of the experiments has been drawn up so as to carry out, for several weeks together, the working of a central station for the generation of current and its transmission to a distance under the conditions that would be met with in actual practice, while analysing all the details, following all the transformations of energy and determining the influence of each of the intermediate elements with respect to leakage and consequently useful result. It is to be set at rest how far this system is advantageous, if it permits of distributing the current transmitted, what reliance may be placed on electric generators; and lastly all the particulars essential for appreciating the industrial value of the invention are to be brought together.

Telegraphic Communication Without Wires.—Under this title *L'Electricien* recalls Professor Graham Bell's experiments on the Potomac river, for effecting communication between two vessels a mile and a quarter apart, one carrying a dynamo and the other a telephone, each with the two leads dipping into the water, but with no conductor except the water

Digitized by Google

between the two vessels, the sole condition being that the two circuits have not the same potentials. Our contemporary then mentions Professor Trowbridge's proposal for the intercommunication of ships at sea, and the fact recorded by Mr. Preece that this system was put in practice for telephoning between Southampton and the Isle of Wight while the regular working of the cable was interrupted, and then goes on to say that the American Association ignored the experiments in this direction made in 1870 and resumed in 1876 by M. Bourbouze, between the Pont d'Iena and the Pont d'Austerlitz, at Paris. If the experiments in question were not followed up by practical results, they do not the less deserve to be put on record; and they would probably have made more noise if the Bell telephone, only just invented, had been known in France.

INCANDESCENT LAMPS V. PETROLEUM.—The owners of the steamer "Maasdam," of Rotterdam, which was burnt at sea on the 24th ult., will probably have their attention very forcibly directed by this costly accident to the advantages of the incandescent system for ship lighting. The danger of using petroleum for ships' lamps has been pointed out more than once, and now we have an apt illustration of it in the destruction of a large vessel in so short a space of time that, to quote the report of the accident in the daily papers, "neither passengers nor crew were able to save any of their effects." Surely the money lost by the burning of the "Maasdam," whether the loss fall on the owners or the insurance companies, would have sufficed to fit many such vessels with electric lights. We know that "the fault of the Dutch is giving too little and asking too much," but surely their well known commercial acuteness will show them that a foolish pennyworth of petroleum is likely to cost them more in the end than a pound wisely spent on incandescent lamps. Even supposing that steamers must carry petroleum, and that a tank of this oil were to leak owing to heavy weather, as in the case of the "Maasdam," there would be no danger whatever in searching for such a leak with a portable incandescent lamp. But to hunt for a leak in a petroleum tank with a flaming oil lamp is as foolish and dangerous as to search for an escape of gas with a light, and in the case before us the result was equally sudden and disastrous.

AN EVIL AND ITS REMEDY.—A correspondent to the *Journal of Gas Lighting* complains of the serious failure of the electric light at the Promenade Concerts one night when he happened to be present. He says that, just as the orchestra was performing a grand selection, and at least 1,500 persons were present, the whole of the electric lights went out, leaving the building in semi-darkness. But lo! in one or two minutes the benignant gas, which had fortunately been kept alight in reserve was turned on; and additional burners were lit as soon as possible. "What would have been the consequences had the gas not been ready lit for this emergency? It is hard to say," he moralises. We say that this backing up of the electric light by gas is a great mistake, besides entailing additional and unnecessary expense. Let every pot stand on its own bottom. What would have been the consequence if the supply of gas had suddenly run short at the gas holder, or the main been cut in two by an explosion, or any other accident? Why the audience would have been where Moses was, just as much as they were when the belt slipped off the dynamo, or whatever might have been the cause of the sudden extinction. The proper course to be pursued is to run the lamps in two or three separate circuits, so that an accident is hardly likely to occur to all at once. Keeping the gas on in reserve is like providing engine tenters with automatic alarms, which only make them neglect their duty. Employ a good steady staff, take every precaution against accident, and trust the rest to Providence.

THE POST OFFICE AND THE TELEPHONE COMPANIES.—The following, of which we could only give a brief note last week, is the full report of what took place in the House of Commons on Thursday, the 30th ult.:—Mr. Kenny asked the Postmaster-General whether it was a fact that a proposition had been made to Government to buy up the telephone interest of the United Telephone Company and its affiliated companies for the sum of £2,000,000. Was it true that, as stated in *The Electrician* of the 25th of October, 1884 (p. 525), the Postmaster-General had recently given a large order for Gower-Bell telephones to the United Telephone Company, and was it true that the price to be paid by Government for these instruments was more than ten times the actual cost; was it true that a law officer of the Crown had given an opinion (advertised in *The Times* and other morning papers of the 28th of October) that there was a telephone which did not infringe the patents of the United Telephone Company; and, if so, whether, in the face of this opinion, the Postmaster-General approved of paying such exorbitant prices to the United Telephone Company for the instruments he required for the public service.—Mr. Fawcett said: In reply to the hon. member I beg to say that no such proposition as that suggested for the purchase of the telephone interest of the United Telephone Company and its affiliated companies has been made to me. An order for 250 Gower-Bell telephones was given to the United Telephone Company on the 25th of May last; but the price to be paid is not ten times, nor anything like ten times, the actual cost. I should have been very glad if I could have got them cheaper than the price paid. The opinion of the Solicitor-General, published in the papers, was not given in his official capacity as law adviser to the Government, and until I read it yesterday in the advertisements referred to I was not aware of it. This being so, I am unable at present to say what course it will be desirable to adopt with regard to the future purchase of telephones for the use of the department.

SOLAR INDUCTION.—In a note to the *Académie* on the elementary force of solar induction, the periodical duration of which is a mean day, M. Quet thinks it best to wait for more complete investigations before coming to any conclusion, and that it is advisable to isolate as much as possible the elementary forces from each other, so as the more easily to examine their characteristics. In following this course for the principal forces, he deals with that one which corresponds with a mean solar day, and puts forward the following general proposition:—"The force of induction produced by any system whatever of electric currents on a particle, m, of positive electric fluid is perpendicular to the speed $o\,v$ of this particle, and to the direction $o\,d$ of the line of force which passes through the point o of the magnetic field; it is directed towards the left of the personified speed and regarding $o\,d$; lastly, it is measured by the area of the paralellogram constructed on $o\,v$ and $o\,d$. If f be this force, and e the angle $v\,o\,d$, the following equation will be obtained: $f = m\,d\,v \sin. e$." In the case of the sun acting on the earth, the action on the mass m at the centre of the globe will be directed from the centre of the earth towards the centre of the sun, or in the contrary direction, according as positive or negative electricity be in question, or according as the Austral magnetic pole of the sun be to the north or south of the ecliptic. For all the other points of the earth, the similar forces will be sensibly equal and parallel to the preceding. The electric currents of the globe are

Digitized by Google

therefore continually subjected to two systems of forces, which converge, some to the centre of the sun and the others to the opposite point. As the celestial sphere revolves, taking with it the sun, which has its own motion in addition, the forces of induction will follow the sun or the opposite point, will revolve with the celestial sphere and will complete their revolution in a mean solar day. These forces will preserve their intensity; and their direction will be subject to a variation of periodical duration equal to a mean solar day. This result, which is obtained by very simple means, may serve to verify those of the general analytical theory put forward.

Ship Lighting.—The following gives fuller details of the lighting of the ss. "Olympo" than our short note of October 25:—This steamer, built by Messrs. A. and J. Inglis, Pointhouse, Glasgow, for the Meusagerias Flureales a Vapor, is sister ship to the "Saturno," recently built by the same firm. The installation consists of 320 incandescent lamps of 20 candle-power, which are divided into six circuits, each of which is controlled by a switch in the engine room. Each state room is provided with a lamp having a separate switch under the control of the passenger. An adjustable resistance is placed in the field magnet circuit, and the speed of the engine is controlled by an Auldo reducing valve placed close to the switch board. The dynamo used is one of the Elphinstone-Vincent type, capable of lighting 400 lamps, and runs at 900 revolutions per minute, with an electromotive force of 90 volts. Over each gangway is placed a large lantern, each lantern containing a group of six incandescent lamps of 20 candle-power. The lights are suspended over the gangways by strong brass swinging brackets which can be shipped or unshipped at pleasure. By these means a splendid light is thrown over the gangways when passengers are being landed or shipped, or when landing or discharging cargo. A novel feature in ship-lighting is the introduction of storage batteries. There are 45 cells which can be charged while the dynamo is running and lighting lamps, and this accumulated energy may be used for lighting any portion of the vessel when she is in port and steam cannot be obtained. The engine used for driving the dynamo is one of J. and H. Gwynne's "Invincible" type. All the work connected with the installation has been carried out by Messrs. Wm. Harvie and Co., Broomielaw, Glasgow, under the supervision of Mr. Montague Scott, their chief electrician. The pendants, brackets, &c., which are of an elaborate description, were likewise designed and manufactured by Messrs. Harvie, who have carried out the work in a highly satisfactory manner. The steamer presented a beautiful spectacle when lighted up, and the steadiness of the light was much admired by the company on board.

Signals for Telephonic Communication.—A very complete system of telephony and signalling is carried out in the shipbuilding yard of Messrs. Denny Brothers, at Dumbarton. As they practically execute the whole of the work connected with the building of ships in their own yard, even to the most artistic parts of the decoration of the saloons, it will readily be understood that a good telephonic system is of great importance. The means adopted for intercommunication are quite unique. The telephonic exchange in use at Dumbarton resembles the central telephone exchanges in London and elsewhere. Every department can hold instant communication with any other department; but there is this important advantage. By means of carefully planned signals, it is possible to call to a given spot the head of any department, no matter where he may be at the time. A mast 90ft. high is erected in the centre of the yard; and, when any member of the firm desires the attendance of another partner, of the manager or any other official, he goes into the nearest telephone station, about thirty of which are distributed over the yard, and puts himself in communication with the switch room at the exchange. Having been connected with the attendant stationed in a telephone cabin at the mast, a signal representing the official who is wanted is hoisted. As soon as this signal is run up, the official called for either sees it or is informed by somebody else that his number is on the mast. All he has to do is to go to the nearest telephone station and connect himself with the person who has called him. Before long, further telephonic communication will be established with the National Telephone Company, Glasgow, so that a conversation may be carried on with any of the thousand subscribers to that exchange; and, by the trunk system of the company, it will also be possible to communicate with the exchanges at Edinburgh, Paisley, and Greenock. To such a pitch of perfection has the telephonic system been brought in Scotland already. Indeed, the longest talking line in Great Britain is that between Edinburgh and Glasgow, a distance of fifty miles; but conversations have repeatedly been held between Greenock and Edinburgh, *viâ* Glasgow, which is a distance of seventy-eight miles.—*Pall Mall Gazette.*

Electric Boiler Alarm.—Herr R. Schwartzkopff has devised an electric indicator which, fitted to a steam boiler, gives warning of insufficiency of water, excess of steam pressure, heating of the plates, and superheating of the water under normal pressure. The apparatus consists of two concentric pipes, the inner of brass, open at top and closed at bottom, and reaching below the lowest water level, and the outer of iron, closed at top and open at bottom, the lower end corresponding with the lowest water level. The annular space between the two is placed in communication with a chamber at the top of the apparatus by a small spiral tube. When the water is at its normal level, and before being heated, it stands at the same height in the boiler and in the annular space; but as soon as the pressure increases, the water rises in the annular space until it reaches the chamber, freed from air by a small orifice, closed by a stop-cock. This column of water is maintained as long as there is sufficient pressure and the water level is above the normal, when the column becomes cooled by radiation, and the temperature of the chamber descends below boiling point. As soon as the water level falls below the normal, so as to uncover the orifice of the outer pipes, the column falls, and the steam rises into the annular space to the chamber, causing the temperature to rise above boiling point, and thus indicating a deficiency of water by means of an electric signal. In the inner pipe there are two copper wires, insulated from one another and connected with the poles of a battery. They are enclosed at top and bottom of the apparatus in brass boxes, the bottoms and covers of which are of an insulating substance. The upper box contains a ring of metal fusible at boiling point; and, as soon as there is a deficiency of water, the ring melts, and the first drops of metal are collected in a funnel-shaped receptacle, thus making contact between the wires, and causing bells to ring or signals to manifest themselves. The lower box, which is immersed in the water of the boiler, has the same temperature as that of the steam; and the ring is formed of an alloy so mixed as to melt at a temperature corresponding to whatever pressure may be fixed upon as the limit. In case the plates should heat, a signal is also given by the lower box, the ring of which melts through the heat radiated from the plates. A Leclanché battery is used to give the current; and it is said that the fusible rings may be replaced, after action, in ten minutes.

CORRESPONDENCE.

MINIATURE INSTALLATIONS.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: Having seen in your paper of October 25th, under the heading of "Notes," a paragraph entitled "A Miniature Installation," could you, Sir, or one of your contributors inform me through your columns as to the *approximate* price of similar installations of sixteen lamps or twenty-four lamps. Such a method of lighting would be invaluable in small country houses, or even in town houses, where gas is bad or unobtainable.—Yours, &c., GEO. H. MARRIOTT.

12, Alexandra-place, St. Andrews,
Fife, N.B., Oct. 29, 1884.

THE HEALTHERIES FOUNTAINS.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: A question has arisen as to whether the coloured lights thrown upon the fountain at the Health Exhibition proceeded from the island or from an elevation in the neighbourhood of the clock. If you will kindly answer it through your correspondence column I shall be obliged.

To make my meaning clearer I would say, Where did the operator stand?—Yours, &c., J. G. A.

Hull, 1st November, 1884.

[A full description of these fountains was given in our issue of September 27, where the desired information will be found.—ED. *E.*]

THE PHILADELPHIA EXHIBITION.—VI.

(FROM OUR SPECIAL CORRESPONDENT.)

PHILADELPHIA, OCT. 16.

The Electrical Exhibition was closed last Saturday at 11:30 p.m., as announced; but there were no ceremonies save a burlesque performance by some of the exhibitors. The hour of closing had been extended from 10 until 11:30 p.m., and about 11 o'clock some of the facetious electricians appeared with silk badges bearing the initials "M.E.O.K.," which being translated became the "Mystic Electrical Order of Kazoos." The kazoo is a diabolical musical instrument sold to small boys at the Exhibition. It makes a horrible noise, and has the disadvantage that anybody can play it without a lesson. Armed with kazoos and preceded by a big bass drum, the mystical order paraded about the hall, and then held a burlesque meeting. Some of the facetious spirits that organised this demonstration had previously distinguished themselves by a witty publication. For the information of the public Professor E. J. Houston had prepared and printed short primers of electricity, which undertook to explain "Batteries," "Dynamo-Machines," "Electric Lighting," and similar subjects, in plain language, and within the compass of little four-page pamphlets. They served their purpose well enough, but were necessarily rather ridiculous to those who understood the subjects thoroughly. They were consequently fair game for satirists, and somebody saw and accepted the opportunity. Primer No. 0 soon made its appearance. It undertook to describe "Dynamite Electric Machines," and some of its passages contained clever hits at the other primers and the inventors and exhibitors. Here are a few passages:—"Dynamite electric machines may be painted a great variety of colours without increasing their efficiency. This affords scope for aspiring inventors." An illustration shows a boy turning a grindstone:—"When the crank is put in rapid rotation by a small boy under the normal conditions of this building, he immediately becomes incandescent —*i.e.*, red hot. This effectively illustrates the transformation of energy."

"There are two kinds of electric lights, namely:—

"*Our* kind and the other fellow's kind.

"Our light is much lighter than the other fellow's light.

"The other fellow's light is surrounded by a cloud of non-luminous verbosity."

This burlesque primer had a very large sale, chiefly among the electricians and exhibitors. I mention it and the tomfoolery of the closing night only because it is characteristic, I believe, of American irreverence. There was plenty of science and hard work, but there had to be a little fun, too, to brighten the scene and lighten the labours of the exhibitors. No accident occurred during the Exhibition, but the managers were extremely fortunate in having forty days of good weather. There were only two or three slight showers of rain in all that time. A soaking rain, penetrating to the building, might have resulted in a very different story.

In round numbers the expenses of the Exhibition amounted to $100,000. This included about $40,000 spent in the erection of a building, which is to be kept standing for four years for other specialty exhibitions. There were about 300,000 visitors, and the cash profits amount to at least $10,000. The Franklin Institute has also obtained a valuable library on electricity, and a large museum of electrical machines, models, &c. The test instruments used by the examiners have been purchased for the Electrical Section of the Franklin Institute, to be used by committees of that body in testing new inventions submitted to them for examination.

On the last day of the Exhibition Griscom's electric railway was put in operation. It presents a few novel features, and so far as preliminary tests go the motor promises to be very efficient. Mr. W. W. Griscom, the inventor, exhibited at Paris, I believe, his double induction motor, a little machine weighing only 2½lb., and run by a battery intended for household use in operating sewing machines. The magnet is a continuous ring with polar extensions inside and wound between these extensions. The armature is of the Siemens or H form. In the electric railway motor the magnets are of the same ring form, but the armature is a modified Gramme ring. Three rails are used, the middle one solely as a conductor of the current used, and one of the other rails as a return conductor. The current is taken up by metal brushes sweeping the rails. It is now being tested. The examiners are still hard at work, and are likely to continue for several weeks. Exhaustive tests are being made not only of electric machinery proper, but of steam engines and boilers used to drive the dynamos. It is not likely that the examiners' reports will be ready before the 1st January.

One of the curious exhibits which I believe I have not mentioned was Dolbear's telephone receiver. Professor Dolbear was one of the early experimenters with the Reis transmitter. He has produced a very different instrument, which is, I believe, the clearest and loudest speaking telephone (except Edison's chalk telephone) yet exhibited. He uses a current of high electromotive force. A diaphragm is arranged to whose centre is fastened a small platinum wire which carries at its extremity a small piece of carbon in rubbing contact with a second piece attached to a fixed support. This arrangement is in the circuit of a galvanic battery which also forms the primary of an induction coil. The secondary coil is continued to the line. The receiver consists of two plates preferably of thin iron, to each of which one pole of the secondary coil is attached. [The circuit may of course be either metallic or with return through earth.] The plates of the receiver are parallel to each other and separated by an air interval of about one-sixteenth of an inch. The secondary or line current is therefore broken or interrupted by an air space, but being of high electromotive force is able to exert an influence on the two diaphragms, and the attractions and repulsions of the two oppositely excited discs are sufficient to reproduce articulate sound. The most curious thing about this telephone is that it may be used without a wire, for a short distance at least. Holding the receiver to one's ear and disconnecting the line wire (the ground being maintained) the line wire may be removed to a distance of at least four feet without any disturbance of the efficiency of the phone. This extraordinary result was frequently shown, but the limits of the experimental room, a mere box, prevented any extensive tests.

I have not space in this letter to describe Delaney's synchronous multiplex telegraph system, but think it worth while to note that it was successfully worked during the

Digitized by Google

Exhibition over two hundred miles of wire, or from Philadelphia to New York and return. The test was a severe one, as the line used is partly aerial, partly underground, and crosses several rivers in cables. Six Morse circuits were worked at average speed over the single line without interference. The system is intended to work either Morse or printing instruments, or both, at commercial speed, a single line accommodating either six Morse instruments or twenty-four printers, or a proportionate number of both. The chief difficulty in the way of success is likely to be delay in getting rid of the static charge on long lines. The synchronism appears to have been mastered, but the description of this I will have to leave for another letter.

LITERATURE.

Die Elektrische Beleuchtung mit besonderer Berucksishtiguny der in den Vereinigten Staaten Nord-Amerikas zu Central-Aulagen vorwiegend verwendeten Systeme. By Dr. Ernst Hagen. [Berlin: Julius Springer.]

A host of books on electrical subjects, written to the publishers' orders, and containing only vague information, but much of would-be scientific small talk, have of late made their appearance in Germany. To speak of that kind of literature is not a pleasant task for the critic, and we have therefore abstained from noticing it in our columns. The above work, however, is a bright exception, and merits to be known. If not quite faultless from a scientific point of view, it at least contains plenty of solid facts and precise information.

The author has been deputed by the municipality of Berlin to inspect the different systems of electric lighting in use in the United States, and to publish an account of them. This mission he seems to have faithfully carried out, so far as that part of the work is concerned which deals with the description of existing systems and with the data as regards cost of installations given by the manufacturers themselves. But if we come to look at his attempts at generalisation we cannot help regretting that he made it on comparatively so narrow a basis. The reader of the book will probably come to the conclusion that Dr. Hagen is not a practical electric light engineer, but rather a scientific man describing a few systems which have happened to come under his personal notice. For all that, the book is very useful, because on these few systems, which are important ones, it contains plenty of facts.

A literal translation of the title of the book is "Electric Lighting, with special reference to the Central Station Systems principally used in the United States."

The introduction contains the usual allusion to the necessity of artificial light for our modern civilisation and the insufficiency and danger of gas for this purpose. An interesting observation not usually made by writers on that theme is that carbonic acid produced chemically is not nearly so injurious as that contained in human exhalations. Of the former 1 or 2 per cent. may be mixed with the air without danger; whilst of the latter an admixture of ·06 per cent. is already insupportable. According to Dr. Pettenkofer, this is due to a subtle poison, the anthropotoxin, which is always combined with the carbonic acid exhaled. If Dr. Hagen be right in his assertion, then the old belief that one gas flame vitiates as much air as five persons would become untenable. Of the two parts forming the introduction, the first deals with the general principles of electro-magnetic induction, lines of force, resistance, current, electromotive force, the dynamic principle, arrangement of lamps in series and parallel connection, and similar elementary matters, which have been explained over and over again in nearly every book on electric lighting, and might, without prejudice to the present work, have been left out, the more so as Dr. Hagen only deals in generalities, and does not increase our knowledge where most needed, viz., in giving precise data by which electromagnets and armatures and their relation could be brought within the realm of exact measurement and calculation. He gives, however, a few tables on the cost of steam power, the efficiency of dynamos, &c.

The second part is more original and more interesting. Those desiring information as regards priority in the invention of the incandescent lamp will find here a brief history of the invention from Tobard's proposal, in 1838, to heat a small piece of carbon in vacuo by an electric current, down to Swan's and Edison's patents of 1879. The author concludes the introduction by saying that although the proposition, often put forward, that Edison is the only true inventor of the incandescent lamp, is utterly untenable, yet he has the great merit of having given the first impulse to make incandescent lighting a practical success, and of having introduced the central station system.

In Chapter I. we find a detailed description of the Edison central station in New York. The building, the boilers, steam dynamos, the apparatus for regulating the potential, cables and street mains are fully described, and a plan of the district served is given. A table giving the pressure at different points of the mains is of interest; from this it appears that the equalisation of pressure is almost perfect, the variation being between 107 and 108·9 volts. The author also gives a description of the manufacture of the Edison lamps in the Newark factory, and mentions the astounding fact that not less than three tons of mercury and 300 pumps are in use for exhausting the lamps.

The part of the description dealing with the Edison meter is somewhat disappointing; it contains nothing new, and no mention is made of the difficulty of incorrect indications on account of counter E.M.F. in the zinc plates. Some time ago there was an impression in this country that the Edison station supplies current throughout the day for motive power, in fact that this branch of the business is more important than the lighting. This Dr. Hagen denies completely; up to September, 1883, there was not a single motor fed from the Edison mains. When speaking of installations in other towns the author, on page 101, says that with any other but Edison lamps they would be simply impossible, since the large currents required by them (as for instance Swan's or Bernstein's lamps) would necessitate too large an outlay in conductors. Here is an instance of the error into which a writer can fall who is but imperfectly acquainted with his subject. The book is dated 1885, and Dr. Hagen ought to to have known that ever since the beginning of 1884 the Swan Company have manufactured 20-candle lamps requiring but ·65 ampere—that is, less than Edison's lamps.

Chapter II. treats of the installations of the United States Electric Light Company, who use Weston machines and Maxim lamps, the manufacture of which is clearly explained. In the third chapter, methods and results of measurements on incandescent lamps are given and tabulated. From these tables the improvements made in the time between the Paris and Munich Exhibitions can be seen. Here again we observe that the book is behind the period.

The cost of installations and the working expenses as compared to gas will be found in Chapter IV. As regards the cost of the plant, Dr. Hagen's figures are based on Edison's original prices, and are decidedly too high. We find, for instance, that a 200-light machine, 200 16-candle lamps, with holders and a rheostat for regulating the shunt current round the field magnets, are put down at £480, whilst at the present time an equivalent plant of English make could be had for about £270.

Chapter V., containing a theory of incandescent lamps, might have been omitted. It contains very little of practical value, and the concluding statement, that the light of an incandescent lamp varies as the third power of the electrical energy, has certainly not been verified by the experiments of Messrs. Preece and Trotter.

Accumulators find a place in Chapter VI., and over sanguine inventors would do well in reading it. Although only Planté's, Faure's, and Brush's accumulators are described, there is a clear theory given, applicable more or less to all the later forms.

The book concludes with some very sensible remarks on the danger of electric light to life and property, or we should rather say, on the absence of danger, if only some very simple precautions are used.

SWEETNESS AND LIGHT.

We are not sure from what source the political slang of the day has borrowed the phrase *to stew in their own juice;* but its application to the afflicted frequenters of what are called "places of amusement" is as accurately descriptive of the fact as it is flagrantly offensive to good taste. Prince Bismarck we believe is credited with this, as with many another inelegant barbarism; but unless the illustrious Chancellor's character has been belied he is not the man to approve of the stewing process unless it can be turned to his own advantage. Managers and proprietors of places of public resort, on the contrary, inflict the operation on their customers through sheer wantonness, or indolence, and in that respect resemble not the German but the English politician, who employs this hideous image as implying that the victims rather like being stewed, and that in any case it is no affair of his. We are glad to notice that some strong protests on the part of the sufferers by this misconception are finding utterance in the newspapers, and that it is being made plain to the caterers of public recreation that neither stewing nor baking ought any longer to have a place on the evening's programme. Both these ordeals have to be endured, apparently, by the audiences of the St. James's Hall concerts. According to a correspondent of the *Pall Mall Gazette* there is a large kitchen and dining room under the floor of the hall, both lighted by gas; and the heat from below thus added to the gas heated vapour above renders the atmosphere almost intolerable, to say nothing of its being in the highest degree unwholesome. It may be hoped that this protest will not pass unheeded.

The prolonged trials of electric lighting for interiors of places of amusement have proved entirely successful in, we believe, every case, and the marked improvement in their comfort has been greatly appreciated by the audiences. What the covered portion of the Health Exhibition would have been even in the autumn months of its existence had it been lighted by gas we can well imagine, but would have certainly declined to experience. Its four millions of visitors and more, sometimes numbering as many as seventy thousand in one day, the bulk of whom remained well into the evening, will we may confidently assert, be vastly diminished were the Commissioners to fall back upon the less wholesome as well as less beautiful system of illumination for a future exhibition. And what is true of the Healtheries applies to every place of public resort where electric lighting has had a trial long enough to assert its superiority over gas in the minds of the people frequenting them.

It is, we say, a great mistake on the part of the responsible managers of such places to suppose that the pleasure-loving public count excessive fuming and fanning—to put it inoffensively—as among the joys of the evening. We cannot all take our coats off as they do in the East End galleries; nor could we endure to see and feel the roof sliding off as it does at some of the theatres on the Continent. It is often alleged that the cause of the discomfort in English places of amusement is defective ventilation. But in this respect we are no worse off than our foreign neighbours. They certainly do *not* do these things better in France. Indeed, a single evening spent in a Parisian theatre would almost persuade us into the managerial axiom that the people "like it"—that is, like having all the preliminary discomforts of a Turkish bath without any of its after pleasures or benefits. But the French have a remedy, or, at all events, a palliative, which is not permitted to an English audience—they go outside in a body between the acts, perambulate the broad footways of the street, or loiter about in the airy *foyer.* The same with the concert halls during the regulated intervals of the performance. Neither our climate nor our thoroughfares will admit of this heroic stampede into the open air; and we have, therefore, to endure the premonitory pangs of suffocation, relieved occasionally by blasts of cold—a special device of the management—the probable consequences of which are even more alarming than the heat. In olden times, the *foyer,* as the name implies, was the place where the audience gathered together between the acts to warm themselves—literally, on the *hearth;* now they retire there to get cool. Nothing could better illustrate the change of atmospheric condition in the modern theatre, brought about entirely by the employment of gas.

The impetus given to the cause of electric lighting by the South Kensington Exhibitions is unmistakable, and the advantage to promoters will be far greater than anything they could have obtained through the winning of exhibition medals. The Commissioners have, we think wisely, abstained from awarding medals to the exhibitors of electric lights. Relative merit in this branch of illumination can only be determined after careful tests and comparisons, and these will be best deferred till the Exhibition of Inventions next year, as was suggested in our columns not long ago. Meanwhile, the absolute merits of the new illuminant have been demonstrated to an extent which cannot fail to be profitable to electric lighting engineers. The complaints to which we have already referred show that nothing less wholesome or less brilliant than the electric light will satisfy the public; and we hope to see before long an equal interest shown for the health and comfort of the dumb creatures who, at Live Stock Shows, are penned up in a stifling atmosphere for

Digitized by Google

nearly a week at a stretch, where the simple introduction of electric light would not only sensibly relieve their sufferings, but greatly add to the comfort of the visitors. A very gratifying proof of the progress being made was afforded in our advertisement columns last week, where the Metropolitan Asylums Board invited tenders from Electrical Engineers and Electric Light Companies for the lighting of the three hospital ships moored in the River Thames, near Dartford. If this installation—which is to be on a large and comprehensive scale—give satisfaction, similar invitations may be expected for town hospitals, where coolness is almost as important as light, and sweetness more than either.

MR. FAWCETT.

At the moment of our going to press the sad intelligence reaches us that Mr. Fawcett, the Postmaster-General, died suddenly at Cambridge on Thursday afternoon. For two or three days previously it was known to us that he was seriously ill, having had a fresh attack of pleurisy, a disorder which prostrated him for some months only two years ago. But Thursday morning's papers gave no inkling that his condition was precarious, and the organ which is generally credited with being in the confidence of the Government simply stated that the Postmaster-General was suffering from a severe cold. This renewed attack, however, notwithstanding the vigorous constitution it had to contend with, has proved fatal, and the country has lost one of its ablest men of letters and most conscientious of politicians. Mr. Fawcett's administration of the Post Office and Postal Telegraphs has been open to criticism; but we have never denied the vigour of his arm or the justice of his heart. He was a professional political economist, and as such his public actions were often guided by what seemed to be cold calculation rather than benevolence or humanity. This, however, was not his character in private life; and the sturdy independence of his political career was only equalled by the rare courage which enabled him to face the calamity that deprived him of his sight at a period of life when most men would have been overwhelmed by it. When stricken with blindness he determined to go on "as if nothing had happened." A public career which has been eminently successful, and, but for this untoward catastrophe, would have been illustrious, proves how resolutely he kept his word. Mr. Fawcett was engaged in important negotiations with the Telephone Companies, and his loss at this juncture will be seriously felt. It is probable that Mr. Shaw-Lefevre may succeed him in the office of Postmaster-General. Mr. Fawcett was in his 52nd year.

ROBERT H. SABINE.

Another electrician has joined the majority, in Mr. Robert H. Sabine, who was joint author with Mr. Latimer Clark of "History and Progress of the Electric Telegraph" and "Electrical Tables and Formulæ." Born at Dorchester in 1837, and educated at Bristol, Mr. Sabine was destined for his father's profession, that of solicitor; but this proving distasteful to him, he was sent to Manchester to study engineering. Here he became acquainted with the late Sir William (then Mr.) Siemens, who, in 1858, engaged him as assistant electrician. In the following year, he carried out a series of experiments with a deep-sea thermometer, invented by Siemens, on board H.M.S. "Firebrand," in the Mediterranean, and was afterwards handed over to Siemens and Halske, Berlin. He carried out the tests of the Malta and Alexandria cable, and also assisted Mr. C. W. Siemens in laying the cable between Oran and Carthagena. In 1867 Mr. Sabine engaged in business for himself as electrical and consulting engineer, being associated with Mr. Latimer Clark in work for the Pneumatic Despatch Company. He subsequently took the management of the late Sir Charles Wheatstone's works, afterwards the British Telegraph Manufactory. For some years he joined Sir Samuel Canning in partnership; but resumed his separate practice about a year before his death. Mr. Sabine, who was married to a daughter of Sir Charles Wheatstone, and leaves one son, was struck down about six months ago, and, although hopes were entertained of at any rate partial recovery, he breathed his last on the 25th of October, being therefore only 47 years of age.

DANIELL'S CELL.*

BY J. T. BOTTOMLEY.

I beg leave to describe a new arrangement of gravity Daniell cell which I have found manageable and convenient

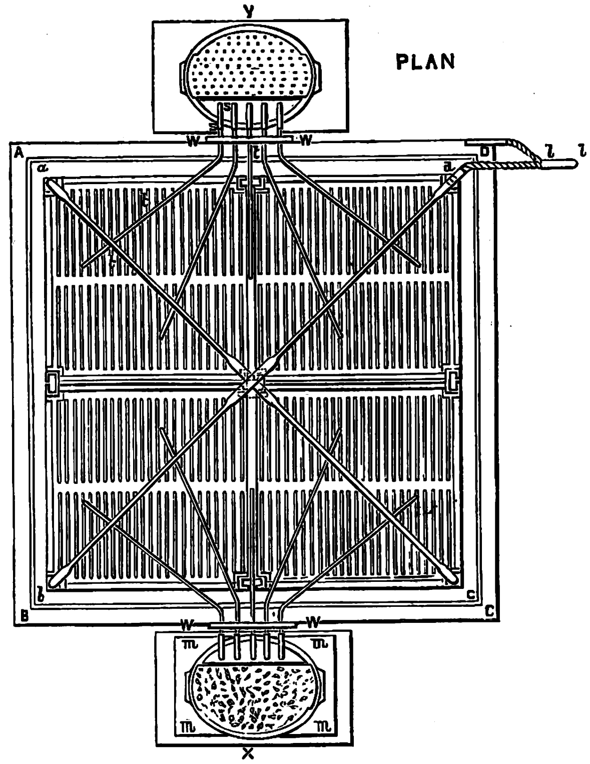

FIG. 1.

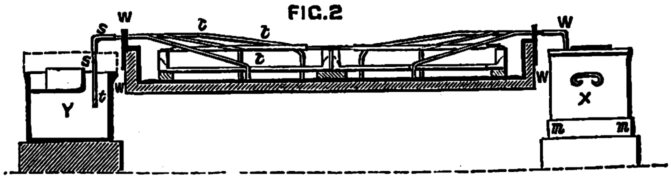
FIG.2



SECTION

for supplying continuously and steadily a very powerful current of electricity. It has proved of great service for graduating ampere-metres and for such purposes.

Fig. 1 shows the cell in plan, and Fig. 2 the same in section. The outer containing vessel is a large shallow tray of wood, very strong, but quite roughly made, and lined with sheet lead. The tray is 3¾in. deep, and with this small depth the lead can be beaten in, and autogenous soldering is unnecessary. The lead tray is very carefully varnished with spirit varnish, several coats being applied; and on the bottom of it is laid a

* A paper read at the Royal Society, entitled, "On a Gravity Daniell Cell of very small Internal Resistance."

Digitized by Google

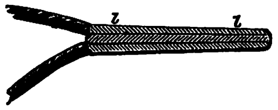
thin sheet of copper (0·2 millim. thick), or rather several sheets thoroughly connected together, as I have not been able to obtain a single sheet of copper large enough for my purpose. The copper sheet, varnished on the lower side, is attached in many places to the lead lining of the trough by soldered slips of copper, the solderings being thoroughly coated with varnish or marine glue. This copper sheet forms the copper plate of the Daniell cell.

The zinc of the cell consists of four of an unusually large size (56 centims., 22in. square) of the gridiron zincs used in Sir William Thomson's well-known tray Daniell, which is largely employed at most of the submarine telegraph stations in connection with the siphon recorder, and is a modification of the constant Daniell battery described *Proc.*, Roy. Soc., 1871, p. 253. These gridiron zincs rest on small blocks of wood at the four corners of each, and they are connected together by strong copper slips at the corners, and by means of two diagonals of thick copper rod which are soldered at the outlying corners and at the four meeting corners in the middle of the square.

Very powerful pairs of electrodes are soldered on at each of the four corners of the cell, though only one of these pairs is shown in the diagram at D. These electrodes are formed of flexible copper rope, terminated with two thick slips of copper which are fastened together mechanically, but electrically insulated, and form the flat duck's-bill shaped piece *ll*, shown in section, Fig. 3. The electrodes of any instrument which is to be connected with the cell may be also terminated with two copper slips, which are pushed on *over* the piece *ll* and held on by india-rubber bands.

The mode of supplying the cell with sulphate of copper still remains to be described, and it is this which constitutes its most important pecularity. The liquid contained ordinarily in the tray Daniell is a somewhat dilute solution of sulphate of zinc (sp. gr. 1·12 to 1·14), the lowest layer of which is saturated with sulphate of copper. The sulphate of zinc solution is kept at the proper density by occasionally drawing off quantities of strong liquor and replacing by pure water, testing by a hydrometer or with specific gravity beads. The sulphate of copper

FIG.3



is supplied by dropping a proper quantity of blue vitriol in crystals into the cell round the edges. This is sufficiently easy when the cells are of moderate dimensions, and where a large number of them are being constantly used and regularly attended to in a business-like way, as at a telegraph station. When, however, the size of the tray is very large, and when the cell is being used intermittently, this simple method becomes difficult and unsatisfactory; and, owing to want of uniformity of the solutions, the cell is rarely obtained in such a condition as to be ready to give the results which ought to be expected from it. The copper sulphate supplied in crystals does not dissolve sufficiently quickly and spread itself over the whole surface of the lower plate, and difficulties arise as to the dilution of the sulphate of zinc without stirring up from the bottom remnants of unused sulphate of copper.

To avoid these troubles, and to make the starting and stopping of the action of the cell easy and rapid, I have arranged to supply the sulphate of copper in the state of solution, and to deliver and to remove it very gently but very quickly, and also simultaneously, at many parts of the bottom of the cell.

X and Y are two earthenware tubs placed one on either side of the cell; and it should here be remarked that the cell is raised up from the floor on common building bricks. From these vessels a number of siphons or delivering tubes, *t*, *t*, *t*, of which ten* are shown in the diagram, proceed to different parts of the cell. The tubes are of thin glass, except the bend *ss*, which is of flexible india-rubber tubing, and enables the extremities to be taken with ease out of the vessels X and Y for clearance or for starting of the siphons. The tubes are held in position by passing through holes in the boards *w w*, and the glass portions are bent in a gas flame to the proper shape for delivering to the various parts of the bottom of the cell. The vessels X and Y are furnished each of them with a shelf of thin sheet copper perforated with many holes, the level of the shelf being considerably above the level of the extremities of the siphon tubes. On these shelves a large quantity of sulphate of copper in crystals is placed.

To raise the vessels X and Y up, and cause the siphons to run, two boards are provided which are pushed in beneath the vessels. One of these, *mm*, is shown beneath the vessel X in the figures. The boards are made of exactly the proper thickness to cause a layer of chosen depth to be run into the cell out of the vessels, or out of the cell into the vessels, according as the vessels are raised up on the boards or are lowered down when the boards are removed. The thickness of the boards depends, of course, on the relative sectional areas of the two vessels and of the cell. The depth of the layer which is spread over the bottom of the cell should be not more than one-eighth of an inch. The bottom of the cell must be very carefully levelled in order that the layer of charged liquor may be uniformly distributed, and that the half-spent liquor may be uniformly drawn off.

In setting up the cell in the first instance I commence with the cell charged with weak solution of sulphate of zinc (sp. gr. 1·12), while the vessels X and Y are charged with nearly saturated sulphate of zinc solution. This liquor is still able to take up a very large quantity of sulphate of copper; and water saturated with both sulphate of zinc and sulphate of copper is much more dense than saturated solution of either salt alone. When the cell is to be started the two reservoirs are raised into position. The thin layer of dense liquor spreads itself over the bottom in a few minutes, and the cell is ready for use. When the use of the cell is to cease the reservoirs are lowered down, and nearly the whole of the dense liquor runs back into them. This should always be done at night, or during any considerable time when the cell is to be out of use.

During the action of the cell sulphate of zinc is constantly being formed, and it is necessary frequently to run off a portion of the contents of the cell and fill up with pure water. I have planned for a system of tubes (arranged similarly to those just described) for siphoning off into independent vessels, and with a cell of very great dimensions such as I am now constructing they will probably be necessary. With the cell which I have been using for nine months, however, I have been able to dispense with them.

It only remains for me to give the dimensions of the cell now in use, and of a new one in process of construction. The tray of the former is 47in. square inside measurement, and 3¾in. deep. The zincs are each 22in. square, and are raised up ¾in. from the bottom. The copper sheet is about 0·2 of a millim., or 0·008in. thick. It is probable that it would be better a little thicker. With this cell I can command about 45 amperes for hours together at any time, only requiring to take now and then a fresh supply of sulphate of copper from the reservoirs. The new cell which is in process of construction is 69in. long by 46in., and 3¾in. deep. It has four reservoirs, and six zincs placed in two rows of three each.

P.S.—In the foregoing paper I have described the construction and capability of a cell, whose dimensions are given, constructed about the beginning of July, 1883. It was found necessary, almost whilst I was writing, to take the cell to pieces, as it had become blocked up with copper deposited in the natural course of nine months' working. In putting the cell together again, with attention to *small particulars*, which I shall not describe, as they will naturally occur to anyone who desires to use the arrangement, but which, I need scarcely remark, make, with such great currents, all the difference between success and non-success, I have obtained, through a current galvanometer of which the resistance is $\frac{1}{500}$ of an ohm, a current of 63 amperes which was quite steady.

* I have recently doubled the number with great advantage.

THE THEORY OF THE DYNAMO-ELECTRIC MACHINE.*

DISCUSSION.

Professor ELIHU THOMSON: Mr. Chairman, I have been at work on dynamo machines for a long time, and my experience teaches me that some of the statements made are not correct. For example, there is a factor that has been omitted in regard to the extension of poles of magnets. We have a figure showing an extended pole piece, under which an armature is revolved. It is stated that the lines of force find it easy to go this way (arrows, Fig. 5). I do not think so. We find, on examining the machine during its motion that the armature

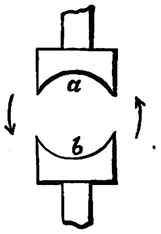

FIG. 5.

itself is a magnet of an opposing character, that it produces poles which are opposing the magnetism of the field poles, and if the armatures are of uniform size and section throughout, that the magnetism developed here in opposition to the field of magnetism will be same as here (indicating). Consequently, you have an opposing force to the field magnet at this point greater than it would be there (indicating), and, consequently, you have again produced a loss of magnetic force by going this distance.

Another fact—and this is what may happen very readily—there is a field running up the side of the magnet and turning in again. By the extension of the poles, carrying your magnet along here, you will obviate to some extent that difficulty.

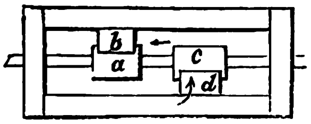

FIG. 4.

Then we had the statement made that one set of magnets is better than two opposing sets, as in certain well known forms of machines. I would like to take exception to that also, and for very simple reasons. Take away one magnet and you give every chance for this kind of action, and taking into consideration the fact that the armatures are crossing the magnetism of the field magnet when it is revolving, it becomes extremely simple to see. Place another magnet here (*a*, Fig. 4), and you force the magnetic lines through the armature, and

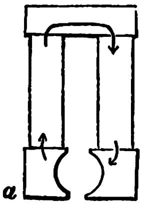

FIG. 3.

you consequently have a much better machine. That leaves out of consideration the fact that you have a small plate of material (of only two and one half or three inches thick in case of Fig. 3) in proportion to the magnet, which has enormous reaching power, if you may choose to call it so. We have an iron plate here (*a*, Fig. 3). Now, taking into consideration again the enormous currents that are developed in that armature opposing the magnetism, that it passes the magnetism of the field down through the armature, you see what a short-circuiting of the field of the armature is made when the iron plate is put in any sort of proximity to the ends of the field poles.

Again, take the form of the machine where we have the field magnet in two pole pieces, and we bring the iron down the side to close the magnetic circuit; we bring the piece out in that manner (Fig. 6). The question arises (I have not investigated the subject fully) whether the loss by magnetic short-circuit will be made up in part by the external magnetisation of the coil upon the iron in this direction (dotted lines). In other words, by removing the iron, not too far away, and again not too near, whether you do not get an external magnetisation of the iron lying close up to the exterior of the coil, which would make up for part of this loss by short-circuiting from proximity of iron to the field pole.

With regard to the use of long or short magnets in the dynamo, if we take into consideration what I have just stated in regard to the magnetising power of the armature, it will depend upon the diameter of the armature, and the length of the magnetic conductor that is in the armature. Assuming the armature to be made up of radial bars, or even discs, the length of magnet you will have to employ will depend upon the opposing magnetic effect of the armature, and I may say also, to the distance between the field magnet and the armature. If you wish to get reaching power or depth of field, in order to reach any distance through the armature, the iron being far away, you will have to use long magnets. If you have an armature which has long projections, making an approximate contact, you can use much shorter magnets with equal results.

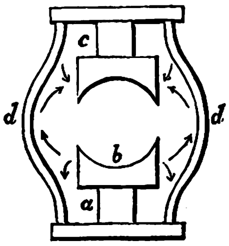

FIG 6.

In regard to the use of steel magnets, it is well known that steel in no condition can accept as much magnetism as soft iron, and it is also well known that if you harden the exterior of a magnet having soft-iron interior, that the radiation to the soft-iron interior of the magnetic lines will cause a short circuit of magnetism through the interior of the magnet. So I do not think we can look for any improvement over soft iron for field magnets. There are many other considerations that might be noticed which show economy lies in using soft iron only where we wish to get the greatest available magnetic strength.

I cannot agree with either of the gentlemen who preceded me in the statement that there is dead wire in the Gramme armature, or in any other armature that encloses a magnetic circuit. If that was the case, then all wire upon bobbins would be dead wire. We could not produce a dynamo machine which had bobbins in it (for what is the Gramme ring but a series of bobbins), which when they pass the field poles—those bobbins are magnetised there in that manner just as they are in the old Holmes and Alliance machine—when they pass from the position where they include the greatest number of lines of force, pass from the position of saturation to the position of less saturation; they go over to a position where the saturation is reversed. What suggests the reason that the outside of the wire would be more efficient than the inside wire is simply because, as I look at it, there is a tendency that is unrestrained for the armature to kill itself while it is passing at this point (indicating). There is a tendency of the armature to magnetise the magnet, making a closed circuit on the inside of the ring, which diminishes the effect of it on this

Digitized by Google

wire. However, this closing of the magnetic circuit on the outside of the core causes the field magnet to lose control of the direction of the lines of force. This closure of the circuit on the inside of the ring, however, is simple and easy to take place, because here the iron is practically removed from the powerful control of the field magnet, and the coils are where they can act as magnet coils to close their own circuit. How can we increase the efficiency of such a machine? Evidently we can prevent that closure by putting some more magnetic material there.

There is an effect in such machines to which attention has not been called. It is that we can take the same sizes of wire applied to a larger machine and exhibit a real and theoretical increase of efficiency. I hold, however, that theory, when it is true and complete, always coincides with true and complete practice; there is no intermediate stopping point. If you take into consideration every variable, you are bound to arrive at the complete practice; you cannot have one thing theoretical and the other practical. It has been proved mathematically, and it is very easy to go over the ground, but I will not take your attention now, that if we use the same size of wire on armature and field we have the power of the machine increased as the fourth power of its linear dimensions. But if we attempt to apply that in practice, we find this: that the surface of the machine clearly increases as the square of the dimensions, whereas the cubic capacity—in other words, its power to retain heat—increases as the cube of its dimensions. The result of that is that in a large machine you will have to provide a greater amount, proportionately, of cooling surface, or enlarge the size of the wire. The power of the dynamo run for series lighting (I may say I have only determined it approximately) increases as the cube instead of the fourth power of the linear dimensions.

In the study of the Gramme armature and its method of commutation I think we have yet to learn a great deal. I cannot see any reason why in the Gramme armature during the commutation there should be any loss at all. Let us figure the ring and study the action of commutation. A coil goes out and comes upon the commutator, passes it and returns, and so on. I hold that the period of contact is such that if the brushes upon these segments are properly arranged there will be no loss; in other words, the time of contact that must exist between these two segments and the brush will be the time that it takes for the coil to lose its current; the commutation must not occur at any other time than when the coil is ready to lose the current and acquire current in the opposite direction of the same amount it is to take when the break shall be made. I do not know that I have made that perfectly clear, but I will go over it again. If the contact remains for a sufficient period to allow the coil to lose its current and the commutation is only being made while it is running down in electromotive force, and continues until the current rises on the other side, until it is fit to go into the circuit; in other words, until it just conducts the current that the other side demands, you will have no loss from commutation. Make it just at that period, and where is there any loss?

In regard to the resistance of armature coils, I think there is an effect that is generally omitted in considering dynamo machines, and it is this—that we cannot consider the measurements of the resistance of the armature at any time as the working resistance. We cannot measure it in any position and let that be taken as the resistance of the armature coil when it is working. Why? Because in any dynamo that furnishes us continuous currents we will have this condition sometimes existing. That is, in the Gramme we have constantly two series of coils; in the Brush, two series of coils, put in multiple arc at times. If you measure the machine while not at work you take it for granted that the current when the machine is running will be equal in those two branches.

Will it ever be equal in those two branches? The energy developed by that armature will depend upon whether the current divides equally for the time being. In other words, whether the ring is equally balanced, or whether the brushes are of equal temperature, or whether the armature is put at the centre of the field. The wire will become more energetic if it is nearer the field pole than the under side, and the effect will be that you are sure to displace your commutator brushes. More current will pass through one side than through the other, and you will have more heat developed in one than in the other, and you will not have a perfect dynamo. You will have more energy consumed in that dynamo; and I may say that there is not a machine that I do not regard as coming under that condition. You measure the resistance of the machine when still, and you will not have the same resistance when running it, because the currents do not divide as in still resistance.

That is about all I have to say in regard to the subject under discussion, except that if I have an opportunity I should like to call attention to a number of other matters that affect the working of dynamos. These matters have been derived from studying dynamos and making very many types of machines and experimenting with them, my whole time being almost entirely devoted to their study.—*Electrical World.*

THE DISRUPTIVE DISCHARGES FROM THE HOLTZ MACHINE.

M. Jamin lately presented to the Paris Academy of Science, a paper on this subject, by the Abbé Maze, of which the following is the substance:—When a Holtz machine is employed, the exciter of which is so constructed that the spark may be drawn, at will, to the right or left of the axis of the apparatus, it is found that the position to be given to the movable part of this exciter is far from being a matter of indifference. Thus, if the movable part be left complete with its balls and its condenser; if, besides, such a position be given to the two movable branches that the ball which disengages the positive electricity be nearer its condenser than the other is from its condenser; in a word, if symmetry be broken by carrying the opening of the balls from the positive side, there will be obtained, with a mean distance between the two, two narrow brush discharges of unequal length, the larger corresponding with the positive pole. These brush discharges do not unite, but produce slight dull detonations. If, without in any way modifying the rest of the machine, the side of the opening be changed, so that the positive conductor be the longer, the phenomena become quite changed.

It is no longer possible, whatever be the distance between the balls, to obtain detonating discharges, but always the ordinary crackling spark. The absence of symmetry may also be demonstrated by removing the ball of the positive pole. If, in that case, the interception be on the side of the negative pole, the discharge will attain at most half the preceding length. If the ball of the negative pole be removed, the influence of symmetry will not be so manifest. These experiments may be repeated after removing the condensers, when the phenomena are generally of the same order as in the former case, but much less intense. Besides, it is not only optical phenomena which prove the importance of the question of symmetry, mechanical facts lead to the same conclusion. In fact, if, after having deprived the exciter of its balls, a strip of paper 10 centimetres by 20 centimetres be suspended between the points, with the opening on the side of the positive pole, the paper will be strongly repelled by the negative pole; but, on the other hand, if the interruption take place on the negative side, the paper will be repelled by the positive pole.

This experiment succeeds with or without the condensers; but the result is more strongly marked when they are suppressed. It is worthy of remark that if the branches of the exciter are placed symmetrically with respect to the axis of the machine, repulsion is manifested by the positive pole when Leyden jars are used, and by the negative pole without them. In conclusion, the Abbé Maze remarks that he has confined himself to simply stating facts, without formulating any theory; but he considers that the causes of the phenomena observed are to be sought in a reciprocal induction of the various parts of the machine.

EXTRACTION OF METALS BY ELECTRICITY.

In the November number of the *Chemical Society's Journal* is the following abstract of a paper originally appearing in *Dingler's* No. 253 :—

R. P. Hermann treats zinc ores with acids, and precipitates the metal electrolytically, after converting it into a double alkaline. M. Kiliani proposes to extract calamine, zinc-ash, &c., with ammoniacal liquor containing carbonate, and then to precipitate electrolytically, employing iron anodes. M. Body recommends mixing the powdered ore with ferric salts alone, or with the addition of common salt, by which advantage is taken of the property of ferric salts to pass into the ferrous state in the presence of metallic oxides or sulphides, under the influence of an electric current. This change leads to the solution and precipitation of the metal; subsequently the ferrous salt can be readily converted into the ferric state, and is again ready for use. The finely powdered mineral is exposed in moist heaps to the action of the air and repeatedly ground. The ore may then be placed in a tank provided with a bottom of pressed coke, in which is embedded the negative pole of a dynamo, whilst the other pole is connected with the ore at one or more points. In treating certain ores of gold and silver a cast-iron drum is employed, which is connected with the negative pole of a dynamo, and is slowly revolved. Within the drum are several cast-iron balls. Through the drum, and isolated from it, passes a fixed axle, which is connected with the positive pole of the machine, and which carries a series of coke or graphite plates dipping into a solution of ferric salts containing the mineral. The axle is hollow, and serves for the introduction of liquid to the drum; a steam-pipe, terminating within the liquid, also passes through it. When the silver is reduced, mercury is passed into the drum, and the amalgam is collected in the ordinary way. The method is advantageous for ores which contain only 0·05 per cent. of silver.

BUCHAREST.

Mr. Jehl, who carried out the work of lighting the Bonn Theatre for the Edison Company, is now engaged in similar work at the Bucharest Theatre National. This theatre will be fitted throughout with the Edison system, using the 10-candle lamps. There will be four dynamos of 300 A lamps (16 candles), but as 10-candle lamps will be used each machine will have to supply current for about 450 10-candle lamps. These 10-candle lamps are held to be very economical, having a high resistance and using only ·5 of an ampere current. The machines will be driven by two high speed steam engines, viz., one Porter-Allen, and one Armington and Sims. The dynamos, steam engines, and boilers will be placed in the front cellar of the theatre, just underneath the entrance. It is singular that this order was received by the society in Paris, through the director Bouron of the Bucharest Gas Company, a man who fully appreciates the new improvements in illumination, and does not let prejudice work against them. If all gas directors were of such honest opinions, there would be less *gasing* (figuratively in the conflicts between gas and electric light) and more electric light. The theatre will also have the various regulators necessary for the production of effect lighting. Red and green lamps will be placed on the stage. The following list shows somewhat the number of lamps intended to be installed :—

Stage Cross Lights.

No. 1.	26 red lamps,	26 green lamps,	26 white lamps.
No. 2.		ditto	ditto
No. 3.		ditto	ditto
No. 4.		ditto	ditto
No. 5.		ditto	ditto
No. 6.		ditto	ditto

Stage Footlights.

Right—	28 red lamps,	28 green lamps, and	28 white lamps.
Left—		ditto	ditto

Stage Uprights : 12 pieces, with three lamps each.

Stage Portable Stands: Two pieces each having eight lamps, making a total number on the stage of 688 lamps.

The auditorium is divided into two circuits, one circuit having a total number of 369 lamps, which are used every night, and are divided in various parts of the auditorium. The other circuit forms what is called the "gala" lighting, used when the king comes to the theatre. There are 307 extra lamps in the second circuit, making a total number of 676 lamps in the auditorium burning when His Majesty comes to a performance. Then there are lamps in the salon, vestibule, grand foyer, &c., in fact all over the building where gas is now used, to the number of about 370 lamps. Summing up this gives to the stage 688, to the auditorium 676, to the other parts of the house 370, making a grand total of 1,734 lamps. However, as the red and green lamps are not always used at one time, the total number of lamps burning will be reduced to 1,512 lamps.

Besides the above the new baths are to be lighted by the Edison system. This is a very large building in the course of erection at Bucharest. There will be used 1,000 Edison A lamps driven by four dynamos of 300 lamps each ; one can then swim by the electric light, and in winter the large basin will be converted into a ball room.

THE USE OF ELECTRO-MAGNETS FOR RAILWAY SIGNALS.*

BY ILLIUS A. TIMMIS.

[Some of our readers may remember an article on "Electric Railway Signals" which was given in our issue for March 22, 1884. The paper of Mr. Timmis refers, but far more fully, to the system described and illustrated in our article. This being the case we must refer our readers to pp. 439—443, Vol. XII., for some of the illustrations, which for reasons of space we cannot this week reproduce ; nor are those reproduced drawn to the scale mentioned in the paper.—Ed. *E.*]

The object of the present paper is to describe a new, powerful, and economical electro-magnet, capable of exerting its pull in a manner suitable for convenient application to the mechanical working of railway signals and points. Its main features are its great power, which is exerted through a long range, and is under perfect control; and its economy, both in exerting the initial pull which effects the mechanical movement required, and also in retaining the moving parts after the desired movement has been effected.

The rapid growth of railway systems, and their consequent complexity, have rendered urgent the application of electricity for the working of railway signals and points, and for checking the work done by signalmen and pointsmen. Though much has been accomplished in this direction both in this country and elsewhere, there has hitherto been always one initial want, namely, an electro-magnet, which, with a low average current and a small electromotive force, shall give a powerful, long, and well-balanced attractive pull. A range of pull of only half an inch, which has hitherto been the practical limit with electro-magnets, is evidently not long enough to be of use for heavy mechanical work, such as pulling signal-arms over or throwing machinery in and out of gear; and although the range can be increased by multiplying gear up to two or three inches, yet the increased current then required for making the attraction powerful enough at the initial half-inch distance is so enormous that two difficulties present themselves which are almost insuperable—firstly, the expense; and, secondly, the destructive violence of the final impact, in consequence of the attraction increasing inversely as the square of the distance of the armature from the magnet, and for part of the stroke inversely as the cube.

In the ordinary form of the electro-magnet, a core or bar of soft iron, wrapped round with a coil of wire or tape, and bent into the shape of a horseshoe, attracts to its poles a plain armature; and, by some natural law, as yet unsolved, the working pull of such a magnet practically ceases, as already stated, when a distance of only half an inch between the magnet and the armature is exceeded. In the electro-magnet of tubular form, thence called a *solenoid*, a hollow core or tubular bobbin of brass is wrapped round with wire or tape; and a central rod of soft iron, sliding lengthways inside it, forms the armature, which is drawn or sucked longitudinally into the core by the attraction of the bobbin coil, until it reaches a central position in relation to the magnetic field; in this position the attraction is symmetrical in all directions, and is therefore neutralised. Although a considerable length of attractive pull can be got with such a magnet, the current of electricity required to give any strong initial pull is so excessive that its cost is prohibitory; moreover it is clear that the holding power falls to zero when the armature reaches its central position longitudinally. In order to obtain adhesive power, or what is called a "retaining" pull, the internal sliding rod or armature is made shorter than the length of the hollow bobbin, and is capped at one end with a disc of soft iron, which, coming in contact with that end of the bobbin, thereby prevents the armature rod from reaching its central or neutral position within the bobbin, and leaves a corresponding reserve of holding power against the end of the bobbin.

Currie Long-Pull Magnet.—In the long-pull electro-magnet, shown double full size in the accompanying diagram (Fig. 1), which is the invention of Mr. Stanley Currie, the principle adopted is a combination of the horseshoe magnet and solenoid, with additions; but the con-

* A paper read before the Institute of Mechanical Engineers, on Wednesday, November 5th, 1884.

Digitized by Google

struction is so materially modified as to give far greater power and efficiency, and the magnetic attraction is more evenly distributed over a longer range, while the initial pull is stronger and acts at a greater distance than in any other electro-magnet of the same weight and with the same current. The range already attained in practice is 3½ inches, and can be increased.

The bobbin B, here shown standing upright on one end, is made with a tubular core, C, of soft iron; and the coil of wire wound around it, coloured red, is surrounded by an outer casing of soft iron, B, of the same weight as the core, with a soft-iron base-plate at the bottom of the bobbin, connecting the core with the outer casing; a brass plate covers the bobbin at the top. The copper wire used in the coil is No. 18 Birmingham wire-gauge, or 0·048 inch thick. The armature consists of three portions, each one playing its part in the work to be done. The central stalk A of soft iron is rather shorter than its own range of motion, and is encased in a brass tube, which is prolonged below it so as to form a guide, fitting within the bobbin core. The soft-iron cap or disc D, fastened on the top of the central stalk, is slightly larger in diameter than the outer casing of the bobbin B. It is made by preference of two or more thicknesses of flat plate, to assist in demagnetisation; but it must be thick enough to prevent saturation with any working current. Round the edge of the disc runs a cylindrical rim or flange, F, projecting downwards; it is so shaped as to suit the attraction required, and it comes within the range of attraction of the outer casing of the bobbin when the lower end of the central stalk has entered within the core. When the rim in turn has done its duty, the disc D comes within range of attraction of both outer casing and inner core.

Uniformity of Pull.—So long as the central stalk or armature rod is altogether out of the bobbin core, the attraction upon it continues to be inversely as the square of its distance from the bobbin; but as soon as the end of the iron rod enters within the orifice of the core, the force of attraction becomes lost upon so much of its length as is inside the core. The same diminution in attractive force holds good in regard to the flanged rim of the armature disc, as soon as its lower edge passes below the upper edge of the bobbin. The force of attraction varies also directly as the mass of the body attracted. Advantage is therefore taken of these two principles in combination, to regulate or adjust the effective attraction in such a way as to obtain some sort of approximation towards uniformity of pull throughout the 3½ inches range of stroke of the armature. This is accomplished by tapering, in the manner shown in Fig. 1, the lower end of the armature stalk A, and also of the flanged rim F, according to the desired adjustment of the attractive force; in addition to which the thickness of the armature disc D and the distance that its flanged rim F projects downwards, as well as the thickness of the rim, can also be varied; and in some cases, moreover, as in some of the examples shown in drawing 9, the bottom edge of the flange is made of a serrated or wavy form, so as to prevent the pull from suddenly increasing as the disc nears the bobbin. The result is that, when the strength of the pull on the armature stalk and flanged rim is decreasing, owing to their having both of them reached and passed the position of maximum attraction, the pull on the disc is increasing as it nears the magnet head. In this way, and in combination with a counterweight acting at a suitably varying leverage, an approximately equal pull is obtained through a considerable range, and violence of contact in the closing of the disc upon the magnet is avoided. By suitably adjusting the several proportions of the various parts, the pull can be so greatly varied both in force and range that it can be adapted to meet almost any requirements.

Double Length of Pull.—A double length of pull is readily obtained by the simple tandem combination shown half full size in Fig. 3. Here a pair of single magnets on the foregoing principle, arranged at a fixed distance apart, have their armature guide-rod, B, in common; the lower armature-disc L is made fast upon the rod, while the upper disc U bears against a shoulder upon it. The range of the lower disc being nearly double that of the upper, the first half of the pull is given by the upper; and by the time the upper disc U has closed upon its own bobbin, it has brought the lower disc L within the attractive range of the lower magnet, by which the second half of the pull is then given, the armature rod R now sliding free through the upper disc U. This arrangement is suitable for working signal-arms that are required to stand at the three positions of danger, caution, and line clear, as shown in Fig. 3.

Railway Signals.—In the application of the electro-magnets to railway signals, the ordinary signal posts and arms are utilised; but it is advisable that the bearings and working parts should be made as true as practicable, because, though friction is not so material when the work is done by manual labour, it is of the utmost importance that it should be reduced to a minimum where electricity is the motive power. As there are no complicated parts, and the movements are all simple and direct, there is no difficulty on this point.

In the accompanying drawing (Fig. 2) is shown the application of a single magnet to an ordinary signal-arm intended to stand in only the two positions of danger and line clear. The magnet M is fixed upright on a bracket at the back of the post, and a chain from its armature pulls upon a quadrant arc centred on a horizontal spindle above it. The quadrant carries a lever and counterweight, W, acting in opposition to the pull of the magnet; and also an arm which is connected by a rod, coloured red, with a bell-crank centred at the side of the post. Another rod, coloured blue, connects the bell-crank with the semaphore and spectacle. When the magnet is out of action, the semaphore is held up at danger by the weight of the spectacle, in conjunction with the counterweight W on the quadrant lever, which then comes against a stop. In this position all the parts are locked, in consequence of the quadrant arm being then on its dead centre; that is, the quadrant arm and bell-crank are so arranged that the direction of the rod (coloured red) connecting them passes then through the centre on which the quadrant turns. For yet greater security of locking, it is preferable, indeed, to let the connecting-rod be even a trifle beyond the dead centre, so that any pull upon the bell-crank, from wind pressure or accumulation of snow on the semaphore, shall hold the counterweight lever W still more firmly against its stop. The locking is thus done mechanically, and is independent of the magnet. On bringing the magnet into action by a current from the signal box, the pull of the armature rotates the quadrant arc, raising the counterweight and spectacle, and lowering the semaphore; in this position the semaphore is retained so long as the electric current is continued. On the cessation of the current, the semaphore is automatically raised again to danger, and locked there mechanically without the use of extraneous catches, which is a most important feature.

In Fig. 3 is shown the application of the double magnet or tandem arrangement to a balanced semaphore centred at mid-length. Here the pair of magnets are fixed on one side of the post, and the quadrant arc on which they exert their pull is fixed on the spectacle spindle. A rod (coloured red) connects the spectacle with a crank on the semaphore, and the weight of the spectacle brings the semaphore to the horizontal position of danger, in which it is locked mechanically as before, by the connecting-rod being then on its dead centre. An electric current sent to the upper magnet pulls the semaphore to an angle of 45° for caution; and a second current sent to the lower magnet pulls it vertical for line clear. In either position it is held by the spectacle acting as a counterweight against the retaining pull of the magnet.

Electric Current.—Under ordinary circumstances a current of 3 amperes is amply sufficient to pull the armature down upon the magnet, and so actuate the semaphore; but to guard against wind pressure, dust, rust, and wear of rubbing parts, a current of 5 amperes is provided. In addition a reserve current of as much as 15 amperes is kept in store at the signal-box, and is at the immediate command of the signalman in any emergency. From the red line in the diagram shown in Fig. 4 it will be seen that with 5 amperes an initial pull is given of 8lbs., at a distance or range of 3½ inches; which is more than double what is required to work any signal arm properly fitted; and the home pull is 321lbs.

If the same strength of current were necessary to hold signals down as to pull them down the use of a continuous current would be prohibited by its cost. But a current of only 0·1 ampere is more than sufficient to hold a signal down; and it is found that a continuous current of 5 amperes for moving the signal, and of 0·1 ampere for retaining it, yields an economical result. Accordingly when the armature has finished its stroke and moved the signal, it is made to switch in automatically a resistance-coil which reduces the maximum or moving current of 5 amperes to the minimum or retaining current of 0·1 ampere. The resistance-coil can take the form of an incandescent lamp, which then serves as an indicator or tell-tale in the signal box, as shown in Fig. 5.

In excess of the greatest possible requirements, it may be assumed that the whole time during which each signal is needed to be held down to show line clear is 12 hours out of every 24; and that the number of times each signal has to be lowered in the 24 hours is 150; and that the time occupied in each lowering is 2 seconds. Assuming also 10 amperes instead of 5 as the moving current, and 0·2 ampere instead of 0·1 as the retaining current, then 150 lowerings × 2 seconds × 10 amperes = 3,000 ampere-seconds or 0·8 ampere-hour; and a retaining current of 0·2 ampere for 12 hours = 2·4 ampere-hours; the total is therefore 3·2 ampere-hours of current C per signal per 24 hours. The resistance R being taken at 5 ohms, the electromotive force E is equal to $C \times R = 3{\cdot}2 \times 5 = 16$; and assuming 746 watts = 1 H.P., the horse-power is equal to $C \times E \div 746 = 3{\cdot}2 \times 16 \div 746 = 0{\cdot}07$ H.P. The cost of providing a current of such power by means of a secondary battery, according to well recognised electrical data, would be only 0·4 penny; while the current actually used being only about one-third of that provided, and the real time less than one-half, the true cost would be less than one farthing per signal arm per day.

The foregoing remarks respecting the electric current employed to actuate the magnets apply to the use of secondary batteries; and the results obtained from these accumulators of electrical power are very satisfactory and economical. In certain cases, however, it may be preferred to use a primary battery, such as the Lalande oxide of copper battery, the working of which is very easy and reliable. The constant and economical current it gives can be used not only for actuating the magnets, but also for lighting the lamps on the signal posts and at the points. With a primary battery, the reduction of the current from a moving to a retaining current cannot be effected in the same way as with a secondary battery, by switching a resistance in; but the same levers and switches are still available for switching *out* the large battery which gives the stronger moving current for lowering the signals, and switching *in* a smaller battery, of smaller cells and with greater internal resistance, which gives the weaker retaining current for holding the signals down.

Railway Points.—In Figs. 6, 7, and 8, are shown full size the magnets and gearing for working a pair of railway points; these magnets are practically of the same construction as for working signals, but are of larger size, and are wound with copper tape instead of wire in order that they may take a maximum current with a minimum of resistance. With a current of 23 ampères and an electromotive force of 40 volts, the force of the pull is as shown by the blue line in Fig. 4, commencing with an initial pull of 33 lbs. at 3½ inches distance, and increasing to 54 lbs. at 3 inches, and to a home pull of 1,064 lbs. As will be seen from the diagram, the points are pulled over and held in either position by the sliding rod R, which is worked by the lever L, and is locked by the locking bolt P. The slot in the rod R is made ½ inch longer than the width of the lever L working in it, so that the first ½ inch of travel of the lever withdraws the locking bolt P by means of the incline I on the extremity of the lever, before the lever acts upon the sliding rod R.

Where a pair of points are covered by a signal, the locking bolt P—in conjunction with the armature of the magnet which pulls the points over into the position corresponding with the signal when down for line clear—

Digitized by Google

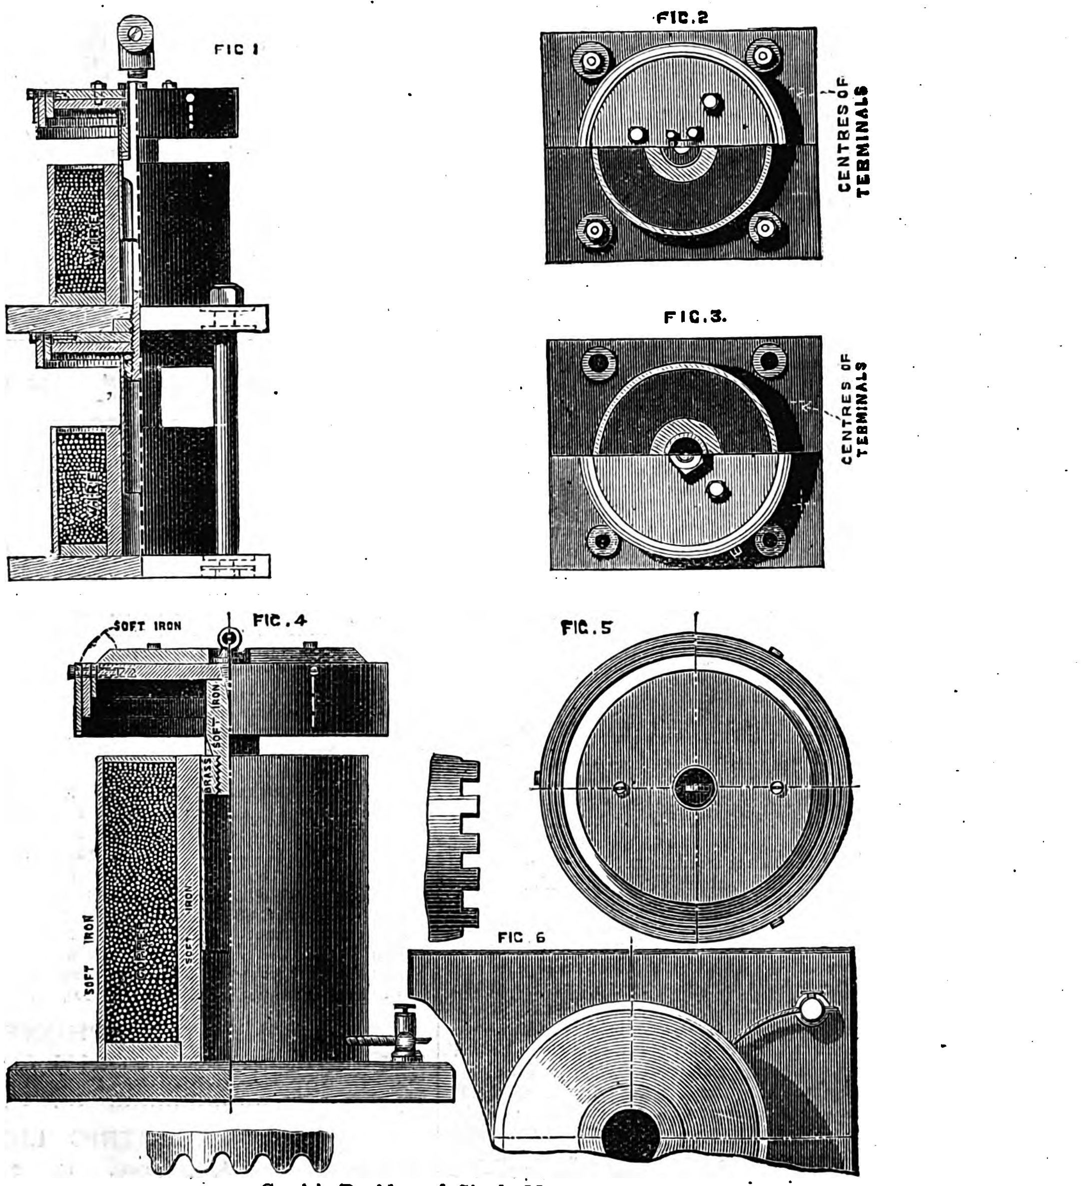
completes the circuit which enables the signalman to lower the signal. The signal is checked by its automatic repeater in the signal box. The other point-magnet completes with the locking bolt the circuit which works a repeater in the signal box.

Advantages.—The advantages of working signals and points by this system are that their distance from the signal-box is immaterial, inasmuch as the electric working gets rid of all the mechanical difficulties which arise from excessive expansion and contraction of lever wires and from the severe pull required to work them through long distances.

Signals.—It is only during the continuance of the electric current that the signal can be held at caution or line clear; its normal position is at danger, to which it returns automatically on the cessation of the current, or if anything goes wrong; and in this position it is locked by simple mechanical means, and not by any electric agency whatever. Each signal is worked by its own magnet, and has a repeater or tell-tale in the signal-box in the shape of a small arm, R (Fig. 12) which shows the position of the signal-arm. If it is desired, the repeater is arranged to show the exact travel of the magnet armature working the signal; that is, if the armature provide a perfect check, without the intervention of manual labour or the will of the signalman.

Application to Railway Junctions.—In Figs. 10, 11, and 12 is given an illustration of the application of this electric system to working the signals and points of an ordinary junction where there is a double line of way both on the main line and on the branch. The signal-box is here divided, as regards the electrical connections, levers, and switches, into thirteen divisions, 1 to 13.

Suppose an up main-line train is required to be turned into the branch (Fig. 10) it will be necessary to work the points P 6, and the three signals on the up main line, namely the distant signal S 1, the home signal S 3, and the station signal S 5. The lever of the points P 6 is first pulled over in division 6 of the signal box, whereby an electric connection is made between 6 and 7, the up-branch points being thus set right for the up train to pass into the branch. The down branch point lever 8 must be back or in its normal position in order to let the current pass through to division 3 for lowering the home signal S 3. As soon as the signal lever is pulled over and the signal lowered, the current can pass on to 1 for enabling the



Currie's Double and Single Magnets.

stops half way, the repeater arm would stop in the same position; in fact, any arrangement that may be desired can easily be effected. At the instant of contact between the armature and the magnet there is a momentary cessation of the main current, and the tell-tale arm indicates this by falling back a little from its extreme position. This affords another infallible check as to the correct working of the magnet. The reduction of the current from a moving to a retaining pull takes place automatically at the moment of the armature reaching the magnet.

Points.—The advantages in working points by these electro-magnets are as great as in the case of signals. Either can be worked at any distance from the signal cabin. There is no need for a cabin to be put up, or a stand of levers, to work any special set of points and signals; any number of points and signals can be worked from a small cabin, and can be locked and interlocked with absolute certainty. They can be so arranged that, if any wrong lever is moved by the signalman in arranging any combination, an alarm bell is rung in the cabin, and the signals already lowered go back to danger; the mechanical and electrical parts being so arranged as to

distant signal S 1 to be lowered. Last of all the current can pass to 5, lowering the station signal S 5.

Suppose another case of a train approaching the junction on the down branch to pass upon the down main line; the home and distant down branch signals S 12 and S 13 will have to be lowered. The points P 8 must first be in their normal position, and their lever 8 must be back, before the electric current from the battery can pass through 8 to 12, and thence to 10 for lowering the home signal S 12, and afterwards to 13 for lowering the distant signal S 13. It is now impossible to lower the home and distant signals S 10 and S 11 of the down main line, because the current for working these signals is prevented from passing by the act of pulling forwards the lever that belongs to the home signal S 12 of the down branch.

For station to station signalling (Fig. 11) the transmitter and receiver instruments are used in somewhat the same way as in ordinary railway working. The continuous current used makes the working very simple and easy and reliable. The signals and points are actuated by a main

Digitized by Google

current, and this is checked and controlled by a subsidiary current, which works the transmitter and receiver instruments. A train travelling along any section of the line protects itself by passing over contact levers or treadles, T, both on entering and on leaving the section; the depression of the treadles by the deflection of the rail breaks the current, which holds the signal arms down, and sets them free to fly up to danger automatically.

COMPANIES' MEETINGS.

Brazilian Submarine Telegraph Company (Limited).

The twenty-second ordinary general meeting of the shareholders of this Company was held on October 31, the Right Hon. Viscount Monck in the chair.

The SECRETARY (Mr. Richard Collett) read the notice convening the meeting and the minutes of the last meeting, which were confirmed and signed by the Chairman. The report of the Directors was taken as read.

The CHAIRMAN reminded them that when he addressed them at that time a year ago he was obliged to give them rather a dismal account of the affairs of the Company. Their cables were at that time interrupted, their business was suspended, and their receipts were annihilated for the moment. He was very happy to state that on the present occasion he could completely reverse the picture. Their property was in every respect in an admirable state, they had a complete and, he believed, an excellent duplicate cable laid, and their old cable was known to be in good condition —not merely from the scientific tests by which that state of things was usually ascertained, but by actual inspection, for they had had occasion, in consequence of breaks in the cable, to lift it in different places three times within the last year. On every occasion the cable lifted appeared to be in as good condition as when it was submerged, except where the outer covering had been destroyed by the friction of the cable on a foul bottom. Two of the breaks had occurred from this cause, but they were unable to account for the other break in any other manner except in connection with the extraordinary volcanic actions which prevailed during 1883 all over the world. With regard to the income of the half year, the cable was interrupted between the 2nd and the 28th of March. That was before the second cable was completely laid, and of course there was a diminution in the receipts. Allowing, however, for the period during which the cable was partially suspended a receipt equal to the weeks immediately succeeding the suspension, the income of the past six months would equal that of the corresponding period of 1883. It might be said that this showed no growth in the receipts; but he did not think that could be correctly said, for the equality in the receipts of the two periods had been obtained in the past half year contemporaneously with a reduction of the tariff and with the competition for the carriage of messages to and from Chili and Peru by what was called the West Coast route. As to the expenditure, there had been an increase in the past half year, as compared with the previous six months, of £641, but in this was included the cost of the repair of the cable in March last, which came to £760. In point of fact, therefore, the direct expenditure on working expenses had been about £120 less than that of the preceding half year. When he addressed them a year ago he announced that they were about to duplicate the cable, a policy to which, he frankly confessed, he gave his adhesion with some misgiving. He had felt loth to put their reserve fund in the sea until it had become necessary to have a second cable, one cable in good condition being abundantly sufficient for performing the work. He had therefore been rather opposed to the duplication at first, but he had given way to the arguments of his colleagues, and he was now very glad that he had done so. The events which had since occurred, in connection with the breaks to which he had referred, had entirely justified the policy which had been adopted. When the break occurred last March there was a loss of income, but when the breaks in June and July occurred, the second cable having then been laid, there was no inconvenience whatever, and their receipts went on just as before. When he announced about a year ago that they were going to duplicate the cable he told them that they would require for the purpose £250,000 —mentioning an outside limit—in addition to the reserve fund; but he was glad to state that the reserve fund, with the addition of only £150,000, had been sufficient. He told them at the time that they would be able to duplicate the cable without increasing the share capital. By raising the money as they had done, by debentures, they had merely created a debt, which they would be able to pay off, whereas had they increased the share capital they would have introduced what would have been practically a permanent participant in their dividend, and an element which must *pro tanto* have diminished the dividend. Their new cable was as perfect—and he was sure it was cheaper—than any cable yet laid, and he trusted that, operating through the two cables, they would enjoy practically as great an immunity from suspension of business and interruption as they had in the first ten years of their life as a single cable company. Bearing in mind the competition against which they had had to contend, and the reduction of the tariff, their receipts had really practically shown an increase in the past half year, and he trusted that this would go on. Without prophesying, he trusted that they would be able at least to pay what the shareholders had been in the habit of receiving the last four or five years, and to make provision which would enable them to repair any future break without drawing on debenture capital or loan of any other description. He trusted that the mode in which the directors had managed the business in the past ten or eleven years had been satisfactory to the shareholders. They began by giving a comparatively small dividend, and they were all aware that when the directors found they could safely do it they increased the dividend. They would go on in the same course, consulting not merely the temporary and fleeting interests of the shareholders, but the permanent and lasting good of the Company. He concluded by moving the adoption of the report and accounts, and the declaration of a dividend of 3s. a share, making, with the interim dividends already paid, 6 per cent. for the year ended June 30th last, free of income tax.

The VICE-CHAIRMAN (Sir James Anderson) seconded the motion.

Mr. W. GRIFFITH, after expressing satisfaction at the report and at the remarks of the Chairman, said he thought it would be very satisfactory to the shareholders to know if the income in the past three months had kept up.

The CHAIRMAN said he was very glad to answer the question. The receipts of the past three months had been almost identical with those of the same period of 1882. There had been a slight diminution, but October, November, and December were generally three of the best months they had. In reply to Mr. Hawkes, he added that the competition to which he had referred in his opening remarks continued. The resolution was then carried unanimously.

On the motion of the CHAIRMAN, seconded by the Hon. W. ST. JOHN F. BRODRICK, M.P., Sir Thomas Fairbairn, Bart., was re-elected to his seat at the Board, as was also Mr. Henry Daniel Gooch, on the motion of the CHAIRMAN, seconded by Mr. FREDERICK YOULE.

Mr. THOMAS BENSON next moved, and Mr. JOHN ANDERSON seconded, the re-election of the retiring auditors, Mr. Henry Dever and Mr. John Gane.

On the motion of Mr. GRIFFITH, seconded by Mr. BARRATT, a vote of thanks was passed to the Chairman and Directors.

The CHAIRMAN returned thanks for the kind way in which the vote had been submitted and carried, and assured the shareholders that it would stimulate the Directors to further exertions on behalf of the Company.

The proceedings then terminated.
